Two usability experts with no clinical expertise (HM and JG) used the heuristics while performing tasks to investigate a blood pressure app independently with the goal of identifying strengths and weaknesses of the application. For investigations aiming to identify potential issues with eHealth literacy, it is advisable that the evaluators do not have clinical expertise, as they may be better able to detect potential content issues (e.g., terminology, undefined acronyms) for representative users.

Results

Favourable Aspects of the Blood Pressure Tracking App

The blood pressure tracking app provided opportunities to share the data users entered (e.g., email, print).

The app color coded text and data point values that were considered out of range leveraging the convention of green for normal values, yellow/orange to indicate prehypertension, red for hypertension, and blue to denote hypotension.

This app offered several different views of the entered data: a) a summary table depicting maximum, minimum, and average values; b) a graph of the data; c) a chart of the descriptive statistics; and d) a frequency table of how many values fell within each range. The date range (i.e., day, week, month, year) for each report is adjustable and also allows showing all values, or only those taken in am or pm. Individual entries can be modified in the history.

The majority of the information in this app was kept above the fold, eliminating the need for scrolling and minimizing the likelihood of missed information.

This app also offers the additional security feature of setting a passcode lock and allows users to backup and restore data through both WiFi and iCloud.

Opportunities to Improve the Blood Pressure Tracking App

For brevity, this section will only outline violations that were deemed moderate or severe, organized according to heuristic. The heuristic Clear and Comprehensive Communication of Risks was not evaluated and therefore not included here.

A total of 40 heuristic violations were identified in this analysis. This blood pressure tracking app had the most issues associated with its complex navigation (9) and display (8) (see Figure 1). Unfortunately, the majority of the violations identified were considered either moderate (18) or severe (17) in nature, either because they were insurmountable usability problems or they had the potential to misinform users. In the interest of brevity, only the violations deemed to be severe will be discussed. Both investigators identified 14 violations. The remaining unique issues were found by one investigator (HM = 23) or the other (JG = 3).

Immediately Inform Users of Purpose and Engage Users, Avoid Registration

The app forces the user to make a profile to enter data. It is not clear what values are mandatory. The app applies default values for birthday, weight, height, gender, goal blood pressure, goal heart rate, goal weight, which is not prudent. There is an explanation of the purpose of the field labeled “color range”, which would likely confuse users. If multiple profiles exist in the app, the active profile is not obvious, which could result in adding data to the wrong profile.

Use Complementary Interaction Methods

This app fails to use any alternative methods to input or output information, which increases the probablilty of inaccurate data entry due to manual error. Additionally, the majority of values are entered using “pickers” (scrollable menus), which maybe be less efficient and more tedious than providing a numerical keyboard for data entry.

Leverage Interactivity

Although this app enables users to share their tracking data, it offers CSV, HTML, and PDF formats but does not describe why a user would select one file type over another. Additionally, this app does not engage users by offering any interactive learning tools or resources on blood pressure.

Provide Accurate, Colloquial, Comprehensive, Succinct Content

This app offers very limited content and therefore does not facilitate understanding the underlying mechanisms of blood pressure nor influencing factors. Unfortunately, the app uses multiple undefined acronyms (e.g., BP, HR, MAP, mmHg, bpm), which may be confusing for some users.

Provide Tailored, Flexible, Layered Content

Despite forcing users to create a profile, default goal values do not vary as a function of what is entered as current values nor clinical guidelines (e.g., using BMI for goal weight). As well, alerts are not provided when the user enters a value that would be considered outside of a healthy range. For example, entering a systolic value of >180 mmHg, which is considered to be a hypertensive crisis [8], does not produce an alert. Moreover, the app fails to incorporate additional information that is clinically relevant for blood pressure monitoring (e.g., whether a user is pregnant or has diabetes).

Use Visuals to Complement Text, But Avoid Tables

Very few visuals were used to complement text information. The few icons displayed were used suboptimally and felt busy, because they were often intermixed with data. Unexpectedly, the camera button captures a screenshot rather than a photo.

Unfortunately, multiple tables were used to display data, which would likely present challenges for users attempting to extract information from them.

Simplistic, Consistent Navigation

The app allows users to navigate through different date ranges; however, when a user navigates to date ranges too far in the past or future, there is no simple way to get back to the most current entries. The button to add a new entry is displayed in the top right corner on most pages, but is replaced with a camera button on some pages. The buttons to add weight, notes, or change the date of an entry are not obvious, which could cause users to become disoriented. Additionally, users are able to enter data for dates in the future, which is inadvisable. Further, it was not obvious that there were multiple different reports, as one of the investigators nearly missed the additional summaries entirely.

Adding a new notification, or reminder to take blood pressure was unnecessarily complex and had a different navigation pattern than other features. Though this is not a critical function of the app, it could be beneficial in facilitating consistent tracking by users.

Simplistic, Consistent Displays

The colors in the app are generally distracting (e.g., gradients, shadows) and low contrast. There are multiple lines (both solid and dashed) on the graphs which provide limited value and increase the impresson of a cluttered display.

When entering a value, no labels denote the systolic, diastolic, and heart rate on either the input component or display of entered information. Additionally, new entry dates are displayed only as numbers, a potentially confusing format.

There were three significant display inconsistencies of note. First, the scales on the graph change when different time spans are selected, presumably according to the range of values on the display. Second, the format of the PDF summary of values that can be shared by email were very different from any of the displays within the app. Finally, red, orange, green, and yellow are used inconsistently. For data points, they indicate thresholds within acceptable ranges, yet on other displays these colors are used strictly for differentiation and do not reflect whether the value entered is in or out of range. This inconsistency could potentially result in misinterpretation.

Clear Depiction of Monitoring Data and/or Test Results

The app uses orange for the systolic line on the graph and green for diastolic. This could create confusion if users interpret that the green diastolic line is always within range.

Although the information is presented in several ways, the tables and charts may be difficult for users to interpret and extract information from, and could potentially confuse them.

Considerations for Mobile Devices

Unfortunately, this app does not allow users to change the size of the font either by reorienting the mobile device or in the settings. Additionally, some of the buttons were small.

Other

Errors are likely to occur because the app automatically enters information. Specifically, the app saves its default values for blood pressure, heart rate, and/or weight values for any new entries, if they are saved without modification.

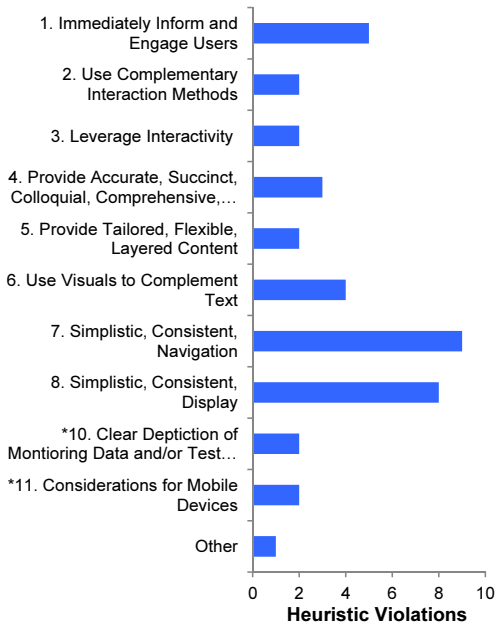

Figure 1 – Frequency of Violations as a Function of Heuristic
** Denotes optional heuristics relevant for this evaluation.*

Proposed Revisions for the Blood Pressure Tracking App

Figure 2 was developed to depict design changes to improve the app, particularly for users with limited eHealth literacy, by resolving some of the issues identified in the heuristic evaluation. Generally, a more minimalistic, higher contrast appearance was adopted, to both emphasize the information and enhance readability.

Given that adding values is a primary task, this function was promoted to having its own button on the menu. Thus, users could easily add a new entry from anywhere within the app. Although this app did not connect with blood pressure cuffs, it is always preferable that where possible, data is automatically uploaded into consumer health applications but allows users to revise or complement data with additional information (e.g., a note). Additionally, as shown in Figure 2a, the proposed redesign provides a holistic view of all of the information that can be added to a new entry. In contrast, the existing app forces users to toggle between screens to add different types of information. This display also shows the labels and units of the information, unlike the existing app. Finally, icons are used to reinforce the data labels.

Several recommendations were used to simplify the graph display (see Figure 2b). Specifically, the acceptable range of values for systolic and diastolic blood pressure were superimposed onto the graph in light green to emphasize values in and out of range. This color coding scheme was continued further, by redundantly coloring acceptable values in green, while hypertensive values were orange or red depending on severity, and hypotensive values were colored blue. Additionally, it is advised that the color coding scheme adopted would be applied to summary tables and individual entries. To prevent disorientation, the revised display constrains users to viewing the graph with today as the most recent entry to prevent disorientation.

It is also recommended that the app would incorporate a glossary of terms and/or links to trusted references and educational resources in the tools (e.g., [8]) to facilitate users understand the concept of blood pressure, related terminology, and what factors affect blood pressure.

Figure 2 – Proposed Revised Displays for the Blood Pressure Tracking App

Discussion

Currently, the blood pressure tracking app has limited value to consumers due to the numerous moderate and severe potential usability and eHealth literacy demand problems identified here. It is not to say that users were not be able to use this system for monitoring, but it would not provide them with an enhanced understanding of what blood pressure is and what behaviours influence it. Users could also potentially misinterpret information or rely on default values. However, design modifications and the incorporation of actionable content could increase the usefulness and usability of this app.

This novel set of evidence-based heuristics derived from studies designing or evaluating consumer HISs for users with limited eHealth literacy, demonstrated utility in revealing potential problems Specifically, this evaluation revealed a number of opportunities to improve the blood pressure tracking app to improve its usability for consumers with limited eHealth literacy and how to more effectively communicate information to these users. The issues identified here stemmed from design issues with either the interface or the content that could be problematic for users with limited eHealth literacy. Moreover, given that users of these systems often have minimal or no clinical expertise, it is imperative that information is written and displayed in a manner that scaffolds understanding.

Leveraging findings from existing literature on usability and eHealth literacy to develop heuristics for inspecting other consumer HISs is a promising technique. Specifically, this method of developing evidence-based heuristics facilitates

mitigating known barriers to both use and comprehension for users with limited eHealth literacy with a single evaluation. Applying these heuristics could help ameliorate system content and design prior to full-scale usability testing.

This study expanded on previous work by incorporating additional evidence on usability and eHealth literacy. Our initial heuristics [6] were more specific, whereas the heuristics presented here were broader. There are advantages and disadvantages to using either set. Investigators with less familiarity with demands on eHealth literacy and usability issues may find it more helpful to use heuristics that provide specific guidance. Whereas, evaluators with more experience in these domains may find it preferable to use more general heuristics, as they are more flexible. This rationale may account for the differences in problem identification between inspectors in this study, as one inspector has more experience in this domain. Moreover, the heuristics presented are still preliminary, as they are still not entirely mutually exclusive and require more refinement. Further, as the body of research on eHealth literacy and usability continues to mount, emerging evidence should be continuously integrated into this set of heuristics.

The findings from this study suggest that additional heuristics are needed to classify all identified problems. That is, the "Other" category of problems had to be created to accommodate problems that were not subsumed in one of the existing heuristics. This suggests that the developed heuristics might benefit from being complemented with other heuristics such as Nielsen's [4] ten heuristics. Amalgamating the set of heuristics generated here with Nielsen's [4] could provide a more comprehensive set of principles for designing and evaluating consumer HISs is thus one proposed line of future research.

There are several other opportunities for further research using these heuristics. First, these heuristics may be useful for comparing and contrasting multiple consumer health information systems with similar purposes (e.g., health risk assessments, blood glucose monitoring apps) in an attempt to determine the most suitable of these systems for consumers with limited eHealth literacy. Another line of research that warrants investigation is testing the validity of these heuristics by comparing the problems found through their application with problems revealed through usability testing of the same system, to determine the correlation between the their respective findings.

Conclusion

As the proliferation of consumer HISs continues, it is important to consider the usability and the demands these systems place on eHealth literacy. Some might argue that low cost applications should not be scrutinized, given their restricted resources. However, users with limited eHealth literacy are equally, if not more, likely to use these inexpensive systems. Thus, it is important to recognize and apply low-cost techniques, such as the one outlined in this paper, to improve consumer HISs of all varieties. Moreover, these heuristics facilitated the identification of both eHealth literacy and usability problems with only a single evaluation.

Consumer HISs have the potential to engage and empower new user groups to monitor and improve their health. That is, these systems could possibly increase users' participation in their own healthcare by providing personalized feedback and tailored interventions that cater to the needs and preferences of their users. However, for this information to be received and applied by the users who have challenges using technology and difficulty understanding health information, it is imperative that they are designed with usefulness, usability, and eHealth literacy considerations.

Although heuristic evaluation with evidence-based heuristics may be valuable for informing the design of consumer HISs to mitigate potential problems for users with limited eHealth literacy, it is not meant to replace usability testing with representative users. Instead, such heuristic evaluation should be used as a preliminary filter to identify and resolve issues commonly experienced by limited literacy users. Thus, it would facilitate development of more usable applications, as less time would be spent repeatedly identifying problems through usability testing that are known problems, previously cited in the literature. That is, using evidence-based heuristics (i.e., design principles for users with limited eHealth literacy) as a preliminary method of improving a consumer HIS, should result in more effective use of representative users finding problems unique to a specific consumer HISs under investigation. Thus, this method should be used in conjunction with other user-centred design methods as a part of an exhaustive, iterative design process to ensure that consumer HISs are easy to use and users understand the information contained therein.

Abstract

Video games have become a major entertainment industry and one of the most popular leisure forms, ranging from laboratory experiments to a mainstream cultural medium. Indeed, current games are multimodal and multidimensional products, relying on sophisticated features including not only a narrative-driven story but also impressive graphics and detailed settings. All of these elements helped to create a seamless and appealing product that have resulted in a growing number of players and in the number of game genres. Although video games have been used in education, simulation, and training, another application that exploits serious gaming is the exploration of player experience in the context of game research. Recent advances in the natural user interfaces and player experience have brought new perspectives on the in-game assessment of serious games. This paper evaluates the impact of player experience in the design of a serious game for upper extremity stroke rehabilitation. The game combines biofeedback and mirror neurons both in single and multiplayer mode. Results have shown that the game is a feasible solution to integrate serious games into the physical therapy routine.

Keywords:

Computer Games; Patient Engagement; Rehabilitation; Stroke.

Introduction

Regardless of the advanced medical technology and highly trained healthcare professionals, individuals under medical supervision do not always follow their treatment courses resulting in decreased adherence. Solutions to this problem are complex with behavioral and psychological factors playing an important role. A recent review of video games' application to improve healthcare outcomes reported therapeutic benefits, especially in the psychological and physical therapies [1].

Video games seem simple entertainment applications, but their use could also open entirely new frontiers. The term serious game has arisen to describe the use of games in education, training, health, and public policy [2]. Serious games modify a learning task into the one that is game-like, which deeply reworks the player experience. Describing such player experiences has become an important branch of research.

Games are used in healthcare to engage individuals and to improve their health outcomes. Several studies have shown positive results with the use of serious healthcare games. This could be because the game environment is aesthetically appealing, graphically engaging, and provides the necessary motivation to endure treatment with joy and less pain.

The technologies for natural user interfaces (NUI), and the rehabilitation tools development environment for the physically disabled individuals, are well documented in the literature [3]. Serious health care games can replace many of the rehabilitation exercises that impaired individuals could otherwise perform in virtual environments. Besides, the physical therapist can shape the treatment by configuring various features of rehabilitation exercises while evaluating and controlling the performance.

For the individuals with motor disabilities due to stroke or aging, performing the rehabilitation exercises is essential while they still have some motor skills [4]. Individuals may start the rehabilitation process by getting involved in the serious healthcare games. The serious healthcare gaming experience is about producing the required stimuli while keeping it amusing. Therefore, the player experience and engagement are the mechanisms that make serious games motivating and fun.

This paper presents a systematic evaluation of player experience in a serious healthcare game designed for upper limb stroke rehabilitation. The game is tested in single- and multiplayer modes on a control group of physical therapists to measure intragroup interactions following a quantitative analysis. A one-way ANOVA is used to compare game modes with respect to challenge, competence, flow, negative effect, positive effect, immersion, tension, functional limitations, and perceived exertion.

This paper is structured as follows: Related Work, The Game, Experimental Evaluation, Results, Discussion, and Conclusion and Further Work. In the 'Related Work' section, the paper presents information concerning serious games and motion capture devices, the importance of biofeedback and mirror neurons in rehabilitation, and the comments on player experience in serious games. 'The Game' section introduces the game platform involving upper extremities' rehabilitation after stroke. The 'Experimental Evaluation' section provides initial setup information, measuring instruments, participants, and procedures. The 'Results' section presets the reasonable outcomes that are hypothesized before conducting a statistical analysis. The Discussion section analyzes the results, and the 'Conclusion and Further Work' section presents meaningful observations while outlining the work for future experimental activities.

Related Work

Serious Games and Motion Capture Devices

Graphical user interfaces are ubiquitous on personal computers and mobile devices. Designers face new challenges from the current user interface technology and applications that integrate touchscreens, 3D depth cameras, and gesture and voice recognition. These interfaces allow user communications with a variety of devices that imitate the real word interaction.

The development of a widespread range of exetreme games has resulted in the use of NUI devices for physical therapy. For example, it is now feasible to measure therapy progress for individuals with motor disabilities, who are instructed to perform exercises, irrespective of their location (home or clinic). A compiled database of regular exercises with quality software must be created to assure flexibility and to support the development of tailored rehabilitation therapies for individuals suffering from a particular disease.

The game industry provides tracking sensors with a broad range of applications and reliability for rehabilitation purposes [5]. Low cost, off-the-shelf availability and response characteristics of these devices have enabled their adoption for the healthcare applications. Their relevance to the individuals with motor disabilities attending therapy sessions is discussed in [6]. Though the extreme games help improve healthcare outcome they were not known to physical therapists until recently and therefore were not used for rehabilitation purposes.

The popularity of Kinect – a motion capture device created by Microsoft – promoted the emergence of several studies exploring its application to serious games for healthcare [7], including those for physical and rehabilitation therapies. A wide range of serious healthcare games has been developed for physical therapy [8]. Serious game-based therapy aims at encouraging individuals with motor disorders to practice physical exercises, however, some of them lack access to the cloud computing applications [9] while others do not have significant technical information that is valuable during physical therapy assessment [10].

Biofeedback and Mirror Neurons in Rehabilitation

The biofeedback is adopted into a bio-inspired user interface. The healthcare applications use integrated biofeedback sensors to process vital bio-signals [11]. Biofeedback measures user experience and engagement in serious healthcare games [12]. Data acquisition is one of the first steps in the evaluation and applicability of serious games throughout the treatment.

Biofeedback involves conscious and visual control of a particular activity. Biofeedback-assisted training aims at developing full control over physiological processes, it helps shaping the posture and profile during rehabilitation and recovery. Biofeedback, among other things, consists of altering sound intensity and visual colors in accordance with the task. Individuals learn to control the activity as per the information acquired from the feedback loop.

Functional damage due to cerebral palsy requires rehabilitation and recovery. Rehabilitation must begin soon after the stroke. Physical therapists may provide detailed diagnostics before the therapeutic approach. Care must be taken regarding neurological and neuropsychological deficits that affect the treatment and length of stay at a rehabilitation facility. For this evaluation, post-stroke monitoring includes clinical tests and modern methods of measurement, such as mirror therapy.

Player Experience in Serious Games

Literature on evaluation of serious games focuses on learning outcomes. Although quantitative estimates are prone to heuristics and biases, it is important to understand them and to work out ways to mitigate their influence on the evaluation. One possible solution is to measure user experience with qualitative or quantitative surveys, and questionnaires. They are amongst the most widely used methods in gathering information on subjects, providing feedback to the player based on actual gameplay data [13].

Experience occurs in response to a stimulus. The stimuli (in general) result from observation or participation in real, imaginary, or virtual events. Experiences are not spontaneous phenomena but are induced, and have a reference (starting point) and intention (aim for something) [14]. Although the concepts of reward and comfort channels are game-related, they must be accounted when considering a player's experience.

The Game

The serious game was developed with scenes that change with the game mode. The control panel lets a physical therapist set the goals in accordance with the required treatment. The game features single and multiplayer modes, as shown in Figures 1 and 2, respectively. In single player mode the patient plays alone reaping as many fruits from the tree as possible over a certain period of time. In multiplayer mode, one may choose to have a competitive or collaborative game. Participants reap fruit towards achieving a target (of a selected number of fruits), which might be specified by the physical therapist. Participants are evaluated by a digital goniometer, displayed on both sides of the screen. A multimedia database is included to store game sessions for game experience assessment, including mirror-neurons and biofeedback.

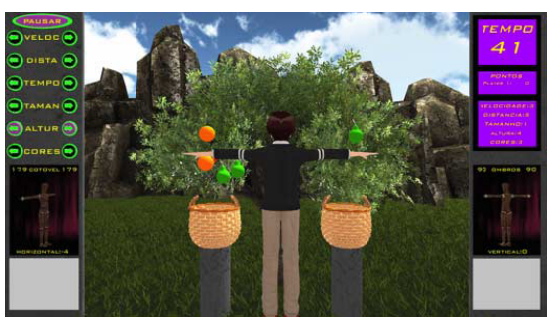

Figure 1 – Screenshot of the serious game for upper-limb stroke rehabilitation in single player mode.

Figure 2 – Screenshot of the serious game for upper-limb stroke rehabilitation in multiplayer mode.

Experimental Evaluation

Initial Setup

The step-by-step instructions for initial setup for the serious game users are listed below:

1. Participants get a brief explanation about the game metaphor and the data gathering process. The trainer instructs participants about the information and consent form needed for clinical trials.
2. Participants must be in the sensor range to play the game. Participant positioning depends on whether the game is played in single- or multi-player mode.
3. Exercises and procedures are taught during a first trial. Evaluation starts only after the participants have their questions clarified and they are acquainted with the game.
4. Game session setup is common to all of the participants. Game sessions are video-recorded for later analysis.
5. The game session lasts until the preset time limit. Also, the participants are instructed to fill out online questionnaires.

Measuring Instruments

The Game Experience Questionnaire (GEQ) is designed to measure different aspects of players' engagement and skills in playing a serious healthcare game. Research has shown the importance of players' social connections to the overall player experience [15]. The GEQ allows game researchers to investigate and test player experience of serious games in a quantitative and inclusive manner [16].

The GEQ analyzes the user experience across various phases of the game and has three modules: the core module, the social presence module, and the post-game module. The core module addresses competence, sensory and imaginative immersion, flow, tension, challenge, and favorable and adverse effect; the social presence module deals with empathy, negative feelings, and behavioral involvement; and the post-game module focuses on positive and negative experience, tiredness, and returning to the reality. Only the core module was used in this research to assess the game experience that included forty-two items. Scores are computed based on the Likert scale.

Two additional measuring instruments were used to assess and record player experience during the gaming sessions. 'Capabilities of the upper extremity' questionnaire (CUE-Q) [17] was applied to measure improvements after upper extremity reconstructive procedures. CUE-Q measures functional limitation, and assesses the amount of difficulty experienced in performing specific actions with one or both arms and hands. Although a measure of functional limitation in tetraplegia, it may also be used to measure how well people respond to a treatment. The Borg rating of perceived exertion (RPE) [18] is a widely used measurement for monitoring and guiding exercise intensity. Despite being a subjective measure, RPE provides valuable information and is sufficiently accurate in capturing the experience pertaining to effort and workload.

Participants

Thirty-eight adults participated in the evaluation. None of the participants were diagnosed with motor disabilities. Participants came from a specific control group constituted by physical therapy students, therapy technicians, physical therapists, and professors. Participants were recruited on a voluntary (no monetary compensation) basis from the rehabilitation ward of the HUSM.

Procedure

The experiment took place at the neuro-rehabilitation ward of the HUSM. The room where experiments were performed has plenty of space for in-game assessment. It also provided controlled illumination, and thermal and acoustic insulation against interferences that might distract the participants. Being at the rehabilitation ward was not a matter of choice, but a necessity. It enabled shorter evaluation sessions and a quicker feedback during the development.

Positioning of devices within the room was driven by the sensor coverage range. The screen was installed on the wall, raised to a comfortable position and providing enough side-to-side space for participants. The Kinect was installed just below the screen. Trainers and physical therapists, while leading the experiment, did not interfere with the participants' performance, but could instruct participants, observe participants' progress, and control the game.

Evaluation data is stored in a database for each participant, including left and right shoulder abduction angles, left and right elbow flexion angles, and horizontal and vertical slopes.

Results

This research aims to evaluate player experience induced by a single player mode against a multiplayer collaborative game mode within the control group of physical therapists. Research hypotheses for the experiment on the data gathered from serious game sessions are :

- H1: Reported levels of engagement will be higher for players in multiplayer mode than in single player mode.
  - Player experience will vary with challenge, competence, and flow.
  - Multiplayer mode will be more intense with respect to sensory and imaginative immersion, resulting in higher engagement scores.
  - Positive effect and tension will be higher in multiplayer mode than those in single player mode. Likewise, negative effect will be lower in multiplayer mode than that in single player mode.
- H2: Measured levels of functional limitation and the amount of difficulty experienced in performing specific game actions will be comparable in both game modes. The same holds for perceived exertion.
- H3: Multiplayer condition provides not only a great deal of fun but also provides an associative learning experience through biofeedback and mirror neurons.
- H4: Participants in either (single- and multi-player) modes will perceive a positive impact on how they interpret their progress. Thus, local and online game scores and achievements will induce an enhanced performance.

A one-way ANOVA was used to determine whether player experience differed based on the GEQ core module, CUE-Q, and RPE, amongst the users of single- and multi-player modes. A one-way ANOVA is used to compare the means for *n* independent groups on a dependent variable. The F-statistic and its p-value depend on the group means and on the spread of the observations within each group. A few values in the

dataset were missing or outliers. Therefore, before the analysis, average values of measures were normalized using a logarithmic transformation – a standard procedure.

As to the challenge in the single player mode, a higher level of difficulty and effort required by the serious game was obtained (items 8, 26, 29, and 37), which indicated that the game was challenging and stimulating while being a learning activity. Time pressure was observed during sessions. A majority of participants agreed that the game was not difficult nor was significant effort needed (items 13 and 36). An equivalent interpretation was observed for multiplayer mode.

The sensory and imaginative immersion that investigates a player's presence in the game indicated a higher percentage of agreement regarding all but item 20, which pertains to the imaginative feeling. These results indicated that a majority of the participants found the game interesting and the serious game provided a creative and rich experience. Single- and multi-player modes did not indicate significant differences concerning immersion. The tension scores, which measured the level of frustration or annoyance, were highly positive implying that the control group of players did not feel tense, annoyed, irritable, or frustrated while playing the game. Average tension was somewhat higher in single-player mode than that in multi-player mode.

Scores on GEQ were measured only for the core module on a 1 (not at all) to 5 (extremely) scale. Both game modes showed high scores ($M > 4.0$) on the items pertaining to positive effect and immersion. Median values were observed for challenge, competence, and flow (M in [2.5,3.5]), while negative effect and tension were rated low ($M < 1.8$) as seen in Figure 3.

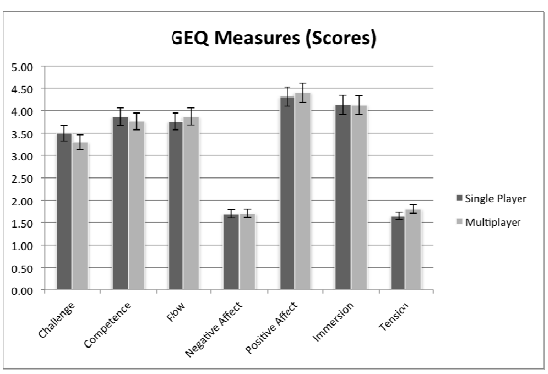

Figure 3 – Comparison of score for GEQ dimensions in single player and multiplayer mode.

Results of the ANOVA reveal that differences between the single- and multi-player modes are more significant regarding challenge. Challenge is high in single player mode with $F(1,74)=6.1715$, $p=.005$. Since $F>F^{Crit}$, the mean challenge of at least one game mode is significantly different. The difference in challenge is statistically significant between single player and multiplayer mode. Mean squares were also higher in single player than in multiplayer mode. Large F values were observed within challenge measurements. A large F-ratio occurs when sampling had large values in some groups and small values in others. All the other GEQ dimensions followed the null hypothesis-driven approach (the population means for both game modes are the same) when evaluating player experience on single player vs. multiplayer mode.

Running a multivariate ANOVA on all seven dimensions showed no significant difference on positive effect, and sensory and imaginative immersion perceived in either mode. This suggests that single player participants enjoyed the game as much as their multiplayer partners. Significantly low scores were found for negative effect and tension. No significant differences were found between single player and multiplayer mode for CUE-Q and RPE.

Discussion

Metaphoric introduction of characters in the game for either game modes may have given participants something familiar to connect with, enhancing feedback, and allowing them to feel more immersed in the serious health game experience. By focusing on the goals, participants had to remain more concentrated on the game, adding to the flow component.

Participants felt more distracted in the single player mode while they had thought about other things in the multiplayer mode. Other than preventing wrong movements by the real-time sensor, audio was not used to its full potential. Sounds and/or soundtracks may be relevant when evaluating negative effects.

Challenge measurement provided a wider range of results when compared to other GEQ dimensions. Although the game metaphor, characters, and interface were the same for either game modes, the very same action or decision choice of collecting fruits from the trees had an unexpected outcome and the challenge is directed by the effort needed to complete the task that does not differ in both game modes.

A majority of the hypotheses were confirmed by the results, while there were some unpredicted results. Challenge, competence, and flow varied in both game modes. A small but significant difference was observed regarding player experience in both player modes with respect to the sensory and imaginative immersion. As expected, positive effect and tension scored higher in multiplayer mode. Conversely, negative affect was almost equal in both game modes. Although average scores on negative affect were low, neither game mode seemed to annoy or frustrate participants.

Measured levels of functional limitations, and perceived exertion, were similar in both game modes. The high scores confirmed hypothesized effects of biofeedback and mirror-neurons on game experience for single player and multiplayer modes. Apart from tension, no significant differences were found. The user-centered design process in both game modes may support these findings.

Conclusion and Further Work

We showed an evaluation of the player experience with a serious game for upper extremity stroke rehabilitation. To assess player experience during gameplay it is essential to consider both the design and simulated environment for the participants while assessing the immersive interactions they undergo in single player and multiplayer modes.

Evaluation participants fit the target user group of physical therapists. Disagreements and misconceptions were observed between participants that created divergences. Open conflicts during gameplay provide means to solve a particular problem while misconceptions might generate negative feelings between participants. Intragroup variability was detected and evaluated using analysis of variance (ANOVA) techniques. Additionally, the measuring instrument must also be appropriate to qualitatively assess and identify experiment outcomes. Engagement was evaluated by means of GEQ dimensions, CUE-Q, and RPE.

Results indicated that engagement were somewhat higher in multiplayer mode (collaborative) than in single player mode

due to the in-game control, which facilitated learning by means of biofeedback and mirror neurons. The same results produced high levels of challenge, competence, flow, and positive affect but also a sense of tension and distraction. The analysis revealed that participants in multiplayer mode had a better understanding of the collaborative tasks.

Apart from limitations due to the amount of participants in the control group and game attributes with desired learning effects for serious games (which can be accessed directly during gameplay) differences between single player and multiplayer mode indicated the presence and influence of behavioral states on player experience. Game developers and physical therapists agreed that, despite the user-centered game design, it was possible to highlight the differences more precisely and in a timely manner.

Further work is needed to assess engagement while monitoring emotional responses in real-time for the treatment group and the control group. Such a research will help the serious healthcare games' designers over the course of development and will provide useful biofeedback to improve player experience.

User-Centered Design of Health Care Software Development: Towards a Cultural Change

Enrique Stanziola[a], María Quispe Uznayo[a], Juan Marcos Ortiz[a], Mariana Simón[a], Carlos Otero[a], Fernando Campos[a], Daniel Luna[a]

[a] Health Informatics Department, Hospital Italiano de Buenos Aires, Argentina

Abstract

Health care software gets better user efficiency, efficacy and satisfaction when the software is designed with their users' needs taken into account. However, it is not trivial to change the practice of software development to adopt user-centered design. In order to produce this change in the Health Informatics Department of the Hospital Italiano de Buenos Aires, a plan was devised and implemented. The article presents the steps of the plan, shows how the steps were carried on, and reflects on the lessons learned through the process.

Keywords:

User-Centered Design; User-Computer Interface; Software Design.

Introduction

Health professionals and patients value health care software, but they demand better products that help them satisfy their clinical information needs [1]. According to reviews, many of the issues that prevent adoption and satisfactory use are related to poor design and low usability [2, 3, 4]. Usability is a measure of the efficacy, efficiency, and user satisfaction [5], and usability has been established as a key factor of applications that provide the needed support while letting them be focused on their tasks [6]. Usable applications are easy to learn, efficient to use, easy to remember, not prone to errors, and subjectively pleasing to use [7]. User-centered design (UCD) is an approach to achieve usable products introduced by Norman and Draper [8]. UCD has evolved from the research field of human-computer interaction, with the contibution of cognitive psychology, software engineering, sociology, and other disciplines that influenced it and developed methodologies that embody their points of view [9] Usability engineering presents an iterative cycle of design and evaluation until the fulfilment of established quantitative goals measured on lab tests [10]. Contextual design includes ethnographic methods for user research while participatory design involves users to set goals and explore design solutions, instead of just taking part of evaluation [11]. UCD has been applied succesfully to enhance adoption and success of products [12].

The Health Informatics Department of the Hospital Italiano de Buenos Aires (HIBA) includes an area of software engineering and a residence for health informatics. The department has been designing and developing administrative and health care software since the late 1990s. However, these applications presented the usability challenges described in the literature mentioned above. While the users valued the availability of online health records and tools for administrative tasks, they also noted lack of desired functionality and difficulties to learn and use the tools. Therefore, acoording to the reccomendations on the cited reviews, the department decided to implement UCD, applying usability engineering, participatory design, contextual design and a user-centered framework for redesigning health care software [13].

The goal of this paper is to describe the process of changing the culture of design and development of health care software at the HIBA, setting UCD at its core.

Methods

Following Schaffer's approach to institutionalization of usability [14], the head of the department devised a plan of three phases.

The first phase was to introduce UCD through an internal course for health informatics residents and software developers and other personnel of the department. The course load was 16 hours of classes, plus extra activities.

The second phase was to demonstrate the feasibility of UCD, applying it to a pilot project. The team for the project would be taken from the attendees of the course that show more interest and developed skills.

The third and current phase is aimed to the widespread implementation of UCD on the mainstream projects of clinical software. It was planned to create a UX team, formed by a group of UX professionals. It has a double function: to offer the service of designing new applications or new versions of existing ones, and to disseminate UCD as a new culture of work.

Results

UCD introductive course

In January 2011, the planned course of UCD was given and it was mandatory for health informatics residents, developers and other personnel from the department. It was a program of 1 class of 2 hours per week, for 8 weeks. User interviews, prototyping and usability testing were required as practical activities outside the class.

Although approximately 30 people attended this course, its impact was mixed since very few developers showed interest on usability. The resistance arguments were that: (1) users have to adapt and learn; (2) health domain is complex and is impossible to make it easier; and (3) UCD would be the right thing to do, but is not possible given the conditions of work in the department.

On the other hand, most of the health informatics residents welcomed the new approach centered on users. But, they usually stay 2 years on the department and new residents have to participate on UCD courses every year. Another challenge

is their few design skills, so they have to learn almost from scratch.

Pilot project

After the course, a team for a project was taken from the attendees of the course that show more interest and developed skills. The team was formed by a health informatics resident, a MD student, and a part-time user experience (UX) professional. Its goal was to redesign the HIBA's patient health portal and it was a test of UCD techniques. That project involved real patients for interviewing and testing usability and proved the worth of this approach by giving new insights that helped to focus the development. The team took a transdisciplinary approach, looking forward that all of its members could develop UCD skills and view health issues from an assistive technology perspective. The result was a revised version of the application, that included a new menu structure, functionality and visual style. Findings of this project are shown on Table 1. After that pilot project, UX professionals were hired by the hospital in a full-time basis and are taking part in several projects.

The UX team

Since January 2014, the User Experience (UX) team at the HIBA is formed by 3 professionals with different skills that complement each other. Its leader was formed and worked in information systems analysis and development, and later studied human-computer interaction. Two members were chosen and they worked on graphic design, usability and accessibility. Their job is to lead the UCD process and promote that methodology among their colleagues in the department. In this way, UX members plan and perform tasks of user research, prototype design and usability evaluation, along with HI residents and developers. Non-UX professionals take part on basic training given by the UX team, and this training allows them to understand the UCD's point of view and its techniques. Due to high demand of projects, each member works on several projects at a time, and delivers different levels of attention for each one. Before implementation, applications get at least design advices and revisions by the UX team. Priority projects get the most attention, which involves thorough user research and testing.

Impact of UCD on real projects

After three years of the formation of the UX team, we can see its achievements on the design of health care software. Table 1 lists the projects that got some contribution from the team, the insights found through user research and its impact on the final design.

Mobile usability lab

The core of the UX team's work is to listen and observe what users say and do on interviews, workshops and tests. So, it is necessary to record their words and actions to be analysed afterwards. The team uses small cameras and cellphones to take pictures, videos and audio on contextual interviews. The team uses a notebook for on-location usability tests. The first notebook used for tests was a Dell Latitude E5510, with a 15.6' screen and 1,366x768 pixels resolution. Its display was smaller than screens installed in doctor's and nurse's offices, so it was replaced by a another notebook, a Dell Precision

Table 1- Projects with contribution from the UX team

Project	Findings of user research	Impacts on the interaction design
Patient health portal [15]	The application is valued even by users with IT challenges. Registering and navigating was difficult. Patients with chronical diseases, including senior citizens, are the most intensive users.	The menu was revised using card sorting technique with participants profiled on age and chronical diseases. A style guide was created, taking into account recommendations for older users.
Problem selection [16]	On problem search, relevant results act as suggestions for selecting more specific problems.	The list of results was ordered by relevance and classified by categories to stimulate the selection of more precise problems.
Anesthetic record [17]	Understanding how anestethiologists record their actions during an surgical intervention.	Interaction design of touch-screen based application created from scratch. Interactive and real-time visualization of vital signs and administerd medication.
Evolutions and documents [18]	While writing evolutions, doctors usually read results and other data. Doctors usually look for evolutions written by colleagues of their specialty. Documents were difficult to find.	A floating window that allows to navigate the EHR while writing evolutions was designed. Faceted browsing was added, including filters by type of document and specialty.
Drug-drug interactions alerts [19]	It is difficult to understand and follow recommended actions embedded on text.	Specific buttons to perform recommended actions were added, customized for each drug-drug interaction case.
Nursing process [20]	Large and complex forms hinders completion of tasks.	Forms were rearranged according to the hierarchy of items to minimize perceived complexity and completion times.

M6800 with a 17.3' and 1,920x1,080 pixels, to avoid distortion of prototype and similar legibility as the user's monitors.

The notebook is equipped with Morae 3.2 software to record the user's face expressions, the application on display, the mouse movements, and the keyboard typing.

Discussion

The plan to adopt UCD in the department has achieved its first goals after 4 years. The projects implemented show quality improvements that were welcomed by sponsors and users. This methodology is now valued and demanded by health informatics residents and software developers. Below, we discusss specific considerations about the lessons we learned in the process.

Teaching UCD in organizations to change the software development culture

We found out some reasons behind the resistance faced during the course. As developers had almost no free time for classes, and many of them were not initially motivated to learn UCD, we believe that elective and shorter courses could have better results.

Health is effectively a complex domain and it is difficult to reach a usable and useful design. UCD instructors have to be careful and avoid putting themselves in the place of 'gurus' that know exactly how to do the right thing, while developers do not. Instead, before teaching UCD it would help to expose developers with real users interacting with the applications and expressing their difficulties. Thus, developers would learn from their users that UCD is necessary for developing applications that deal better with the genuine complexity of health domain. This is based in an essential principle of UCD: to know the users [21]. In our case, there is a great variety of users, regarding their profiles, demographics and roles: patients, clinicians, surgeons, nurses and other health professionals. For each project listed on Table 1, the user's capabilities, needs and goals were inquired. The profiling of these users can be consulted on the respective cited publications.

It is necessary to know more about how projects are carried on at the organization before proposing a new process of design. Learning UCD is, above all, learning a new way to work. For that reason, the instructor, along with the course attendees, have to find out the necessary steps to get from the current situation to the desired one. The know-how has to be constructed, not imposed, if we want it to be embraced rather than resisted.

UCD as service

UCD became accepted when developers recognized its valuable contribution to their projects. The UX team helps the work of developers by designing the interaction and the user interface. Now, they can focus more on the difficulties of systems, database and communications. Users and sponsors show more satisfaction; therefore, developers get more recogniticon for their work. When this virtous circle was evident, developers begin to ask the UX team for help on their projects, even in informal ways.

The key factor for the change in the developers' attitude towards UCD, from resitance to demand, was that the UX team is at their service to work with the developers.

UCD as culture

Progressively, UCD is becoming pervasive, and it is not just the UX team's job. Developers and HI residents are conscious that their goal is to get satisfactory user experiences. The department is getting a common view of UCD as a key of success of its work. This goal was achieved primarily by practicing methodologies and showing good results in user performance and satisfaction. Since the first attempts in teaching UCD faced resistances, the team's main effort was not on telling but showing its value. The change of culture was not immediate, but durable and contagious. Now, very few developers still resist UCD.

Perspectives of UCD for health care software

The practice of UCD for health systems has to be transdiciplinary in order to be viable and effective. Projects are better run by teams formed by staff with diverse knowledge and skills, including medicine, nursing, UX and development. The methodology includes aspects of participatory design, since each member learns the basics of the others' disciplines.

The design of applications should integrate in an overall service that offer a continuous experience for professionals and patients. If not, there is a risk of getting well designed but disconnected touchpoints, that may pose risks as well as dissatisfaction.

Conclusion

This article shows the process taken in the Health Informatics Department of the Hospital Italiano de Buenos Aires to set UCD at the core of the design and development culture, in order to enhance usability of health care software. We carried out a plan that included teaching a course, experiencing a pilot project and forming a UX team for service and dissemination. The article reports how it was implemented and the obtained achievements: impacts on the design of health care software applications, and a positive cultural change in the department towards the adoption of UCD as essential for its practice.

Abstract

A continuing medical education (CME) course was implemented for Latin American nephrologists in 2013. The topic was Immunopathology in native and transplanted kidneys. The course was given in Spanish and Portuguese. The activities included a distance education seven-week asynchronous online modality with multiple educational strategies. Thirty hours of study workload were estimated to complete the course.

Four hundred and ninety-eight physicians coming from 18 countries registered for the course; 442 of them participated in it. Of those who participated, 51% received a certificate of completion and 29% a certificate of participation. Sixty-five percent of registrants participated in the case discussions. Eighty-six percent were very satisfied and 13% were satisfied. Lack of time to devote to the course was the main limitation expressed (62%), while Internet access or difficulties in the use of technology were considered by only 12 and 6% of participants, respectively. There was a significant increase in knowledge between before and after the course; the average grade increased from 64 to 83%.

In conclusion, technology-enabled education demonstrated potential to become an instrument for Latin American nephrologists.

Keywords:

Internet; Continuing Medical Education; MOOC; Nephrology; Latin America.

Introduction

Latin America is a large and diverse region, where the predominant languages are Spanish and Portuguese, comprising more than 600 million inhabitants in over 20 countries, from Mexico in the North to Argentina and Chile in the South.

The number of nephrologists in the region is approximately 8,000, with a widespread variation across countries (1.77 to 53.9 per million population (13.2±14.0)) [1], and also within each of the countries.

SLANH (Latin American Society of Nephrology and Hypertension) is a scientific regional society with over 40 years of existence, integrates 24 Latin American National nephrology associations (www.slanh.net). STALYC (Latin American and Caribbean Transplantation Society) is the transplantation regional federation, with over 30 years of existence (www.stalyc.net). Both joined efforts in this educational initiative.

The use of information and communication technologies (ICT) is evolving constantly, with innovations and the potential for more interactive and engaging strategies to be incorporated into educational programming [2-5], still allowing for massive participation of physicians, some of them from more remote locations of the countries [6]. Therefore, in 2013, EviMed was invited by SLANH and STALYC to implement the integration of ICT into their more traditional formats, based on its record of blended multifaceted programs in Latin America [7-11].

This paper describes the design, implementation and results of a multi-country bi-lingual CME program for Latin American nephrologists.

Methods

The course was implemented in the months of September and October 2013. The topic, Immunology in native and transplanted kidneys, focused on diagnosis, categorization and therapy for these conditions, currently undergoing major discoveries. The target population was Spanish- and Portuguese-speaking nephrologists and other physicians caring for these patients working across the Latin American region. EviMed provided a multidisciplinary team of communication and educational experts, clinicians, system engineers, medical information specialists and translators to design and implement the course, together with regional and international domain experts provided by SLANH and STALYC. There were 33 lecturers, including 25 from Latin America (20 clinical nephrologists and five immunologists), as well as six European and two North American experts. Including the tutoring roles, 59 domain experts participated in the design and implementation of this course.

A multifaceted approach was used, in order to maximize opportunities for physician and health care professional participation and ensure that participants could interact and reflect on the material. Accordingly, the activities began with an on-site and online synchronous launching event, followed

by a distance education seven-week online modality with multiple educational strategies, and ended with a closing lecture. Reading resources, videos and voice-over-presentations were published, together with pre- and post-tests, patient aids, and electronic rounds (e-rounds) on clinical cases. Additionally, a clinical simulation using a custom tool developed with the School of Engineering, Universidad de la República, Uruguay [12], was used to provide applied learning through knowledge discovery and automatic feedback. It was implemented in module 6, almost the end of the course, and it had multiple possible pathways, some better than others, not only right or wrong paths, as in real settings (Figure 1).

The e-rounds were asynchronous discussion groups in either Spanish or Portuguese, coordinated by experts and tutors. This modality allowed physicians to participate whenever they could and wished to, lacking a fixed schedule to access the e-round.

A total of 30 hours of study workload along two months was estimated, in order to complete the course.

Course evaluation, participation, satisfaction and knowledge gain were quantified through pre- and post-tests.

The requirements for the certificate of completion were:

- Access to at least 70% of the study materials.
- Grading of at least 70% of tests in each module.
- Completion of the clinical simulation.
- Participation in at least 50% of discussion forums.

The requirements for the certificate of participation were:

- Access to the virtual campus.
- Access to at least 10 study materials, and/or active participation in clinical discussions.

Wilcoxon signed-rank test was used to compare pre- and post-test results.

Results

Registration

There were 498 physicians coming from 18 Latin American countries who registered for the course (Table 1), along with 59 experts and tutors and 55 observers (total=612 participants).

Table 1 - Distribution of participants by country of origin.

Country	Number	Percentage
Mexico	62	12
Brazil	59	12
Uruguay	53	11
Argentina	48	10
Peru	40	8
Ecuador	32	6
Chile	31	6
Bolivia	27	5
Costa Rica	24	5
Cuba	24	5
Guatemala	23	5
Venezuela	23	5
Colombia	13	3
Dominican Republic	12	2
Paraguay	11	2
El Salvador	8	2
Honduras	4	2
Panama	2	0
Europe	2	0
Total	*498*	*100%*

Regarding the characteristics of the audience, 49% were women and 51% men. Eighty-five percent were nephrologists and 11% were nephrology residents, while the rest were internists, pediatricians, or pathologists, among other. Seventy-seven percent were 34 years or older.

Figure 1 - Example of a graph with multiple intermediate states and paths, in a clinical simulation developed with the mentioned tool.

Participation

Ninety-six percent of registrants (n=479) accessed the online campus, and 92% of them (n=442) participated in the course. Of those who participated, 51% received a certificate of completion (n=226) and 29% a certificate of participation (n=128).

There was a slight decline in participation along the course, as is usually seen in CME courses that occur over a period of time (Figure 2).

The devices used by participants to watch the video-lectures are shown in Table 2. Thirteen percent of accesses were from tablets or smartphones.

Sixty-five percent of registrants participated in the case discussions with peers, tutors and experts, with an average of five participations per registrant out of six forums. Regarding the clinical simulation, 58% of registrants went through it, with an average of 15 pathways explored, out of 33 pathways available.

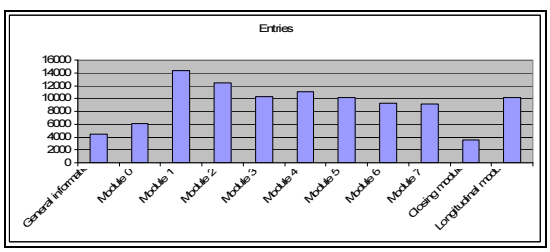

Figure 2 - Number of entries by module.

Satisfaction

This survey was responded to by 174 participants. In a Likert scale of 1-5, 86% were very satisfied, 13% were satisfied, 1% were neutral, and none were dissatisfied or very dissatisfied. Regarding the components of the course that were judged most useful, the video lectures, reading materials, discussion forums and case simulations (in this order) were selected.

Lack of time to devote to the course was the main limitation expressed (62% of participants who answered this question), while Internet access or difficulties in the use of technology were considered by 12 and 6% of participants, respectively.

Regarding perception of commercial bias, less than 1% (1/157) considered there was a commercial bias.

Table 2 - Type of devices used to watch video-lectures

Type of device	Reproductions of video lectures *Number of accesses (%)*	Mean duration (in minutes)
Computer	16,081 (86.2%)	12:03
Tablet	1,951 (10.5%)	11:09
Mobile phone	529 (2.8%)	07:52
Smart TV	57 (0.3%)	07:35
Unknown	46 (0.2%)	05:17

Knowledge acquisition

There was a significant increase in knowledge between before and after the course. Of 200 participants who took both tests, the grade increased from 64 to 83% ($p<0.001$) (Figure 3).

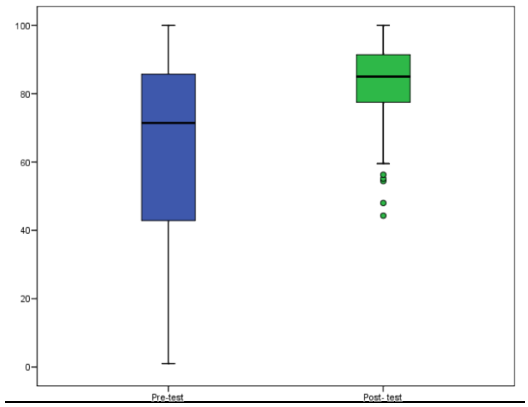

Figure 3 - Knowledge gain.

Discussion

The results of participation and retention shown are aligned with what could be expected in a voluntary online sequential CME program. In particular, the fact that 58% of participants went through the clinical simulation in module 6 is a good indicator of retention. There also was a high level of satisfaction, shown by participants relating to the study materials and experts involved in producing them, the existence of interaction among participants, and the use of innovative educational methods, such as the clinical simulations. The learning gain obtained was significant, as usually occurs with CME based on several features used in this course [13]. The fact that the program was bilingual, and both audiences were integrated in the online platform, received no mentions or criticisms; this is the best possible scenario, where translation was invisible to the user.

This educational activity reached about 7% of nephrologists in Latin America, including faculty and students. In a region as large as Latin America, this kind of program can facilitate participation, no matter the location of the professional.

This initial pioneer program has prompted both SLANH and STALYC to continue using this educational strategy in 2014, with new topics (peritoneal dialysis and solid organ transplantation, respectively). In the case of peritoneal dialysis, the online program for physicians and nurses working in dialysis centers was further integrated with an effort to provide practical support to participants who wish to implement such a dialysis method after the course, from a network of nephrology excellence centers within the region. This kind of strategy increases the chances of implementation of new knowledge and skills learned into clinical practice [14,15].

The cost structure of online education is different from live education [16]. Latin America, a geographically extensive region, but with good internet connectivity and only two main languages, allows for cost savings by avoiding costly transportation and hotel expenses necessary for live events, while engaging participants and experts in a more horizontal and prolonged exchange of experiences.

The two international associations improved their professional networks after the course; in the case of SLANH, its direct membership increased by 50%. This seems to be the result of new communication spaces being created through an online course [17].

The main limitations are related to the fact of having a one-group pre-post test study design, with no control group. Nevertheless, it would not be feasible for these associations to withdraw access to an educational program to a control group. The results regarding enrollment, participation, satisfaction and knowledge gain are useful in themselves, for this given context. Moreover, long-term knowledge retention was not measured, this would be a useful variable to consider in future research. Additionally, there was no formal attempt to measure satisfaction in those who did not answer the survey, who may differ in their perspective related to the course. Finally, no clinical outcomes were measured after this educational intervention; however, this is the norm and not the exception in CME, due to the difficulties related to measuring physician performance or patient outcomes in relation to a course.

A challenge for future courses in Nephrology and for other specialties is the possibility of massive participation of professionals, in the number of thousands, not hundreds, since Latin America has approximately one million physicians. This course had tutors who moderated group discussions, and if the same model is applied with very large audiences, the number of tutors may become difficult to manage. The models used by Massive Open Online Courses (MOOCs) [6] could then be applied here, where either more automatic interaction (e.g., with more use of clinical simulations), and/or more horizontal exchange (e.g., with more peer-to-peer discussions) would lessen the number of faculty required to moderate the discussions.

Conclusion

Technology-enabled education demonstrated good potential to become an instrument for nephrologists as well as other groups of physicians and healthcare professionals working in Latin America. It could help reduce heterogeneity in access to human resources training across regions in the countries.

Acknowledgements

The authors wish to thank the Boards of SLANH and STALYC for their support of this project, as well as the faculty involved in the implementation of the program. We also wish to thank Dr. Alejandro Ferreiro for the statistical analysis.

Danish Citizens and General Practitioners' Use of ICT for their Mutual Communication

Pernille Bertelsen[a], Lone Stub Petersen[a]

[a] *Danish Centre for Health Informatics and Department of Development and Planning, Aalborg University, Denmark*

Abstract

This paper reports on selected findings from a Danish national survey of citizens' perception and use of information and communication technology (ICT) for their health care [1]. Focus is on citizens' use of ICT and on communication with their General Practitioner (GP). It also focuses on citizens' experience of their GPs' ICT use and no use during medical consultations. The responsibility for medical service in Denmark is to a large extent handed over to the primary sector where the GP is the gatekeeper. Our data display that 65% of the adult citizens or their relatives have been using ICT to communicate with their GP. Twenty-two percent have experienced their GP use a computer screen to actively show them something while they have a consultation. Further, our data supports the assumption that the higher the education people have, the more likely they are to use ICT for their health care. The understanding of the use of ICT in communication with the GP is central to monitoring and developing an ICT that supports all citizens and considers new ways in which to enhance quality of care.

Keywords:

Citizens; General Practitioner; eHealth.

Introduction

Citizens' use of Information and Communication Technology (ICT) for their health care (eHealth) has received increased attention in Denmark. The public health care system is under pressure (demography, chronic illness, comorbidity, etc.). eHealth has, to a large extent, given better quality and also a faster turnover of patients in hospitals. In Denmark, the number of days a patient is admitted to a hospital has decreased from an average of 9.8 days in 1978, to five days in 2002, to 3.6 days in 2013 [2][3]. From 2005 to 2010, the number of outpatient visits increased by 32% [4]. The Danish health care sector is witnessing a structural change; responsibility for medical service to an even larger extent is being allocated to the primary sector where the General Practitioner is the main gatekeeper. Investments in advanced health care technology including eHealth make the hospitals provide treatment that is more specialised, leaving the primary sector (Municipalities and General Practitioners) to be responsible for care and medical follow-up.

Denmark has an international reputation of being a country of fast adopters of eHealth [5]. An international survey in the 2010 Commonwealth Fund International Health Policy Survey found that <10% of adults in the 11 countries that participated in the survey had used email to pose a medical question to their regular GP or place of care in the last two years [6]. In contrast, the 2013 survey (n=1,058) of Danish citizens' use of eHealth, from which we report in this paper, disclosed that 65% of respondents, or their closest relatives had used ICT to communicate with their GP [1].

ICT has the potential to play a pivotal role in facilitating contact between citizens' and their health care providers in daily health care. In the communication between GPs and citizens there has been a slow but steady change in communication as seen in Table 1. From 2007 to 2013 there has been a steady increase in e-mail consultations from 0.8 million to 4 million while phone consultations have decreased from 14.7 million to 11.8 million [7]. The reasons for this change are many; e.g., structural changes of payment for GP consultation, changes within GP clinics like cutbacks on telephone hours, the availability of e-mail consultation as well as the citizen's level of ICT literacy [8].

Table 1 – Development in citizen's communication channels with GP's [7].

	2007	**2010**	**2013**
Face to face consultations (daytime)	18.580.394	19.112.781	19.951.578
GP telephone consultations (daytime)	14.778.738	13.834.199	11.816.462
Email consultations	802.581	2.266.020	4.073.007

The GPs are gatekeepers in the Danish healthcare system and an increasing amount of tasks are moved to the primary sector. Understanding the use of ICT in communications between citizens and the GP becomes central to the development of Danish health care services and important in relation to changing and/or expanding the possibilities of ICT use in this area. Further, it is important to have a focus on the citizens' perspective. For many stakeholders within Danish healthcare, the central role of the citizens in eHealth is debated; healthcare managers, healthcare professionals, citizens, patient associations, system developers, vendors, and politicians advocate that eHealth has the potential to enhance citizens' positions in treatment and care [8][9]. The 2011 and 2013-17 Danish National and Regional eHealth strategies support the potential of using eHealth as a means to involve and empower the citizens in healthcare [8][9]. In the 2014 government health care policy and investments strategy for health and

welfare it is expressed as: "Patients across the country must take advantage of the new technological possibilities for telemedicine treatment and follow-up at home, where it provides better and cheaper treatment" [10]. However, it is not enough to focus on providing more efficient and effective treatment. In order to support patient empowerment, we need to understand the citizens perspective [11] and make sure that we avoid developing ICT for "People like us", that is for well educated, ICT-literate system developers and health care professionals [12].

In 2013, inspired by Canadian and Australian studies of consumer experience with eHealth [13][14], the Danish Center for Health Informatics (DaCHI) commissioned MEGAFON, a Danish market research agency, to carry out the first National Survey on Danish citizens expectations and perspectives on eHealth with a population sample of (n=1,058) [1]. DaCHI has many years of experience in monitoring eHealth implementation in Denmark, e.g., the national implementation of Electronic Health Record (EHR), as well as more recent experience with the national monitoring of health care professionals' use of health informatics in their daily clinical practices [15]. This paper reports on selected findings from the survey [1]. The following questions were investigated:

- Have you or your closest relative used ICT to communicate with your GP? (Yes/No)
  - (Yes) For what purpose did you use ICT to communicate with your GP?
  - (No) Why do you or your closest relative not use ICT to communicate with your GP?
- Last time you visited the GP clinic; did your GP use a computer while you were present? (Yes/No)
  - (Yes) Did the GP use the computer screen to show you anything?

Method

The study questionnaire was drafted with inspiration from the Canadian consumer survey [13]. The baseline data consists of the number of children in the household, educational level, access to Internet (both in private and at work/school), mobile phone and smartphone, and chronic disease occurrence. For those questions inquiring about citizens' views and attitudes, it was possible to elaborate on the answers.

We tested the questionnaire twice in minor pilot studies both asking the respondents to fill in the questionnaire and give feedback on the design of the questions, as well as adding the issues they experienced and elaborating on their views. Then, the refined survey was handed over to the market research agency. They tested the survey again, and certain questions were reformulated. The enumeration was designed as a combinational survey where both e-mail and telephone were used to question respondents from their citizen panel. In total, the survey had 1,058 respondents, which is equivalent to the needed number of respondents for a country which is the size of Denmark. Of the respondents, 80% participated by e-mail and 20% by telephone.

In addition to general baseline data and subjects concerning the use and perception of eHealth, the respondents were questioned whether they or their closest relative had used ICT to communicate with their GP. If that was the case, they were further asked what issues they had communicated about.

Further, we were also interested in getting an insight into citizens exposure to use of ICT when they physically visited the GP's office. Therefore, we asked the respondents if they had experienced their GP using a computer while they were present in the consultation room? And additional, if the GP used the computer screen to show them anything during consultation.

The population comprised of people who were already part of a citizen panel. Two-thousand one-hundred e-mails were sent, and 500 phone numbers were called. The selected respondents reflected the Danish adult population with respect to age, education and geographic distribution. Of the 1,058 respondents, 51% were female, and 49% were male. The population age was between 18 and 70+ years, with a distribution of 15% to 19% of the respondents in the six age groups.

The data was sampled over a period of one week in October 2013, and sorted into frequency and cross tables for further analysis.

Results

As already mentioned in the introduction 65% (n=684) of respondents reported that they or their closest relatives had communicated with their GP, using ICT while 33% (n=350) had no experience in doing so. The difference between age groups was minor. Of respondents between 18 and 29 years old, 68% of them or their relatives had used ICT to communicate with their GP; in the age group 70+ years, it was 62%. Seventy-one percent of the female respondents had used ICT and 59% of the male.

When we looked at the educational background of the respondents', 72% of those holding a medium or higher educational background or their relatives, had been using ICT, while 46% of those with no professional education or their relatives had used ICT in connection with their healthcare.

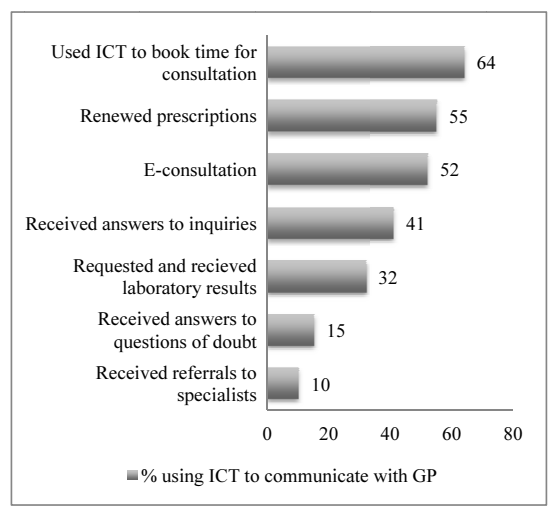

Figure 1 – Answers to questions about the use of ICT in communication with the GP (n=684)

The respondents that had experience using ICT to communicate with their GP were asked to elaborate on the activity or activities for which they had used ICT (Figure 1). Out of the 65%, a majority (64%) of the citizens had used ICT to book a consultation, while 55% had renewed their prescriptions. Fifty-two percent had used e-consultation, and 41 % had received answers to inquiries, while 32 % had been requesting for laboratory and blood test results using ICT. Fifteen percent received answers to questions of doubts, while 10% received referrals to specialists.

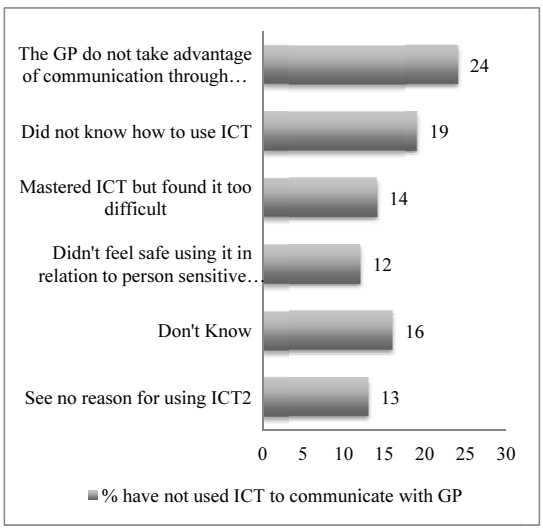

Figure 2 – Answers to questions about not using ICT in communication with the GP(n=350)

Figure 2 concentrates on the 33% who had not used ICT for communication with their GP. Twenty-four percent stated the primary reason to be that their GP did not encourage communication through ICT. Nineteen percent stated that they did not know how to use ICT, while 14% expressed that though they master ICT, they find it too difficult. Further, 12% did not feel comfortable using ICT for communicating about person-sensitive issues, while 16% answered, "Do not know." Twenty-six percent selected "other" as a reason for not making use of ICT to communicate with their GP. When they were asked to elaborate, 13% stated that they saw no need to use ICT to communicate with their GP. Other respondents indicated that they preferred to be physically present during consultation, while others commented that they preferred to use a telephone to contact their GP.

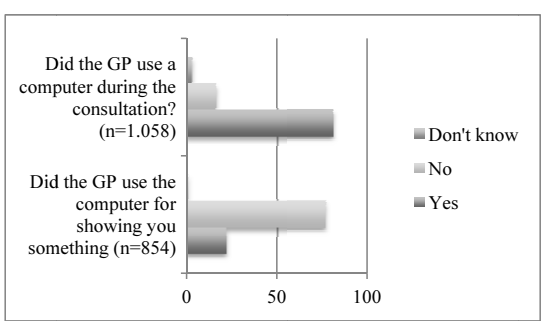

Figure 3 – The GP's use of ICT to communicate with the Citizens

The data in Figure 3 show that the majority of Danish GPs use computers during a consultation while the citizens are in the consultation room. Eighty-one percent (n= 854) of the respondents had that experience, while 16% (n=170) had not.

Twenty-two percent of the respondents (n=99) experienced that ICT was used interactively by the GP to show them something on the screen during consultation. There were differences between the age groups. Of respondents between 18 and 29 years old, 18% had been shown something during consultation, while this was the case for 36% from the age group 70+.

Of the respondents, 27% with a long professional educational background, and 20% without any education had that experience during a consultation with their GP.

Discussion

The Danish health care sector is undergoing structural changes and the important role of the primary sector is being emphasized. These changes make it pivotal that citizens can have easy access to their GP as he/she is their primary contact and gatekeeper to other health care services.

The activities that had the highest score were to book appointments, renew prescriptions, ask health related questions in e-consultations and get information on test results. More or less the same issues that the telephone consultation with the GPs clinic also can provide answers to. However, the number of email contacts is much higher than the decrease in telephone contacts. The difference from using the telephone is the flexibility, making communication independent of time and place. More women than men are using ICT to communicate with their GP. Data from the National Danish Statistic Service show that women generally have greater contact with the GPs than men. In 2007 men made 5.4 million phone calls to their GP and sent 0.3 million e-mails while women made 9.3 million calls and sent 0.5 million e-mails. In 2013, men made 4.4 million calls and sent 1.3 million e-mails, while women made 7.4 million calls and sent 2.6 million e-mails [7]. The difference in contact with the GP can partly be explained by maternity related consultations, however further studies would be needed to verify this hypothesis.

The General Practise is allowed a flexibility in organizing their work when the citizens use ICT to communicate with the GP. They do not have to answer the phone and deal with citizens needs in real-time but can attend them whenever time allows. The citizens on their part get the flexibility by not having to meet telephone hours but can write and request for information and services 24/7.

When we look at the educational background of respondents, 72% of those holding a medium or higher educational background, had been using ICT, while 46% of those with no professional education had used ICT to communicate with their GP. Therefore, our data support the assumption that the higher the education, the more likely the citizens are to use ICT for contact with their GP. Knowing that, in Denmark, the severe healthcare problems, followed by high public expenditures, are to be found among citizens with no or very low educational background (and, hence, low socioeconomic status) [16], it should be taken seriously that the citizens with these attributes are weakly represented in use of ICT. As mentioned in the introduction, a solution to this could be to focus development of eHealth on the needs of the low educated citizens perspective, not just on the perspective of "people like us" [11][12].

Eighty-one percent of the citizens had experienced GPs using ICT during a consultation. This number indicates that ICT is aspiring to become a well-integrated part of the GPs clinical work practise and their communication with patients in the consulting room. However, our data does not specify the different tasks for which the GPs use ICT, except one. The fact that 22% of the respondents had experienced the GP show them something on the computer screen, is an indication that ICT is being used during consultation. It demands further studies to assess the full status and potential for integration and use of ICT in consultations between GP and citizens. Data further indicated that elderly citizens had a slightly higher experience of the GP showing them something on the

computer screen which could indicate that they are more often consulting the GP and with more complex issues than younger people. For citizens with a high education, the percent that had experienced the GP using a computer screen were slightly higher than for those with no education. This could be an indication that this group asks questions and pays attention to understand how and why. However, the difference is not big enough to make any conclusions without further investigation.

Conclusion

According to the pressented self-assesment survey of Danish citizens, more than half of adult citizens or their closest relatives use ICT to communicate with their GP. ICT is used by citizens of all age groups and educational background though not equally distributed. The increase in use of ICT in communication with GP is also evident in the increase in e-mail consultations from 0.8 million in 2007 to 4 million in 2013. However, the survey also showed a difference in use of ICT between men and women, and between different age groups. There can be different reasons for this, but evaluation and further studies are needed in order to understand and possibly bridging the social gaps in use of ICT for health care.

The survey showed that the higher the education level, the more likely citizens are to adapt to new eHealth services. This raises the concern that eHealth is designed by and for people with high education ("people like us") [12]. Designing eHealth for people like us affects other social groups' ablility to access and use eHealth. People with low education and low eHealth literacy but large health problems (the disempowered, disengaged and disconnected – DDD's) need to participate in defining and designing eHealth that supports their needs and comptencies [12].

As more and more heath care services, telemedicine and eHealth is targeting GPs in the primary health care sector, it becomes vital to pay attention to design *with* citizens that have the largest health problems and low skills to support their own treatment and care, and not *for* these social groups. The adoption of ICT is increasing, however, we should not forget that with a public health care system we should be designing eHealth for all, especially those with the most need.

The Online Availability of Multilingual Health Promotion Materials Produced by Local Health Departments: an Information Assessment

Daniel Capurro[a,b], Shomir Chaudhuri[b], Anne M. Turner[b,c]

[a] *Department of Internal Medicine, School of Medicine, Pontificia Universidad Católica de Chile, Santiago, Chile*
[b] *Department of Biomedical Informatics and Medical Education, University of Washington, Seattle, WA, USA*
[c] *Department of Health Services, School of Public Health, University of Washington, Seattle, WA, USA*

Abstract

Objectives*: Local Health Departments (LHDs) are a key source of health promotion information. For ethnically and culturally diverse communities, it becomes important to provide minorities with language appropriate health information. This project sought to assess the availability of multilingual health promotion materials on LHD websites in Washington State (WA), USA.* ***Methods****: We performed a cross-sectional study of all 34 LHD websites in WA. We collected and classified health promotion documents available to the public, specifically, whether translated versions were available. We also assessed the extent of document sharing between LHDs.* ***Results****: We identified 1,624 documents across 34 LHDs. Topics most frequently covered were communicable diseases and emergency preparedness. Fewer than 10% of documents were available in non-English languages. We found little evidence of document sharing between LHDs; only 5% of all documents were shared between LHDs.* ***Conclusions****: WA LHDs provide a variety of health promotion materials for the public, but few multilingual materials are available online. New technologies for facilitating document sharing and machine translation may improve the present landscape.*

Public health practice; Translation; Health Promotion; Limited English Proficiency; Public Health Informatics.

Introduction

Washington State (WA), like the rest of the U.S., has become increasingly culturally and linguistically diverse. In the past decade, the Hispanic and Asian populations in WA have increased by 71% and 49%, respectively [1, 2]. Many of these individuals do not speak English well and are considered to be limited English proficient (LEP) [3]. Individuals who are LEP have less access to health care and worse health outcomes [4-7]. Low English literacy has been consistently associated with reduced access to recommended health care services [8] and increased prevalence of risk factors for chronic health conditions [9], a sign of currently existing health care disparities. Reducing such disparities is a U.S. priority [10]. Implementing culturally and linguistically appropriate services in health care is one of the means by which Healthy People 2020 [11] intends to address these disparities.

The need for culturally and linguistically appropriate written materials is well acknowledged. However, the availability of high-quality health information in languages other than English is limited. Health information translated into Spanish, the second most common language in the U.S., has been shown to be of poor quality and inconsistent [12,13]. This limited availability of health information materials in non-English languages in the U.S. persists despite legal requirements to provide equal access to health services for LEP individuals [14].

Public health agencies have a very important role in educating the population about issues of public health importance. One of the ten essential public health services is to "inform, educate and empower people about health issues"[15]. At the local level, this includes providing "health information, health education, and health promotion activities to reduce risk and promote better health" [15]. This makes LHDs, the fundamental territorial unit enabled to provide public health services in the U.S., an ideal avenue for disseminating culturally and linguistically appropriate health promotion materials to LEP communities. Furthermore, people are increasingly obtaining health information online. The 2007 Health Information National Trends Survey (HINTS) conducted by the National Cancer Institute (NCI) found that 58% of the U.S. population obtains health information through the Internet, up from 50% two years before [16].

Despite the importance of the Internet for disseminating health information, and the increasing frequency with which consumers are using such information, little is known about the current state of health promotion information provided by LHDs through the Internet, and the availability of multilingual health promotion materials for LEP individuals. To our knowledge, only one study has addressed this question [17].This study surveyed public and private mental health care providers in New Mexico about their current practices around language access services, including the availability of translated materials. The authors reported that 81% of agencies translated at least one piece of consumer education material, with a higher percentage of translated materials in locations with a higher proportion of non-English speaking residents. Although the study offers interesting insights regarding language access practices, the investigation was limited to mental health care organizations, relied solely on self-reported information, and the coverage of translated materials was not quantified.

Our own research investigating the potential use of machine translation in public health settings indicated that time and costs were the major barriers for providing multilingual health materials [18]. Since machine translation relies on the availability of training materials—that is, pairs of documents in two languages—the availability of manually translated documents in public health promotion was the main goal of this study. In addition, we sought to better understand the availability of such documents and to assess whether LHDs were meeting the LEP health information needs of their communities. In particular, we aimed to identify the range of topics covered, the types of health education materials, and the percentage of translated materials available online. We investigated the correlation of available translated materials with the percentage of non-English speaking residents in each county. Finally, we describe the use of a specific public health terminology to classify the documents we identified.

Materials and Methods

Study Setting and Document Identification

We identified all 39 counties and the 34 associated LHDs in Washington State. For each LHD we located the corresponding website. We then systematically reviewed each website to identify English and non-English health promotion materials over a five-month period. Health promotion materials were defined as (1) written documents targeting the general population that (2) provided information on how to prevent, manage or treat health conditions, or modify risk factors of public health relevance. We included all documents hosted on the LHD's website produced by the LHD. We excluded documents produced by other entities and links to externally hosted documents, forms and documents that only provided contact information to public health services and programs, and those targeting professional groups, health providers or other public health workers.

Document Classification

For each document, we captured the title, the topic, and the availability of a translated version of the document. In order to estimate the overall translation burden handled by LHDs, we also classified documents based on the amount of text. Each document was classified into three categories: (a) Low Text, for documents with mostly images and a few words or sentences and no complete paragraphs; (b) Medium Text, for documents with at least one complete paragraph and up to two pages in length; (c) High Text, for text-heavy documents of more than two pages in length.

To identify a suitable terminology to classify the topics covered by the health promotion documents, we conducted a thorough literature search using Medline (www.pubmed.gov), the National Centers for Biomedical Computing BioPortal and the Unified Medical Language System (UMLS) (www.nlm.nih.gov/research/umls/). The terminology had to include health promotion or public health topics and be comprehensive enough to describe the full range of available public health documents. Despite the importance of health promotion, we were unable to find a standard terminology on health promotion or public health topics that fulfilled all our requirements. The terminology that best approximated our needs was the European Multilingual Thesaurus on Health Promotion (EMTHP) [19]. We adopted this terminology and extended it where necessary. This included adding new terms and modifying existing terms to reflect the current topic classification practices used by the LHDs we studied.

Statistical Analysis

We conducted descriptive statistics to quantitatively describe the current status of the availability of multilingual health promotion materials. We also calculated the correlation coefficient between the proportions of multilingual documents available and non-English speakers in every LHD.

Results

Document Collection

We identified websites for the 34 LHDs serving WA's 39 counties (three LHDs serve more than one county). All LHD websites contained written health promotion materials. The number of documents available on each website varied greatly and did not have a normal distribution. The median was 24 documents per LHD website, with a range of 2 to 289 health promotion materials available on a given website. Public Health – Seattle & King County (PHSKC), the largest LHD in the state, offered the largest number of health promotion materials. In total, we identified 1,624 English health promotion documents from the 34 LHD websites.

The five topics most frequently covered were Communicable Diseases (36%), Environmental Health (22%), Emergency Preparedness (7%), Addictions (4%) and Injury Prevention (3%). In addition, 8% of the identified documents were newsletters covering more than one topic. Coverage for chronic and non-communicable diseases was remarkably low; only 1.4% of all documents covered these highly relevant conditions. The vast majority of documents (88%) were under two pages long. Longer documents (> 2 pages) were primarily newsletters, detailed handouts and small booklets (12%).

Translated Materials

Of the 1,624 identified documents, 152 (9.4%) were translated into at least one additional language. All translations were available in Spanish. Among the other available languages, most frequently are Vietnamese, Chinese, Korean, Russian, and Somali. The majority of non-Spanish translations came from PHSKC.

The most frequently translated topics were Cancer (57%), Geriatric Health (50%) and Mental Health (25%); however, the absolute number of English language documents available for these topics was remarkably small, with 7, 2 and 8 documents available respectively. Of the most frequently covered topics, 13% of Communicable Disease documents were translated; 5% of Environmental Health and 11% of Emergency Preparedness documents had translations available. No public health newsletter was translated into any non-English language (Table 1).

Table 1 - Frequency of translated health promotion materials for the most commonly available topics on Washington State Local Health Department websites

Topic	Translated – n (%)	Not Translated – n (%)	Total
Communicable Diseases	76 (13.1%)	502 (86.9%)	578
Environmental Health	18 (5.1%)	333 (94.9%)	351
Emergency Preparedness	15 (11.5%)	115 (88.5%)	130
Injury Prevention	4 (7.3%)	51 (92.7%)	55
Addiction	8 (13.8%)	50 (86.2%)	58
Chronic Diseases	0 (0%)	23 (100%)	23

The percentage of translated documents varied widely across different LHDs. The median percentage of translated documents was 2% and ranged from 0% to 50% (Adams County); 15 of the 35 LHDs (43%) had no translated materials on their websites.

The proportion of translated health promotion documents was highly correlated with the proportion of non-English speaking individuals living in each county, $r(30) = 0.90$, $p < .01$. This indicates that counties with higher proportion of non-English speakers are translating a greater proportion of their health promotion materials. Despite this positive correlation, several LHDs (such as Chelan and Douglas) that serve counties with a high proportion of non-English speakers offered remarkably few translated health promotion materials (Figure 1).

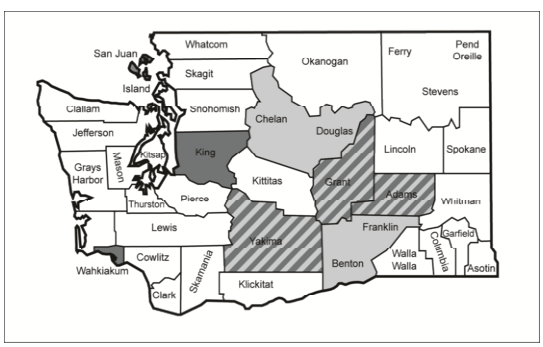

Figure 1 - Map representing Local Health Department (LHD) jurisdictions with the highest proportion of non-English speakers (light gray) and the highest proportion of translated documents (dark gray). Striped areas represent LHD jurisdictions where these two conditions overlap

Document length restrictions

We also conducted an analysis of documents produced by entities outside each LHD. We identified an additional set of 380 documents, 19% of the total documents hosted on LHDs' websites. When looking at the original source of these documents, we found little evidence of document sharing between LHDs. The most frequent external sources were the Washington State Department of Health (WA DOH), with 77 documents (20%), and the CDC with 62 (16%). Only five percent of the documents were created by other LHDs in Washington State, with the most frequent source being PHSKC.

We found little evidence of sharing of translated documents between LHDs. Twenty percent of all translations available in the state were authored by another department, similar to the proportion of shared English materials. Only one document was produced by a different LHD within Washington State; either the WA DOH or departments outside the state had originally produced the rest.

Terminology

Despite the fact that the EMTHP was specifically developed to cover health promotion materials, we found it was not sufficiently broad to adequately classify many of the health promotion documents collected in our study. Although we were able to classify most documents using this terminology, many of the principal categories listed in Table 1 were not included in this thesaurus. One notable example was the insufficient representation of environmental health topics and the complete lack of an "Emergency Preparedness" category. The EMTHP had a "Disasters" category with very few sub-concepts, which did not capture the large number of documents produced by LHDs for informing the public about Emergency Preparedness. In addition, the EMTHP did not have a general "Chronic Disease" category. On the other hand, the variety and number of available communicable disease topics was insufficient. For example, extremely relevant public health communicable diseases such as varicella and pertussis were not classified under the "Communicable Diseases" category but were assigned to "Childhood Diseases." We chose to classify all communicable diseases of public health importance into a broader "Communicable Diseases" category. Overall, our impression was that the EMTHP was "clinical condition centric", as opposed to "health problem or program centric," which is how most Washington State LHDs organize topics.

Discussion

Increasingly, the Internet is becoming a crucial method for distributing information to the public [20]. This includes dissemination of health information to providers and the general population by government and other health care organizations [22, 22]. In addition, seeking health information on the Internet has become common. This provides a unique venue for delivering high-quality public health information for vulnerable communities. However, the accessibility and quality of language-appropriate health information on the Internet remains a concern, especially for LEP individuals.

We found more than 1,600 health promotion documents available on LHD websites. Those documents were available for the general public and for public health practitioners to print and distribute. Our finding that fewer than 10% of all WA LHDs websites' health promotion documents are available in non-English languages underscores the lack of availability of translated materials. This situation is concordant with previous findings. A 2001 study found that a majority of websites only covered clinical topics minimally, and all English "and 86% of Spanish websites required high school or greater reading abilities" [23]. Left unchecked, this situation may further widen health disparities for LEP communities.

Multiple reasons could account for the lack of non-English documents in spite of federal and state requirements to provide multilingual materials. Although outside the scope of this study, informal interviews suggest that the high cost of current translation processes is a reasonable explanation. Numerous steps are involved in producing a culturally and linguistically appropriate translation of a health-related document [24], which ultimately affects the overall cost of the process. The burden of manually translating documents and the associated costs is probably not sustainable for underfunded departments such as LHDs, thus explaining the small number of translated documents. Additional forms of disseminating culturally and linguistically appropriate documents, such as video or audio documents are even more expensive to produce.

Informatics tools and principles can aid public health in fulfilling the need for translated health materials in several ways. One way is through web-based document sharing systems. We conducted an additional analysis of documents that were produced by other LHDs to estimate the amount of document sharing. In this case, we found only one translated document that had been produced by another LHD in Washington State. Overall, external entities produced only 20% of all translated materials. This is consistent with findings of a statewide survey, also conducted by our group, which showed that almost 80% of LHDs in the state did not share their translations or did not know whether efforts to share translations existed [25]. There is definitely room for improvement. This is especially relevant in the context of previous efforts implemented by Washington State.

The WA DOH has established the Health Education Resource Exchange (H.E.R.E) (http://here.doh.wa.gov/). This is a website that hosts, among other content, health education materials for use by other LHDs for free. Some of these materials are translated into multiple languages. Despite the availability of this trusted resource, and the number of translated documents it contains, its contribution to the overall pool of translated documents in our study was small. In our experience, LHDs tend to tailor documents to their communities, including local information and context.

Another approach to increasing the availability of translated health promotion documents is to partially automate the translation processes though statistical machine translation (SMT). Google Translate is an example of a free and publicly available SMT (http://translate.google.com). At least one health department currently uses SMT for translating their English materials into Spanish [26]. Although such tools hold promise for making translated materials more readily available, they currently perform poorly in the domain of public health [27]. SMT optimized for health promotion documents has the potential to reduce the time and costs associated with human translation of documents and increase their availability to LEP communities [27, 28]. The use of SMT for public health information has been insufficiently explored. Our research group will investigate the use of SMT to improve access to public health information. However, the small proportion of translated materials may severely limit the ability to adequately train a statistical machine translation system.

At the beginning of our study, we chose the EMTHP as the terminology to classify the documents. Although not surprising, it was remarkable to find the mismatch between the way LHDs organize their documents and the way the EMTHP is built. LHDs organized their documents based on the public health programs and services they offer. In contrast, the EMTHP has a clinical focus, which fails to capture this feature of US public health. As with other clinical vocabularies, the EMTHP is centered on classifying by disease conditions without considering public health importance. The current lack of a terminology to adequately classify public health documents is a significant gap. Despite all the progress that has been made in medical terminologies and ontologies, public health remains underrepresented ontologically. A 1997 study found that terminologies focused on clinical information systems, and only 8% of terms "were specifically identified as needed for population-based public health" [29]. Thirteen years later, preliminary results of a project to extend the Unified Medical Language System to include public health were presented at the 2010 Annual Symposium of the American Medical Informatics Association [30] but final results are still unavailable. Further work on creating public health domain specific terminologies or modifying existing terminologies to reflect the domain of public health are needed to improve the organization and access of health materials for all residents, including those who are LEP.

Limitations

We only included documents that were posted online, which means that we could have missed translated documents available only in print. However, in a recent survey conducted by our research team, with a 59% response rate from LHDs in Washington State, 86% of LHDs reported using the Internet to communicate non-urgent information to their communities [25], which suggests that the impact of only looking at materials online was minimal. We also limited our study to Washington State LHDs. Although the programs and services provided by these health departments are typical of other LHDs across the country, it is possible that the characteristics and the availability of translated materials may differ from state to state. However, the variety of size and complexity of the LHDs included might still represent realities outside this state. Finally, we focused our document collection on LHDs and did not include other relevant public health organizations such as non-governmental organizations (NGOs) or large integrated health maintenance organizations (HMOs), which are important sources of consumer-based health promotion materials.

Conclusions

Despite U.S. federal and state requirements that public health departments make available such materials, the number and scope of translated materials on Washington State LHDs' websites is limited, a situation that might not change easily if we consider the burden of translating health promotion materials. Potential application of new information technologies, such as document tools that help foster document sharing and exchange practices between LHDs, and automatizing aspects of translations with statistical machine translation should be investigated for their potential in improving access to low cost, high quality, bilingual health promotion materials. The limited availability of publicly available manually translated public health promotion documents might limit the ability to train such a system.

Abstract

Younger generations are extensive users of digital devices; these technologies have always existed and have always been a part of their lives. Video games are a big part of their digital experience. User-centered design is an approach to designing systems informed by scientific knowledge of how people think, act, and coordinate to accomplish their goals. There is an emerging field of intervention research looking into using these techniques to produce video games that can be applied to healthcare. Games with the purpose of improving an individual's knowledge, skills, or attitudes in the "real" world are called "Serious Games". Before doctors and patients can consider using Serious Games as a useful solution for a health care-related problem, it is important that they first are aware of them, have a basic understanding of what they are, and what, if any, claims on their effectiveness exist. In order to bridge that gap, we have produced this concise overview to introduce physicians to the subject at hand.

Keywords:

Serious games, games for health, patient education, user-centered design, mhealth, behavioral health, medical education.

Introduction

Younger generations are extensive users of digital devices[1] to the extent of being designated by some as ''digital natives''[2,3]. For them, these technologies have always existed and have always been a part of their lives[4]. Video games are a big part of their digital experience. Already in 2004, the average video game player was aged 30 years old and had played computer games for almost 10 years[5]. The average child aged 8–10 years old spent 65 minutes per day playing video games; 52 minutes/day among youth aged 10–14 years and 33 minutes/day among teenagers aged 15–18 years[1]. Today, most of these stats have remained the same or increased in number[6]. Video games reach a large and diverse audience who expect extended contact; suggesting games can attract and maintain attention, a key component for effective behavior change[7].

User-centered design (UCD) is an approach to designing systems informed by scientific knowledge of how people think, act, and coordinate to accomplish their goals[8]. UCD design practices employ both formative and summative practices in order to achieve systematic discovery of useful functions grounded in an understanding of the work domain. The user experience of video games has itself become a substantial topic of human computer interaction, with researchers developing models and methods as well as heuristics for the usability or playability of games[9–11]. There is an emerging field of intervention research looking into using these techniques to produce video games that can be applied to healthcare. Games with the purpose of improving an individual's knowledge, skills, or attitudes in the "real" world are called "Serious Games"[12]. Serious Games applied to medical or health-related purposes are growing rapidly in number and in types of applications; however, physicians might not be aware of such developments.

Before doctors and patients can consider using Serious Games as a useful solution for a health care-related problem, it is important that they first: are aware of them, have a basic understanding of what they are, and what, if any, claims on their effectiveness exist. In order to bridge that gap we have produced this concise overview to introduce physicians to the subject at hand. We will first explain what Serious Games are and how they are fundamentally different from entertainment games. Secondly, we will provide a theoretical framework to understand why games and gaming can be appealing. Thirdly, we will dissect and elaborate on the elements and principles that make up Serious Games. Fourthly, we will summarize some examples and success cases of serious game design used to promote skill acquisition or modify behavior in other health and educational domains. Finally, we discuss and provide recommendations for future intervention research regarding the use of Serious Games to aid and promote health care.

Definitions

Humanity has played games since prior to written history[13], suggesting that playing games meets enduring psychological needs[14]. A game is a physical and mental contest with a goal or objective, played according to a framework, or rules, that determines what a player can and cannot do inside a game world[15].

A video game is any game played on a digital device and encompasses a wide range of games played at arcades, over the Internet on personal computers, or on dedicated game consoles (e.g., Nintendo Wii, Sony PlayStation, or Microsoft Xbox) or handheld units (e.g., Smartphones, Nintendo Game Boy, Sony PSP). To win the game, video games challenge players to use the information they obtain as they navigate the game world[16,17] thereby providing an interesting education and training modality[18].

The emerging genre of "serious video games" or "Serious Games" employs the medium's rich, role-playing, story-based

environments to teach, train, and change knowledge, attitudes, and behavior[19]. Serious Games are often referred to as games for health when they target health behaviors[20]. Unlike regular video games, Serious Games have the dual goal of entertaining, while promoting behavior change[12,21]. Achieving the proper balance between "fun-ness" (ie, components that entertain) and "serious-ness" (ie, the components that promote behavior change) is both essential and difficult to attain [12].

The Theory Behind Serious Games

Games are played primarily for entertainment or "fun,"[22] but what constitutes "fun" is not well understood. Serious game design draws from a large body of empirical research suggesting that learning is maximized when it is occurs in relevant contexts that engage learners[23]. They employ principles of video game design to create enjoyable and immersive environments but, importantly, they are also grounded in theories of learning and development[24]. Serious Games focus on providing feedback related to achieving long-term goals and enhancing intrinsic motivation for learning by providing players with information about their progress toward incremental and primary learning goals[25].

Reviewing the literature on the subject, we find that there are several theories and models used to explain the appeal of games. Next we will present a small selection of theoretical models that often show up in literature regarding Serious Games.

Self-determination theory (SDT) is a macro-theory of human motivation that has been applied to identifying which factors sustain individuals' motivation within video games[26]. SDT postulates that the more often basic psychological needs for autonomy, competence, and relatedness are satisfied within a game context, making both the experience more enjoyable and the motivation more sustainable[27]. When considering games as a set of behavior changes, Social Cognitive Theory (SCT) is another commonly cited theory[7]. SCT proposes that behavior change is a function of enhanced skills and confidence (self-efficacy) in doing the new behavior[7], while modeling[7] and feedback[28] are keystones for learning skills. A comprehensive model of learning for behavior change in video games is based on SCT and the elaboration likelihood model[29] and includes the following steps: attention, retention, production, and motivation.

The role of play in learning is informed by Vygotsky's social constructivist theory[30,31] and the concept of ''flow'' theory in task engagement[32], related to providing achievable challenges in learning, are often used. For example, flow theory suggests that engagement in learning is highest when perceived challenges and skills are well matched[32]. Garris et al.[19] suggest that learning is enhanced when participants discover and use information rather than memorize it.

In sum, serious game design merges learning theory and empirical findings about maximizing skill learning and generalization of learning together with principles of game design to create a unique intervention tool that can target any set of cognitive, social, affective, and/or health-related skills with the goal of improving outcomes beyond the context of the game.

Dissecting Serious Games: Principles and Elements

Hunicke et al.[33] developed a game design framework called MDA (signifying Mechanics, Dynamics, and Aesthetics), to help understand games. Fundamental to this framework is the idea that games are more like artifacts than media, they need to be thought of in terms of the behavior they produce via interaction.

Jesse Schell in his book "The Art of Game Design: a book of lenses"[34] and Ralph Koster in "A Theory of Fun for Game Design"[35] point out common video game components such as immersive storylines, characters, goals directed around targeted skills, rewards and feedback about goal progress, increasing levels of difficulty, and the provision of choice. These same elements are highlighted by Baranowski et al[20] and Kapp et al.[25] in their work on Serious Games.

Storylines engage individuals by means of their empathy with the protagonist and enable individuals to experience content in meaningful contexts[20]. In a serious game, the story narrative is built to support learning of the specific educational content targeted by the intervention[36]. This ''interactive storytelling'' technology allows for players' interactions with computer-controlled characters and subsequent decisions within the game to shape the goals and outcome of the storyline[37]. Characters in these stories can be protagonists, who serve as models, and antagonists, who attempt to impede the protagonists, thus adding tension and conflict that act as the motivating factor behind the story's action and plot[12,20]. Character modeling and dialogue can convey knowledge, demonstrate skills, and enhance self-efficacy[38].

Goals in games are objectives that players need to accomplish to succeed. These changes in behavior convey a statement of intention and give focus and direction to efforts[39]. Goals provide a standard, or benchmark, against which goal attainment can be assessed[40]. Continuous feedback and rewards for progress are critical for shaping behavior in Serious Games as learners work towards achieving challenging goals. In designing rewards and feedback, both intrinsic and extrinsic motivation needs to be considered[41].

As suggested earlier, SDT states that provision of choice is one of the important tools of fostering intrinsic motivation and enjoyment in Serious Games[14,42]. In addition to providing individualized levels of difficulty, provisions of choice within a serious game can allow learners to maintain a sense of autonomy and control over their learning experience[43].

Healthcare Applications

Serious Games have been shown in a systematic review to be at least as effective as conventional tests in improving cognitive abilities in the elderly[44]. In a randomized controlled trial (RCT) they seemed more effective than conventional neuropsychological interventions when it comes to improving neuropsychological abilities of alcoholic patients[45].

There are RCTs of computer-based interventions being used to improve emotion and face identity recognition abilities in autism[46] and meta-analyses on language and social skills[47] with the goal of improving psychosocial outcomes in both mental health and developmental disorders.

Serious game-based interventions have been used in RCTs to support rehabilitation in disabled patients, showing equal effectiveness compared to conventional training programs[48].

Games have been applied to promote healthy behavior in children[49] and to educate patients[50]. Serious game-based patient education has also been shown to increase the treatment adherence among adolescents with leukemia in an RCT [51]. The characters in educational games can include mentors who facilitate learning by providing guidance in the game[36,52].

Serious Games have been shown in RCTs to add to training medical personnel[53] and reviews show improvement of understanding of geriatric principles among medical students compared to conventional training methods[54]. One strategy for personalizing training/game play is to use adaptive progressions. In other words, on a trial-by-trial basis, the level of difficulty of the training is specifically adapted to the player's in–the-moment game performance.

Conclusions and Directions for Future Research

Video games are an experiential activity, rather than a presentation requiring memorization or assimilation of out-of-context facts. Video games can promote "situated learning"[55] in which players discover and learn through exploration and experimentation[56,57]. Through gameplay, players "vicariously" experience desirable and undesirable consequences without putting themselves in harm's way[57]. When using Serious Games in health care, end users (clinicians, patients, or educators) must decide whether games are safe and effective enough to be used for their intended purposes. In order to do so, they need consistent, transparent, and reliable assessments, however, studies on Serious Games'validity and effectiveness remain scarce[53,58].

Lewis[59] and Albrecht[60] have recently published guidelines reporting standards to support clinicians and patients in distinguishing high quality mHealth apps yet these have two important shortcomings when it comes to games. First, explicit information on a serious game's content and didactic features is required, as the external purpose of a serious game is frequently less obvious to the user than in the case of mHealth apps. Second, Serious Games require additional validation steps (eg, construct and predictive validity), compared to non-interactive information platforms. Gameplay is dynamic and learning goals in gameplay are often not disclosed to the user. In fact, the user learns by playing the game, whereas discovery in itself may be part of the gameplay. Disclosing learning goals could thus be counterproductive[61].

The Dutch Society for Simulation in Healthcare (DSSH) developed a consensus-based framework[62] based on Lewis'[59] and Albrecht's[60] work. This framework could be a valid tool to assess Serious Games but further exploration is required. It should also be considered that a game's validity does not predict a game's success nor its attractiveness to the user, which also depends on its entertainment capability and distribution method[63].

There is a need for more literature on Serious Games and their potential in informatics specific areas as well.

Finally, player expectations should also be considered. When faced with regular games players simply expect to be immersed in the story or gameplay of the product. Players may have different expectations for health video games and might be more critical as to the "fun" they are having.

Serious Games' potential make them something that physicians should be aware of but their complexity and lack of valid ways of assessment can play against their widespread use. Regardless, Serious Games are a promising tool which, if properly crafted, could be used to create high-impact interventions.

Living with Lung Cancer – Patients' Experiences as Input to eHealth Service Design

Maria Hägglund[a], Peter Bolin[a, b], Sabine Koch[a]

[a] *Health Informatics Centre, department of Learning Informatics, Management and Ethics, Karolinska Institutet, Stockholm, Sweden*
[b] *Stockholm County Council, Sweden*

Abstract

The objective of the study is to describe the lung cancer care process as experienced by patients, as well as to perform a qualitative analysis of problems they encounter throughout the patient journey. A user-centered design approach was used and data collected through two focus group meetings with patients. We present the results in the form of a patient journey model, descriptions of problems related to the journey as expressed by patients and proposed eHealth services discussed by patients in the focus groups. The results indicate that not only is the patient journey fragmented and different for each patient going through it depending upon their specific type of lung cancer and treatment options, but their experiences are also highly individual and dependent on their personal needs and interpretations of the process. Designing eHealth to improve the patient journey will therefore require flexibility and adaptability to the individual's needs.

Keywords:

Consumer health informatics; Patient journey mapping; eHealth; Participatory design.

Introduction

Consumer health informatics [1] is a growing field of research, as more and more applications are developed for patients and citizens rather than for health care professionals. The term eHealth was introduced by Eysenbach in the year 2000 as "an emerging field in the intersection of medical informatics, public health and business, referring to health services and information delivered or enhanced through the Internet and related technologies" [2]. eHealth has the potential to revolutionize the way health care and prevention is provided, shifting the balance of power and responsibility from healthcare professionals to patients and citizens [3, 4]. Yet many applications developed for patients are either designed from a healthcare provider's perspective, e.g. applications to collect patient reported outcomes, or stand-alone health applications, e.g. mobile apps for activity tracking. A more balanced way for initiating eHealth service design taking patients' experiences of the patient journey into account is suggested in this study. To design eHealth services that provide patients with a holistic overview of their often fragmented care requires a deep understanding of their experiences of the patient journey. In service design [5], customer journey mapping is often used to capture the consumers' experiences of using a service, and this method has lately also been applied in healthcare to describe the patients' experiences [6, 7].

My Care Pathways

The work presented in this study was performed within the Swedish research project "My Care Pathways" [8]. The project aims to create new mobile citizen e-services that allow patients to follow, own, and manage their care process related information. The project also aims to adapt and further develop the Swedish National platform for citizen e-services and provide an open software development kit (SDK) for developing new e-services [9].

In the initial stages of the project, three patient groups were involved in the e-service design: stroke patients [10], lung cancer patients and patients undergoing planned hip surgery. In this paper, we focus on the lung cancer patients. The objective of the study is to describe the process of being diagnosed with and treated for lung cancer as experienced by patients, as well as a qualitative analysis of problem areas in this care process. In this paper, we present the patient journey model, examples of problems as expressed by patients as well as examples of proposed eHealth services to address them.

Methods

We applied a user-centered design approach [11] to the analysis of problems and needs and actively involving patients in the process. An overview of the approach is shown in Figure 1.

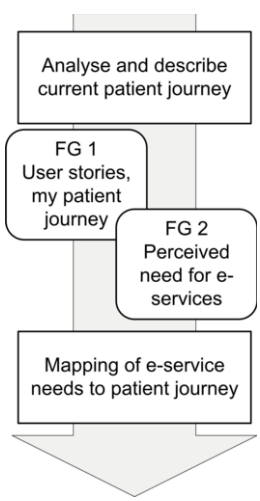

Figure 1 – Overview of the Needs Analysis Process

The first stage of the process was to do an initial analysis and description of the current patient journey. The initial patient journey model was based on literature and materials gathered from clinicians at the Karolinska hospital who are involved in different stages of the lung cancer diagnosis and treatment process. The model was then presented to the patients to validate that we had indeed captured the stages that are important for the patients.

Two focus group interviews were held to explore the problems and experiences of the patients and how these problems change throughout the patient journey. An overview of participants is given in Table 1. All participants were recruited by convenience sampling via the lung cancer patient organization Stödet (http://stödet.se) in Stockholm, Sweden.

Table 1- An overview of participants

Focus Group	Number of participants
FG 1	Patients (n = 4)
FG 2	Patients (n = 5)

All focus group meetings were facilitated by a moderator (first author of this paper, MH) and notes were taken by two researchers (PB, SK). Each focus group lasted 2-3 hours. The focus group meetings were audio recorded and transcribed. Content analysis [12] was used to identify categories and themes related to the patient experience. In addition, current paper-based information given to patients at different stages was gathered and studied.

The collected qualitative data was used to model a patient journey, referring to "the experiences and processes the patient goes through during the course of a disease and its treatment" [7]. The patient journey model aims to provide a common picture of the processes and the way the patients experience them.

Ethical approval for the study was obtained from the regional ethical review board (2011/2093–31/5).

Results

The results are presented in the form of a patient journey model, important patient experiences and proposed eHealth services.

The Patient Journey Model

We distinguish between phases and events in the patient journey model (Figure 2). A phase is extended over time and may incorporate several events. An event is a specific interaction between patient and healthcare, where information is created, shared or communicated. Patient journey models often only include phases, but to use the patient journey as a basis for design of eHealth services, it is important to also map these events, typically called touch points in customer journey maps [5].

We identified 5 distinct phases that the lung cancer patients go through: (1) pre-diagnosis care (primary and/or acute), (2) diagnostic examinations, (3) treatment, and finally (4) rehabilitation (when the patient is in remission), or (5) palliative care.

The *pre-diagnosis care (primary and/or acute)* phase can be a long and often uncertain process. Patients sometimes seek care on several occasions before the suspicion of lung cancer is actually raised, and a high proportion of patients who are finally diagnosed present with advanced disease [13, 14]. The first contact is often with a primary care physician, and if the suspicion of lung cancer is raised in primary care, referrals are sent for further assessments. However, it is not uncommon that patients seek acute care after having been misdiagnosed and treated with antibiotics in primary care and the referral to specialist care is sent from the acute care department [14]. An important event that all participants in this study described was when the decision was made to refer to diagnostic examinations.

The second phase, *diagnostic examinations and specialist assessment*, can be fragmented since many different clinics are involved in the examinations, which may include laboratory tests, chest X-ray, computer tomography (CT scan, CAT scan), positron emission tomography (PET scan), sputum cytology, fine-needle aspiration biopsy of the lung, bronchoscopy and many more. This phase is often perceived as time consuming and frustrating by the patients, as they are anxiously awaiting the results of the examinations. The phase is often coordinated from a pulmonary clinic, and begins when the patient is referred there for diagnosis and staging. After lung cancer has been diagnosed, the phase continues with further examinations to determine the type of lung cancer (non-small cell and small cell lung cancer) and staging, i.e. to determine how far the

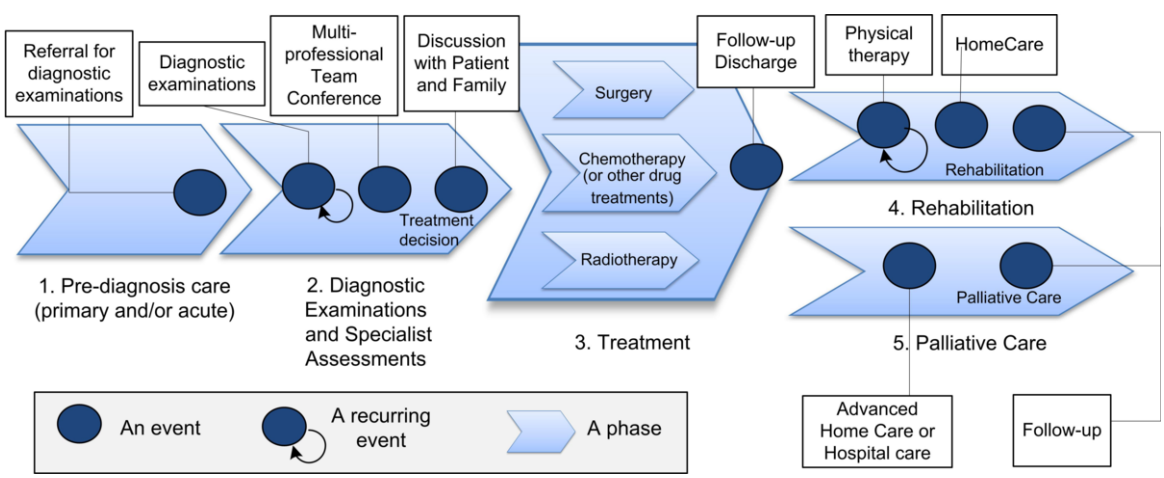

Figure 2 – The Lung Cancer Patient Journey Model

cancer has spread. The phase ends with a multi-professional conference where clinicians with different specialities meet to discuss the diagnosis and treatment options. The preferred option is then discussed with the patient and family members before treatment begins.

The *treatment* phase depends very much on the choice of treatment, but usually consists of surgery, radiotherapy, chemotherapy, or a combination of these. Different specialist clinics are responsible for different treatments, thorax for surgery, oncology for radiotherapy and chemotherapy, and pulmonary clinic for palliative and post-surgery care. Patient experiences varied depending on the type of treatment they had received. Patients who received care at different clinics expressed frustration at the poor communication between clinics and lack of coordination of activities. One participant who fell ill with breast cancer while undergoing treatment for her lung cancer described the lack of coordination:

"But I think the communication between the Radiology clinic and Thorax is poor. It feels like I have to… this spring when I was receiving treatment that would last until summer, I asked if it could clash with the medication I was getting from the Radiology clinic. […] The chemotherapy is a drug given for breast cancer too so they could 'take each other out' and it turned out no one told me to stop taking this medicine I was taking everyday. And they clashed. I got pretty ill."

Yet, once the treatment finally began, many patients felt relief, *"… it had been 3-4 months, I think, when they put the needle in my arm [for chemotherapy], and then I felt; now I will get better, now I have received help!"*

Not all patients undergo curative treatments, many lung cancer patients are diagnosed at a late stage and suffer from co-morbidities such as COPD (chronic obstructive pulmonary disease) or heart disease, so that curative treatments are deemed unwise and it is decided to go directly to palliative care instead. The treatments described above may still be used, to relieve symptoms, but not with a curative purpose. If treatments have been performed with a curative aim, the patient hopefully goes into remission and moves on to the rehabilitation phase, but if the treatments are not effective, a *palliative* phase begins with focus on pain management and quality of life.

Rehabilitation was an important topic for our participants, as it was not available to all patients automatically. Depending on which clinic the patient was treated at (oncology, thorax or pulmonary) rehabilitation was more or less available despite patients suffering from similar symptoms. This was expressed as frustrating and a sign of inequity.

The Patients' Experiences

Describing the process in terms of phases and events is important, but designers of eHealth services also need guidance when patients experience problems. Table 2 shows problems experienced by lung cancer patients related to the phases.

Table 2 – Patient Experienced Problems

Phase	Problem	Description
1	Unnecessary delays before diagnosis	Several of the participants expressed that it took too long for primary care to acknowledge their condition. One participant had to visit the emergency department and was then recommended to contact the pulmonary clinic directly. Participants felt that they had to fight to get to get the right care and that it depended on the individual healthcare professional they met.
2-3	Poor communication with health care	Participants expressed frustration at reaching the clinics at the hospital. Especially when receiving care at different clinics, finding contact information and reaching the right person was challenging. Different clinics at the same hospital also had different approaches to communicating with patients making it more difficult to manage.
2-3	Poor coordination	As both diagnostic and treatment activities are distributed on many different clinics, patients suffered from poor coordination when e.g. appointments were scheduled two days in a row rather than after each other on the same day. The patients also lacked information about who (which department/clinic) is responsible for which part of their treatment.
2-3	Understanding of procedures	Some of the procedures are major and the patients are naturally worried and concerned beforehand. An issue that was brought up in the focus groups was that patient information was often not up to date, or was provided in what they interpreted as "homemade" brochures. This did not improve the patients trust and confidence in health care.
4-5	Patient follow-up	The patients receive different types of patient surveys. They are often repetitive and far too long. As a patient you do not have the strength to answer the surveys all the time.
All	Poor support for multi-morbidity	Many lung cancer patients also suffer from other conditions, yet health care is not adapted to this. Frustration was expressed at having to repeat information and act as the coordinator between different clinics and clinicians.
All	Learning to manage one's care	Several participants expressed that it took time for them to understand where and how to find information and to manage their care. If the patient participated in a study, then they received more information, more continuity and more visits.
All	Lack of channels for giving feedback	At the same time, the patients lacked a channel for giving their feedback, either immediately after a meeting or long-term. Instead, the patient organization receives this information, without being able to pass it forward.
All	Understanding of rights to choose	The patients lacked information about what opportunities they have to e.g. choose doctor and treatments, second opinion. Trusting your physician was expressed as crucial, and several participants had asked to see another physician after a bad experience. However, this option was not something everyone was aware of, and it took some time for the participants to realize how important this was.

Examples of Proposed eHealth Services

Based on the modeled process and the identified problems, we suggested a number of potential eHealth services, and some examples of these are presented in Table 3.

One participant expressed an overall need for eHealth services in the following way:

"… I can't demand to have total control over the entire process, but I should at least have as much control so that I can trust health care and focus my energy on getting well".

It was important for the participants to have information and insight into the care processes, but they stressed that the responsibility needed to remain with health care – eHealth services should not be a means for health care to leave the responsibility for coordination and communciation to the patients.

Table 3 – Proposed eHealth Services

Problem	Proposed eHealth service
Overview of the diagnostic procedures	An e-service showing the **progress of the different diagnostic examinations** made was requested. The participants did not want to receive the results online, but wanted an expected time frame and did not want to have to wait for an appointment once the results were ready. *"So, it had taken time, but then I was supposed to wait 3 weeks for a doctor's appointment so I could find out what it was when they were done. Then I lost it completely..."*
Poor coordination	Participants suggested that health care should be working more with logistics to get the processes right. An **overview of the "normal" care process** would be useful to both patients and professionals. If it could also show the patient's current position and who is responsible for different parts of the process it would be even more useful.
Understanding the procedures	Available information beforehand is necessary to decrease anxiety. The information should be updated and easy to understand to make patients feel confident. Online information sites in various designs were recommended.
Patient follow-up	**Online patient surveys** which could make the answers available during the whole care process were requested.
Lack of channels for giving feedback	**e-services for giving immediate feedback** to healthcare were deemed useful by the participants, but they also wanted a way to communicate feedback later on when you have more perspective on the care process. Channels for making formal complaints are available, but the participants lacked an easy **means for communicating feedback and improvement suggestions**.
Poor communication with health care	**Improved services to communicate with health care** were requested. Individual patients have different preferences for synchronous and asynchronous communication, and alternatives should be available. However, overview and responsibility was again stressed – who do I contact about this specific issue?
Learning to manage one's care	Many participants expressed that it took them time to learn how to navigate through health care, where to find information and how to ensure you get the care you need. If this process could be faster it would be helpful, and support from other patients in combination with other **guiding or e-learning eHealth services** could be useful.
Understanding of rights to choose	e-services **clarifying patients' rights** both in terms of choosing a health care professional you trust, and when it comes to requesting second opinions, choosing treatment etc. Most participants expressed that they trusted the judgments made by health care professionals, especially during the multi-professional conference – but at the same time they had all experiences of questioning individual professionals' judgment and requesting to meet new physicians in the future.

The proposed eHealth services in Table 3 are not an exclusive list, but rather suggestions made by participants in the focus groups. Anyone reading about the problems may come up with their own ideas for eHealth services that could improve the situations for people living with lung cancer. This is one of the strengths of using patient journey mapping and patient experiences as a basis for design.

Discussion

We used the patient journey model to understand the processes a patient goes through before, during and after lung cancer treatment and the problems they experience during this journey. Gaining this insight is important input to proposing new eHealth services for lung cancer patients.

A limitation of this study is the low number of participants involved in the focus groups. Still, even this limited case study points to important insights into the patients' experiences, and important ideas for eHealth services were produced. These results will be used together with an in-depth content analysis of the patients' information and communication needs to further understand the content and functionalities eHealth needs to provide to support lung cancer patients throughout their patient journey.

All participants were recruited locally, and had received their care within the same county council. This limits the transferability of the results in terms of the patients' experiences and some of the proposed eHealth services. Yet, as a designer of eHealth services one may recognize similar problems from other contexts where these results can be applied. The important, transferable, result of this study is however the method of using patients' experiences as a basis for proposing new eHealth services to improve health care from a patient perspective. The approach can be applied locally in any context to explore patients' experiences and propose solutions to identified problems.

The lung cancer patient journey in Stockholm, Sweden, is fragmented and different for each patient going through it depending on their specific type of lung cancer and treatment options. In addition, their experiences are also highly individual and dependent on their personal needs and interpretations of the process. Designing eHealth to improve the patient journey therefore requires flexibility and adaptability to the individual's needs.

It is also important to acknowledge that health care is a socio-technical system [15, 16], and not all the problems identified in this study can be solved through new eHealth services. Therefore, it is crucial to involve healthcare professionals and other stakeholders within the healthcare organization to

address the problems from more organizational and work process perspectives too. In addition, when designing and implementing new eHealth services to support patients throughout the patient journey, it is imperative to consider what impact these will have of the surrounding organization and how do thenew tools for communication between patients and professionals affect the daily work.

Conclusion

Patient journey models and qualitative analysis of patients' experiences are powerful tools that can be used to improve health care from a patient perspective. In this study we show how such tools can be used as input to the design of eHealth services, but by creating a patient journey model and describing patients' experiences of going through this journey, we also create opportunities for reaching a common understanding of issues and problems experienced by patients, thereby facilitating improvement work and in the long run increased patient satisfaction.

The results indicate that not only is the patient journey fragmented and different for each patient going through it depending on their specific type of lung cancer and treatment options, but their experiences are also highly individual and dependent on their personal needs and interpretations of the process. Designing eHealth to improve the patient journey will therefore require flexibility and adaptability to the individual's needs.

Acknowledgments

The study is supported by VINNOVA – Swedish Agency for Innovation Systems through the project "My Care Pathways" (2011-02536). We also wish to thank all the participants in the study who shared their experiences openly with us.

Applying a Geospatial Visualization Based on USSD Messages to Real Time Identification of Epidemiological Risk Areas in Developing Countries: A Case of Study of Paraguay

Silvia Ochoa[a], Julia Talavera[a], Julio Paciello[a]

[a] *Polytechnic School, National University of Asuncion*

Abstract

The identification of epidemiological risk areas is one of the major problems in public health. Information management strategies are needed to facilitate prevention and control of disease in the affected areas. This paper presents a model to optimize geographical data collection of suspected or confirmed disease occurrences using the Unstructured Supplementary Service Data (USSD) mobile technology, considering its wide adoption even in developing countries such as Paraguay. A Geographic Information System (GIS) is proposed for visualizing potential epidemiological risk areas in real time, that aims to support decision making and to implement prevention or contingency programs for public health.

Keywords:
eHealth, mHealth, GSM, USSD, GIS.

Introduction

Health is one of the most critical areas regarding the use of information due to many existing regulations and primarily, public management.

In Latin America and the Caribbean, considerable inequity exists in the access to public health services . This is a result of a number of factors , including: lack of human resources, infrastructure, equipment, and medication. Further, a physical and cultural gap exists between the public health system and the population, related to low incomes and different ethnic backgrounds in developing countries. Thus, vulnerability is determined by income levels, geographic location, and ethnicity, causing an exclusion of millions of households in the region [1].

Information and Communication Technologies (ICT) increase the chance of improving the life quality in the community, as shown in previous works [2,3]. This paper focuses on applying ICT as a tool for public health surveillance. Thus, this initiative can be considered within the topic of *eHealth*. According to the *World Health Organization* (WHO) [4] eHealth is *the cost-effective and secure use of information and communications technologies in support of health and health-related fields, including healthcare services, health surveillance, health literature, and health education, knowledge, and research.*

The purpose of the present work is to optimize the geolocated data collection process for suspected or confirmed disease occurrences through the use of mobile devices to enable the identification of potential epidemiological risk areas in real time. Visualization of collected data is proposed through a *Geographic Information System* (GIS).

The proposed model can be implemented via mHealth as an application that allows users to report disease occurrence from their mobile devices through the exchange of *Unstructured Supplementary Service Data* (USSD) messages. USSD is a feature included in *Global System for Mobile Communications* (GSM) mobile technology (known as "2G"), that allows bidirectional transmission of information between the mobile device and an operator-defined application. With the collected information, this work proposes a geospatial visualization to identify epidemiological risk areas. Also, it can be used as a supporting tool for improving the actions of the organizations responsible for health.

We propose involvement of the community members in data collection, using the community as an actor in the process of epidemiological surveillance. The model of *Community Health Workers* [5] arises as part of the community auxiliary health team, where workers are selected and trained in order to work for their own communities.

In the next sections of this paper, a description of the problem is presented, including statistical information about the penetration of technologies in Paraguay. Also, the proposed model and considered scenarios are presented in detail. Finally, a comparative analysis between the proposed model and other alternatives is presented, along with conclusions of the work.

Background

In Paraguay, the *General Office of Health Surveillance* (DGVS, for its acronym in spanish) of the *Ministry of Health and Welfare* (MSPBS, for its acronym in spanish) is responsible for providing continuous information about monitored diseases in order to support decision making regarding prevention, control, and elimination of these diseases.

All the information related to mandatory surveillance of diseases in Paraguay is centralized by DGVS. Every week, the *Data Management Unit* (UGD, for its acronym in spanish) receives a notification form – which is printed (fax or mail) or in digital format (e-mail) – from the health regions. The forms are received mainly in printed format. Each health region has an Epidemiological Unit, which is responsible for collecting information from all reporting units.

The UGD unit performs a manual process of digitizing and unifying the collected information in order to obtain an electronic spreadsheet, which indicates for each record the

reported disease and the specific health region during a epidemiological week, as defined by the MSPBS.

Finally, the information is sent to the *National Center of Communications* (CNE, for its acronym in spanish), where statistical analyses of the collected data are performed. An epidemiological newsletter is published weekly, showing the current status of the country. Typically, risk maps are used for visualizing the information.

According to statistical information from Paraguay in 2013 – with an estimated population of 6.700.000 – 95.5% owned a mobile device (97.1% urban areas, 93.4% rural areas). Additionally, 19.4% had landline communication subscription [6].

The General Office of Statistics and Census (DGEEC, for its acronym in spanish) announced that of all Paraguayan households, 26.6% have Internet-connected computers. However, it should be noted that Paraguayans have recently increased their access to the web using mobile devices (such as smartphones and tablets). For this reason it is estimated that the actual Internet penetration is approximately 30% [7].

From the mentioned statistics, the mobile technology – particularly GSM networks – represents a communication channel with a greater penetration in households than landlines or the Internet. This makes it an ideal tool to optimize the process of gathering information.

Based on these statistical values, we propose that an efficient way to penetrate more extensively in the territory of Paraguay is through GSM technology. Currently, internet and smartphone penetration remains insufficient in a developing country such as Paraguay, where the territory is mostly rural. Also, it should be considered that individuals typically excluded from public health services are those with low incomes or of different ethnicities.

Materials and Methods

Natural disasters, such as wildfires, floods, epidemics, and oil spills, can be modeled and presented through a GIS [8]. In public health, GISs have been used mainly for processing medical and epidemiological research that explores the magnitude and distribution of several health problems. In addition,, for analyzing, monitoring, and decision making related to this field.

The use of USSD communication protocol is considered, due to its ability to send information and instructions bidirectionally (between the mobile device and the applications that process the data). Thus, real time information can be provided by users, which will feed into a GIS, to allow the surveillance of epidemic risk areas. This will allow saving both economic and human effort, considering that, having this tool, the citizens and health workers would spend less time in the early identification of epidemiologic risk areas in order to support establishing policies, strengthen planning processes, and guiding actions to improve citizens' quality of life.

As shown in Figure 1, the information was collected in a centralized system, which may be accessible in real time to the actors involved in the information collection process. This will support the decision making at all levels and ensure that plans and policies are fully justified based on the evidence gathered. Thus, an improvement over the conventional non-automatic model was obtained, where the information originally reaches the levels required for decision making with a considerable delay.

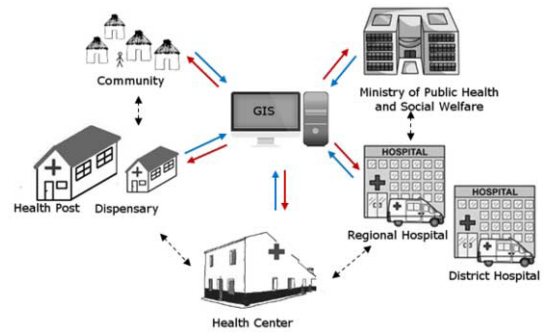

Figure 1 - Real time access to information

The posed problem in this work has been detached into two parts: data collection and visualization. A USSD module was designed for the first one, which provides greater coverage in terms of the number of citizens who will be able to access the service. For the second one, a GIS module was implemented, responsible for rendering (in real time) the information gathered for geographic visualization. The proposed model including the modules mentioned is shown in Figure 2.

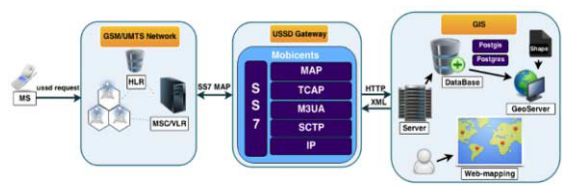

Figure 2 - Proposed model

The proposed model begins with the user or subscriber, who initiates a USSD dialogue by dialing a *Service Code* (SC) from the *Mobile Station* (MS). This message is encapsulated in a message *Mobile Application Part* (MAP) and is sent through the GSM network elements to the USSD Gateway (USSD module) which is responsible for receiving the request and identifying (based on the SC) which application has to be accessed in order to forward the request to it establishing a session. The application returns the initial menu to the USSD Gateway and this back to the user.

In this way, a USSD dialogue starts between the mobile device and the USSD application, where each entered option is logged in a georeferenced data base.

Finally, the data collected through the USSD module was processed and analyzed in the GIS module, which allows for visualizing real time information obtained from such data. In the following sections, both modules are explained in detail.

USSD Module

This module is responsible for data collection through a USSD application that uses RESTful web services to get an interactive menu of disease reports and registration.

The collected information was categorized according to the user who has made the notification. Every type of user will have a different notification accuracy level. This distinction has been deemed important because it is necessary to ensure the quality of the information. Inconsistent data or false positive notifications would not reflect reality, so the actions

taken or applied on these data cannot be used to improve or eliminate the identified health problems. Thus, the notifications can be visualized and compared in real time and for each user type. Among the possible types of users, the proposal includes: a citizen, a community health worker, and/or an official of the Ministry of Public Health. The last two types of users are able to implement more rigorous and reliable checks and verification to reduce false positives.

The Mobicents [9] platform was used to simulate the USSD dialogue, which is an implementation of *Open Source Software* (OSS) for development of USSD applications based on the *Signalling System No. 7* (SS7) stack protocol. In Figure 3, the message flow of a typical MAP protocol is presented for transferring data between a network node, the Mobicents platform, and the USSD application.

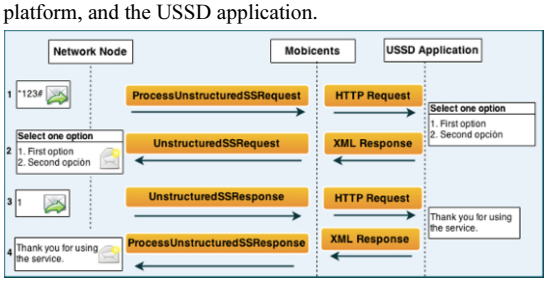

Figure 3 – USSD Dialog

The user dials the SC USSD code (e.g., *123#). A network node can represent the MSC, HLR, or VLR. The MAP protocol is used by the Mobicents platform to communicate with the network node and HTTP and XML protocols are used to communicate with the USSD application. The USSD application handles the business logic and sends the response back to the user in the same session.

GIS Module

The GIS Module is responsible for processing, analyzing, and categorizing data collected in the previous module, and allows the definition of thresholds on when to consider an area as being at risk for an epidemic. Finally, analysis of information is performed by a map viewer in real time.

This module aims to provide to the government, non-government organizations, and agencies that work on health services a tool to obtain georeferenced information of areas or regions affected by some kind of disease.

As shown in Figure 2, the GIS module consists of several components: a server application that is used by the USSD module to obtain interactive menus and persist the notifications of the users in the database, and a map server, which is responsible for analyzing the collected data and publishing the diseases layers with styles specific to each one of them. Finally, a web map visualization is included, where the available layers are passed to the map server and rendered to the final users.

Considered Scenarios

The scenarios considered in this work are differentiated by the locating mechanism used (that is, the mechanism that allows the mobile device's position to be determined). This information may be provided by the GSM network operator or by the user.

Automatic localization based on Cell-ID

There are several methods to determine the location of the MS. They can be different according to the technologies used to determine the location and the expected precision. In our scenario, the location method using the MS's Cell ID was used, considering its low cost and its inclusion in the GSM network, in order to determine the mobile device's location. The antenna identifier (the Cell ID) to which the device is connected is used to geographically locate the antenna, which is an approximation of the user's location.

For this scenario, the operator must provide geographic information of their *Base Transceiver Station* (BTS) antennas, so they can be identified by the visualization component of the GIS module. Since the information regarding the connected mobile device's antenna is handled by the telecommunication company, once a user's request is received, the USSD gateway simulates the consult to the HLR in order to determine the antenna to which the device is connected [10], and returns a MAP message with the Cell ID for that particular antenna.

The accuracy of this method depends on the cell size. We assumed 500 meters of accuracy within a city and about 10 kilometers in rural areas, representing an acceptable range considering the necessary resolution for identification of risk areas.

Manual localization

For this investigation two additional menu fields were included in the USSD application: the department (state) and city must be selected by the users in order to map to their corresponding latitude and longitude in the GIS, based on its own geographic data.

This scenario was considered as an alternative way to determine location when the system fails to obtain the proper information from the the telecommunication company. It is noteworthy that in these cases the accuracy of the model decreased significantly, and also required the user to know and select their department and city.

Results

The software evaluation process allows us to justify investing in the technology, based on the goals and needs of the consumer.

The development and selection of high quality software represents a critical point in the process, considering that the development and implementation of our method drives the success or failure of processes that are supported by these tools. This can be achieved by defining appropriate quality characteristics, taking into account the purpose and use of the software [11].

To verify the benefits and drawbacks of the conventional model currently used by the DGVS, and of the proposed model, a comparative study was conducted , considering each of the characteristics and subcharacteristics defined in Table 1.

The comparison is based on a set of general characteristics and subcharacteristics which were defined in order to fix the problems that emerged during the present study and considering the characteristics and subcharacteristics of ISO 25010 that are comparable to the evaluation models.

Table 1– Quality characteristics

Characteristic	Subcharacteristic	Evaluation	Weight	Conventional Model	Proposed Model
Territorial Scope	Data Collection	Complies with this subcharacteristic if data collection covers at least 70% of the population as potential notifiers.	1	0	1
	Disemination Information	Complies with this subcharacteristic if the model allows access to information to support decision making.	1	1	1
Availability of Information	Data Collection	Complies with this subcharacteristic if data collection is done in real time.	1	0	1
	Disemination Information	Complies with this subcharacteristic if the information is disseminated in real time.	1	0	1
Product quality	Functional Pertinence	This subcharacteristic counts one point for each tool supported by the model.	3	2	3
	Documentation	Complies with this subcharacteristic if the model has adequate documentation to facilitate the use of the product to the end user.	1	0	1
	Accessibility	Complies with this subcharacteristic if the product can be used by illiterate or blind users.	1	0	0
Reliability	Objectivity	Complies with this subcharacteristic when the information provided is not biased towards a particular opinion.	1	1	1
	Topicality	Complies with this subcharacteristic if the displayed information is updated on a weekly basis, considering the epidemiological calendar.	1	1	1
	Credibility	Complies with this subcharacteristic if is possible to determine that the information provided is reliable and relevant with respect to the subject matter.	1	1	0
Interoperability	Exchange Formats	This subcharacteristic counts one point for each format (GIS, Web Services, or images) supported by the model.	3	1	3
	Open Data	Complies with this subcharacteristic if the data are made openly available.	1	0	1

Discussion

The score obtained by the models evaluated in each characteristic can be seen in Figure 4, where the scores for our proposed model far exceed those of the conventional model. With regard to *Territorial Scope* – and considering the process of data collection through the use of USSD technology – the proposed model outperforms the conventional model. The *Availability of the Information* (in real time) is a characteristic of vital importance, because our study is within the health sector, and whose subcharacteristics are dependendientes. In other words, since the information is available in real time, data should be collected in real time. Considering *Product Quality* (specifically when users interact with the collection or visualization tools) the conventional model provides the option to view historical information from the epidemiological newsletter from previous weeks, but has no tools to interact with the information provided. Of the three subcharacteristics evaluated with respect to functional pertinence, the conventional model complies with two, while the proposed model complies with three. Additionally, the conventional model provides little documentation, which hinders the understanding and interpretation of risk maps displayed in the epidemiological newsletter. This is opposite for the proposed model, which displays official documents in the same application. Finally, considering accessibility, both the proposed model and the conventional model cannot be used by people with certain physical impairments, such as people who cannot read and/or write, or who are blind. A drawback of using the proposed model is its low score in *Reliability*. This is because the reporting user base is much broader than that of the conventional model. The *Interoperability* characteristic was not highly rated for the conventional model since it only allows the display of static information, which does not allow share and reuse of the information. Instead, the proposed model complies with all considered formats of information exchange, and also openly shares data.

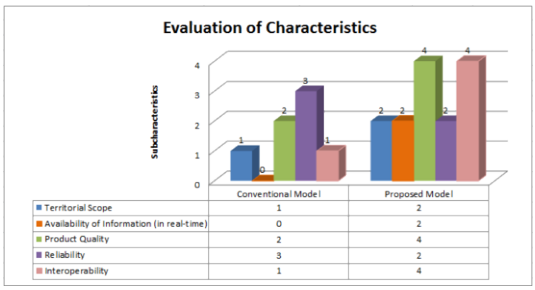

Figure 4 – Final Evaluation of Characteristics

Figure 5 shows the final scores of the models evaluated. The proposed model has a final score of 89.33%, the highest score, wheras the conventional model has a final score of 43%.

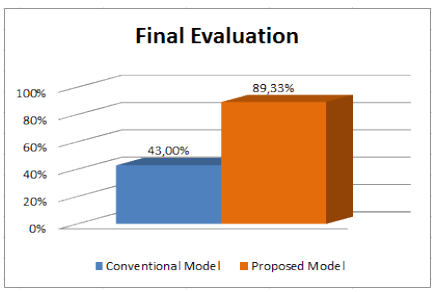

Figure 5 – Final Evaluation

Conclusion

This work highlighted the potential and benefits of a proposed model used for ICT-based epidemiological surveillance, which can easily be extended to other areas, towards the implementation of *Electronic Government* (eGov) and *Mobile Health* (mHealth) paradigms.

The emergence of new strategies for public health play an important role in Paraguay, for parties including primary health care (and family health units), community workers, and community empowerment towards personal health.

We have designed a USSD application that utilizes web services to provide an interactive disease menu on mobile devices connected to a GSM network, so that they can send notifications to a georeferenced database. A Web GIS module, which obtains spatial data from the database mentioned previously, allows the visualization of potential risk areas, and makes them available in real time to all stakeholders through web-mapping.

The proposed model is provided to governmental organizations, NGOs, and agencies working on health areas, and contains a tool for obtaining georeferenced information on areas or regions affected by some kind of disease while providing decision support for public health professionals. Note that the effectiveness of a GIS system generally depends on the nature of the problem and the selected software, as well as the reliability of the data and the ability of the users to understand their results.

Future work includes an implementation plan that will be drafted for applying the model to a Healthcare institution like the MSPBS in Paraguay. Additionally, a refined cost-comparison model is needed in order to better justify the benefits of the proposed tool.

Abstract

The use of patient focused technology has been proclaimed as a means to improve patient satisfaction and improve care outcomes. The Center for Medicaid/Medicare Services, through its EHR Incentive Program, has required eligible hospitals and professionals to send and receive secure messages from patients in order to receive financial incentives and avoid reimbursement penalties. Secure messaging between providers and patients has the potential to improve communication and care outcomes. The purpose of this study was to use National Health Interview Series (NHIS) data to identify the patient characteristics associated with communicating with healthcare providers via email. Individual patient characteristics were analyzed to determine the likelihood of emailing healthcare providers. The use of email for this purpose is associated with educational attainment, having a usual place of receiving healthcare, income, and geography. Publicly available data such as the NHIS may be used to better understand trends in adoption and use of consumer health information technologies.

Keywords:

Health Information Technology; Email; Consumer Involvement.

Introduction

There is increased national attention focused on the use of patient-centered technologies in an effort to engage patients and families in their healthcare, particularly in an effort to address the rise of chronic conditions and managing the complexity of health conditions. The Centers for Medicare and Medicaid Service's (CMS) Electronic Health Record (EHR) Incentive Program and its Meaningful Use objectives have drawn attention to the value of using patient portals and personal health records to better connect patients with their health information. The EHR Incentive Program has four goals: 1) "Improve quality safety, efficiency, and reduce health disparities"; 2) "**Engage patients and families**"; 3) "Improve care coordination, and population and public health"; and 4) Maintain privacy and security of patient health information" [1].

The use of patient portals, personal health records and other patient-focused technologies is intended to improve the level of patient engagement. The Agency for Healthcare Research and Quality (AHRQ) recently completed an Environmental Scan on the topic of patient and family engagement. AHRQ defined patient engagement as "a set of behaviors by patients, family members, and health professionals and a set of organizational policies and procedures that foster both the inclusion of patients family members as active member of the health care team and collaborative partnerships with providers and provider organizations" [2].

A study of US hospitals showed that the adoption of "basic" EHRs has increased by 82% between 2010 and 2011. More importantly, the rates of "comprehensive" EHR use by US hospitals have increased fivefold from 1.6% in 2008 to 8.8% in 2011 [3]. A recent study found similar results regarding patient portals specifically—approximately 50% of US hospitals have patient portals of some kind [4].

There is considerable evidence related to the benefits of using the secure messaging functionality of patient portal systems. In a study involving 35,423 patients with diabetes, hypertension, or both diabetes and hypertension, Zhou, et al. assessed the impact of secure patient-physician email on the quality outcomes as measured by diabetes and hypertension-related quality measures included in the Healthcare Effectiveness Data and Information Set (HEDIS) [5]. The study used administrative data on secure email use between patients and providers, as well as nine HEDIS measures. They reported that "The five leading reasons for patients to email their physicians were to report a change in a condition (16%), discuss lab results (14%), discuss a new condition (12%), discuss changes in prescription dose (11%), and discuss the need for a new prescription (10%)". Physicians receive, on average, between two and twelve messages per day, each requiring an average of 3.5 minutes per response. The findings show that users of secure email had significant improvements in outcomes related to HbA1c screening and control, retinopathy screening, nephropathy screening, and blood pressure control. Interestingly, those patients who had multiple email threads with the provider had an increased likelihood of improved performance on four of the diabetes measures. In other words, the frequency of messaging between a patient and provider is associated with some measures of clinical outcomes improvement.

A similar study focused on provider productivity related to the use of secure messaging tested the impact of the adoption of a patient portal on appointments with physicians, nurse practitioners, and physician assistants in adult primary and urgent care [6]. The study also tested the impact that patient portal adoption had on telephone contact rates with internal medicine and family practice physicians, nurse practitioners, and physician assistants. To evaluate the impact of secure messaging on primary care physicians, the study compared the difference in primary care office visit rates and documented telephone call rates among users and non-users of secure email. In the cohort study, primary care office visits among the sample decreased significantly by 9.7%. Similarly, in a matched control part of the study, the annual office visit rate for those patients using secure messaging decreased by 10.3%, as compared to a 3.7% decrease in the control group. The difference between groups regarding documented telephone

contacts was also significant—controls made 13.7% more telephone contacts than those patients using secure messaging.

Wade-Vuturo, Satterwhite Mayberry [7] conducted a mixed methods study to evaluate the use of a patient portal by patients with type 2 diabetes, secure messaging within the patient portal, and the relationship between secure messaging and glycemic control. The study found that there was a significant association between patients who self-reported frequently using secure messaging within the patient portal—either messaging a provider or requesting an appointment—and lower Hemoglobin A1c values (i.e., glycemic control) [7].

Harris, Haneuse [8] conducted a cross-sectional study to test that secure messaging through a patient portal was associated with higher quality of care and lower care utilization. The patients within the secure messaging group were slightly younger than those in the non-secure messaging group (average age of 58 vs. 63) and were significantly more likely to have a female primary care provider. Regarding the quality measure of HbA1c <7%, patients who had a patient portal account and sent secure messages had higher rates of control than those who had patient portal accounts and did not send messages. In fact, among patients with greater than or equal to 12 threads of secure messages, HbA1c <7% was 36% greater than those in the control group [8].

Despite all of the focus on these patient centered technologies, there has been little growth in the uptake of these technologies among the general population or among those most likely to benefit from its immediate and prolonged use. One major reason for the slow adoption is the slow adoption by healthcare providers and organizations [4]. According to Tenford et al., users of these technologies are most likely to be educated, female and Caucasian [9]. There is not a clear understanding regarding the average age of users, but studies indicate that the majority of users are between 50-70 years of age [10, 11]. Health literacy is cited as a primary barrier to the effective use of personal health records and patient portals for the self-management of chronic disease [12]. According to a study that examined the utilization of patient portals, 88% of Caucasians had a college degree, compared to 49% of African American users [11]. There are also clear ethnic/racial and educational disparities of patient portal use in large integrated delivery systems [11]. While Caucasians are more likely to utilize patient portals, African American patient portal users are significantly more likely to have the presence of a chronic disease [10]. According to one study, "those with limited health literacy were less likely to activate their patient portal account, sign in using their personal login and password, and to use any of the functions" [11].

Many of the major healthcare policy initiatives in the last decade have heavily emphasized patient engagement through the use of technology as a primary objective for improving health outcomes and thereby reducing costs. While the literature is growing on this topic, there is still not adequate knowledge about patients who are using patient portals and how they are using them. Knowledge about use of patient portals by geographic region of the country is minimal. The vast majority of the research on the use of patient-provider email has been within healthcare organizations who were early adopters of health information technology and are overwhelmingly part of integrated delivery networks. There is a need for research on the self-reported use of patient-provider emailing including those with self-reported chronic conditions. The purpose of this study is to use data from the National Health Interview Series, a national, weighted random survey of adults regarding healthcare delivery, to identify the patient characteristics associated with communicating with healthcare providers via email.

Methods

Data Sources and Limitations

This study examined survey data collected as part of the U.S. National Health Interview Series (NHIS) and was recoded, maintained, and distributed by the Integrated Health Interview Series (IHIS) [13]. The NHIS is an in-person, interview data collection program conducted by the Centers for Disease Control and Prevention's National Center for Health Statistics. The purpose of the survey is "to secure accurate and current statistical information on the amount, distribution, and effects of illness and disability in the United States and the services rendered for or because of such conditions". The NHIS uses a multi-stage probability sampling to select a random sample of approximately 35,000 households and 87,500 persons. The average response rate for the survey is near 90% of eligible households in the sample. Samples are drawn from each U.S. State and the District of Columbia and it is representative of the U.S. population. The NHIS has been conducted annually since 1957 [14]. Further details about the survey have been published [15, 16]. Data was extracted from the IHIS as a SAS text file, and the SAS text file was read into R and converted into a CSV file. The CSV file was imported into R and converted to a data object for all analysis.

For the purposes of this study, survey data regarding adults ages 18 or greater from 2009, 2011, 2012, and 2013 were combined (Note: the 2010 survey was excluded since it did not address use of email). Between 2009-2013, 492,948 individuals were interviewed across 191,395 households. Analysis of the NHIS data was deemed exempt from review by the University of Minnesota IRB.

The data used in this study included 363,564 individuals 18 years of age or greater. The NHIS includes questions on a variety of health outcomes, demographic variables, and individual characteristics. We used self-reported data on whether the respondent has ever used email to communicate with a healthcare provider. The questionnaire item reads "During the past 12 months, have you ever used computers [to]…communicate with a health care provider by email". Responses were categorized into "Yes", "No", "Refused", "Don't Know", or "Not Ascertained". Only those individuals responding "Yes" or "No" were included in the analysis resulting in a study sample size of 128,100 adults. The following variables were also included in the analyses: sex, gender, race, age, education level, health status, income, geographic region, care access, and diabetes prevalence. Education level was recoded into five categories (less than high school, high school or GED, some college or two year degree, bachelors degree, and graduate degree). Income was recoded into five categories (<35k$, $35-49.9k, $50-74.9k, $75-99.9k, and $100k +). Any response of "Refused", "Don't Know", or "Not Ascertained" were treated as missing values in the analysis.

Analysis

In order to understand the characteristics of adults who email their healthcare providers, proportions, standard errors, and a multiple logistic regression were computed using the R version 3.1.0. Proportions were used to calculate the overall use of email across multiple variables. Logistic regression was used to determine which variables are related to the use of email to communicate with healthcare providers. The following variables were included as independent variables in

the logistic model: sex, gender, race, age, education level, health status, income, geographic region, care access, and diabetes prevalence. The answer to the question about email use was the dependent variable. The results of the logistic regression are presented as odds ratios with the corresponding standard errors 95% confidence intervals, coefficients, standard errors, and Wald Statistic.

Results

The study sample consisted of 128,086 respondents across the four years. The average age of respondents was 37.2 years, and 56% were female. Sixteen percent of respondents had less than a high school diploma, 22% had a high school degree or GED, 30% had some college or a two-year degree, 18% held a bachelor's degree, and 10% held a graduate degree. Table 1 summarizes the survey's respondent characteristics.

Regression results are presented in Table 2. Overall, 5.7% of respondents reported emailing their healthcare provider between 2009 and 2013. Males were significantly less likely to email their provider than females (OR 0.75, CI: 0.71-0.79, $p<0.001$), African American (OR 0.82, CI: 0.76-0.89, $p<0.001$) and Asian (OR 0.85, CI: 0.77-0.93) respondents were significantly less likely to email their healthcare providers than all other races. Age is significantly associated with emailing healthcare providers. Respondents between the ages of 51-60 are significantly less likely to email their providers than those under 30 (OR 0.91, CI: 0.84-1.00, $p<0.05$).

Education level and income were significant predictors of emailing a healthcare provider. The likelihood of emailing a provider is significantly greater for each level of education obtained. Respondents holding a four year college degree significantly more likely to email their provider (OR 11.48, CI: 9.61-13.28, $p<0.001$). Respondents holding a graduate degree were the most likely to email their provider (OR 15.88, CI: 13.25-19.19, $p<0.001$).

Health status is associated with emailing healthcare providers. Adults who report being in excellent health (OR 0.71, CI: 0.59-0.85, $p<0.001$) or good health (OR 0.83, CI: 0.70-1.00, $p<0.01$) are significantly less likely to email their healthcare provider than those who report being in fair or poor health. Patients who report having diabetes are more likely than those without diabetes to email their providers (OR 1.28, CI:1.16-1.41, $p<0.001$).

Geographic region was significantly associated with emailing healthcare providers. Those living in the West were twice as likely to email their provider than those in any other part of the country (OR 2.02, CI:1.88-2.18, $p<0.001$). There was also a significant difference in the likelihood of emailing healthcare providers based upon reporting year. Respondents in 2013 were more likely to email their providers than those responding in 2009 (OR 1.17, CI: 1.10-1.26, $p<0.001$).

Adults who reported having a usual place for obtaining healthcare were also more likely to email their provider than those without a usual place (OR 2.07 CI: 1.88-2.30, $p<0.001$).

Discussion

The study attempted to understand the use of email to communicate with healthcare providers by a nationally representative sample of adults. Because of the nature of the NHIS methodologies, the sample represents the diversity of the United States in terms of age, sex, race, geographic location, and other demographic characteristics. To the best of our knowledge, this is the first study to use a nationally representative sample for assessing email communication between patients and healthcare providers.

Despite increased national attention and increased access to secure email from healthcare organizations, there continues to be a relatively low rate of use of email between adults and their healthcare providers. Overall, 5.6% of adults reported emailing their healthcare provider between 2009 and 2013 (see Figure 1).

Table 1– Email Use with Healthcare Provider by Respondent Characteristics

Many of the findings from the current research are consistent with previous research—age, education level, income, and race are associated with emailing healthcare providers[10, 11, 17]. Previous research has indicated that the most significant users of secure email are between 50-70 years of age, but our research indicates that younger individuals under the age of forty are somewhat more likely to email their healthcare provider.

Of particular interest for this research and potentially related to the impact of the CMS EHR Inventive Program is that respondents in 2013 were significantly more likely to email their healthcare providers than those in 2009 (5.4% in 2009 and 6.6% in 2013). Females increased their use even more significantly over the four years (5.6% in 2009 to 7.4% in 2013). The level of EHR adoption has increased dramatically in both outpatient and inpatient areas since 2008 likely due to the federal EHR Incentive Program, particularly the program's requirement for healthcare organizations to provide patients the means to send and receive secure email messages from their healthcare providers.

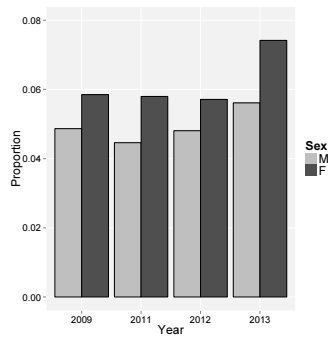

Figure 1– Proportion of Respondents Emailing Healthcare Providers By Year and Sex

Education level is a major factor related to emailing healthcare providers. Educational attainment has been shown to be positively related to overall "health literacy" [18], and adults with lower levels of health literacy are less likely to use internet based patient portals to communicate with healthcare providers [11]. Our findings indicate that those with lower education levels risk falling behind as healthcare organizations increasingly turn to health information technology for coordinating healthcare services, providing health information to patients, and communicating with patient about their care.

Moreover, research has shown that individuals with lower health literacy are less likely to use health information technology [7, 11] and individuals who use health information technology have improved clinical outcomes [8]. Our research indicates that health status is significantly associated with using email to communicate with healthcare providers. Those individuals who report being in fair or poor health are significantly more likely to email their healthcare provider than those who report good or excellent health. Future research should investigate the relationship between health status and education level on reported email use with healthcare providers.

Another interesting finding relates to healthcare access. Those adults who reported having a regular place of care were significantly more likely to email their healthcare providers than those who do not. As the Affordable Care Act increases access to the healthcare delivery system for millions of Americans, these individuals with increased access to

healthcare services could potentially have an impact on the use of email communication with healthcare providers.

This study has several limitations that need to be taken into consideration when reviewing these results. It is not clear from the data what the reasons are for emailing healthcare providers or how the email communication influenced the healthcare encounter. The data are also limited in that email is a self reported measure and does not provide the frequency of emailing providers. Future research should also consider investigating the multiple relationships among socio-demographic characteristics, patient-provider email, and clinical outcomes.

Conclusion

Healthcare stakeholders are increasingly aware that technology is a critical factor for monitoring chronic conditions, improving decision-making, and creating a healthcare system that is more proactive and less reactive. As the United States healthcare system continues to move additional services online and expect patients to interact with their care providers via the Internet, those individuals already suffering from health disparities risk falling further behind.

The use of patient-centered technologies to improve chronic disease management is increasingly important [19, 20]. Generally, these technologies have had limited functionality, with much of the capabilities revolving around entering or reviewing health data. The technologies, however, are increasingly intelligent and interactive, thereby providing both patients and clinicians with triggers regarding for example interactions of drugs or allergies that could lead to an abnormal medical event [21]. As the HIT industry continues to advance these patient-centered tools, this study's findings regarding the frequency of such email use and the predictors of email use between U.S. healthcare providers and adults should be considered when developing tools, developing educational materials, and promoting the use of these new tools to patients.

Health Information Technology Evaluation Framework (HITREF) Comprehensiveness as Assessed in Electronic Point-of-Care Documentation Systems Evaluations

Abstract

We assessed the Health Information Technology (HIT) Reference-based Evaluation Framework (HITREF) comprehensiveness in two HIT evaluations in settings different from that in which the HITREF was developed. Clinician satisfaction themes that emerged from clinician interviews in the home care and the hospital studies were compared to the framework components. Across both studies, respondents commented on 12 of the 20 HITREF components within 5 of the 6 HITREF concepts. No new components emerged that were missing from the HITREF providing evidence that the HITREF is a comprehensive framework. HITREF use in a range of HIT evaluations by researchers new to the HITREF demonstrates that it can be used as intended. Therefore, we continue to recommend the HITREF as a comprehensive, research-based HIT evaluation framework to increase the capacity of informatics evaluators' use of best practice and evidence-based practice to support the credibility of their findings for fulfilling the purpose of program evaluation.

Keywords:
Evaluation studies; Technology evaluation; Health information systems; Medical informatics.

Introduction

The increase in health information technology (HIT) implementation worldwide has created a need to better ensure the realization of the system's intended benefits using rigorous evaluation methods. Informatics evaluators tend to use frameworks, that is, models that describe the interrelationships among variables [1], describe the relationship between a framework dimension and a result [2, 3], or describe an implementation model [4]. However, most frameworks do not include the three contextual aspects – organizational, systemic and environmental (political), and professional – that influence whether or how the system will be used. Furthermore, frameworks with social and organizational evaluation dimensions lack clarity or specificity of their evaluation criteria, or have inadequate focus to assess both individual and organizational aspects of evaluation. For example the HOT-fit framework, which is theory-driven, does not include the professional contextual aspect [5].

To address the three-contextual-aspects deficit, the author (PS) developed and assessed the HIT Reference-based Evaluation Framework (HITREF) in the evaluation of an EHR implemented in a geriatric day care center[5, 6]. The framework included health services research evaluation methodologies to extend the informatics evaluators' focus beyond user, technical, and organization interactions to include organizational contextual considerations and other stakeholders' perspectives. The HITREF is a comprehensive HIT evaluation framework firmly grounded in research evidence that identifies a range of clinician satisfaction characteristics and dimensions to be measured. This framework was the result of a comprehensive literature review of over 2000 HIT evaluation studies [5] that expanded on the work of Ammenwerth and de Keizer who reviewed 15,000 articles [7]. The HITREF provides a comprehensive list of 22 criteria related to clinician satisfaction with HIT as themes for the study analyses, as shown in Figure 1. The criteria are organized along the following axes: Structure/Logistics/Process/Outcome with two additional concepts: *Barriers/Facilitators to Adoption* and *Unintended Consequences/Benefits*. Three components added the organizational context: Diffusion; HIT Selection/ Development/Implementation/Training; and Unintended Consequences/Benefits. Also Barriers/Facilitators to Adoption added systemic and environmental (political) contexts. Lastly, three components added the professional context (e.g., patient perspective): Patient Privacy; Patient Satisfaction with EHR; and Patient Satisfaction with Care [5].

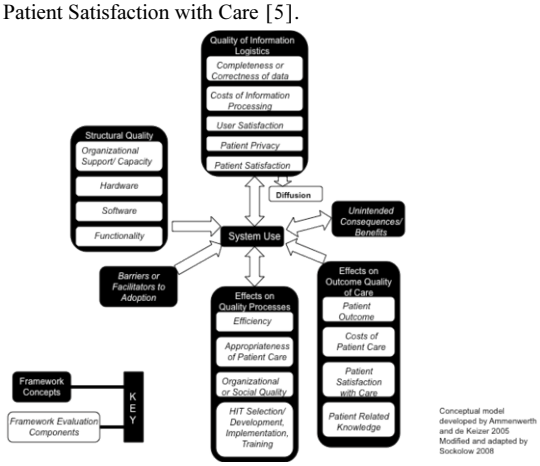

Figure 1 – The Health Information Technology Reference-based Evaluation Framework

This manuscript describes further assessment of HITREF comprehensiveness when used in evaluations of HITs in settings different from that in which the HITREF was originally developed. The new systems evaluated were point-of-care documentation systems used by health care professionals on multi-disciplinary teams who delivered direct patient care: a home care agency electronic health record (EHR) and a

hospital nursing information system (NIS).

Methods

To assess HITREF comprehensiveness, the clinician satisfaction themes that emerged from the home care and the hospital studies were compared to the framework. The home care study used an embedded mixed methods design to collect and analyze actual system usage, and post intervention clinician interviews and survey responses to assess satisfaction with the system [8]. The hospital study, carried out in two hospitals, employed scenario testing with qualitative analysis to assess clinician usage and satisfaction. The scenario study design was presented as a modified think-aloud protocol [9]. This protocol is a standard methodology used to elicit data about cognitive reasoning that occurs during a problem solving task. Twelve users were presented with typical usage scenarios and allowed to walk through how they would complete the action requested using the NIS [10]. Institutional Review Boards approved the studies.

Both the hospital and home care sites had implemented commercially available point-of-care documentation systems in which clinicians recorded care plans, interventions, and outcomes. The EHR was implemented in the home care site in 2009. It supported documentation management and had limited interoperability with health system hospitals. The study was conducted from 2008 to 2011 [8]. The hospitals implemented an NIS in 2011 that functioned with the Computerized Provider Order Entry system within the EHR. Nurses selected from the NIS's approximately 200 interdisciplinary evidence-based clinical practice guidelines to guide and document patient care. The NIS was evaluated in 2012 [10].

In the home care study (PS), semi-structured interviews were conducted until saturation eliciting information about clinicians' areas of concern or satisfaction with the EHR. Content analysis of interview responses started with the HITREF and was followed by mapping the coded themes to the framework, creating a conceptualization that encompassed all participants' experiences [8]. In the hospital study (KB,PS,MR), a convenience sample of consented nurses from selected floors participated in the scenario testing until saturation was reached. Satisfaction with NIS was assessed using scenario testing, which entailed the researchers' presenting to participants previously prepared scenarios and follow-up interview questions while observing their NIS use in a conference room on the unit. For each audio-recorded transcript, researchers coded themes independently and then coded together in relation to the HITREF. A 10% double reliability check was performed. Researchers retained any theme that did not match HITREF criteria (i.e., component within a larger HITREF concept) to add it to the framework as a new HITREF component. An unmatched theme was of special interest as it indicated an area where the framework was not comprehensive [10].

Results

Reported here are the results from both the home health agency and the hospitals studies related to HITREF comprehensiveness. The home health study included analysis of survey responses from 71 clinicians (52% of eligible participants) as well as observations and interviews with 6 (4%) clinicians [8]. The hospital NIS study involved 12 nurses on 2 units who participated in the scenario testing [10].

Home health clinicians were dissatisfied with initial and ongoing training and field support. They were satisfied with the hardware availability and dissatisfied with frequent system problems, as well as with EHR software related to usability and functionality. Overall clinicians were satisfied with the EHR data completeness and timeliness, which improved data availability and supported providing care and team communication. Some clinicians were dissatisfied with the unintended consequence of problems using the EHR, which negatively impacted patient care. Clinicians were also dissatisfied with EHR impact on efficiency resulting from a mismatch between the task requirements and the software functionality. While the EHR was observed to improve accessibility to clinical information, clinicians were dissatisfied with EHR impact on appropriateness of care. Clinicians perceived that the computer disrupted their establishment of patient rapport thereby impacting patient adherence. Clinicians were mostly satisfied with EHR impact on organizational/ social quality related to team communication. On the other hand, clinicians were particularly dissatisfied with their perceived lack of involvement in system selection/ development/ implementation/ training. Lastly, clinicians identified a barrier to adoption: inadequate interoperability as exemplified by their inability to access laboratory results from sources external to the health system [8].

In summary, home health clinicians commented on the following 12 HITREF components, organized within 5 *HITREF concepts* (examples are provided in Table 1):

- *Structural Quality*: Organizational support/capacity, Hardware (e.g., system availability [5]), Software (e.g., usability [5]), Functionality (e.g., tools and resources [5]);
- *Quality of Information Logistics*: Completeness/correctness of data (e.g., data quality [5]), User satisfaction;
- *Unintended Consequences* (e.g., benefits or adverse results [5]); and
- *Effects on Quality Processes*: Efficiency (e.g., time required for tasks [5]), Appropriateness of Patient Care (e.g., "medical efficiency" such as adherence to protocols [5]), Organizational or social quality (e.g., cooperation or communication [5]), HIT Selection/ Development/Implementation/Training; and
- *Barriers or Facilitators to Adoption* (e.g., perceptions related to implementations [5]).

The hospital NIS study findings indicated that the participating nurses universally preferred documenting in the NIS rather than return to paper records. As seen in the home health study, hospital nurses were dissatisfied with the ongoing HIT training as well as software usability and functionality. They were dissatisfied with computer placement, which required standing while using the computer. Also as seen in the home health study, nurses were satisfied with the completeness and timeliness of the documentation. Nurses were dissatisfied with the changes introduced by the NIS, which included redundant documentation and bottlenecks, thereby reducing efficiency. They were also dissatisfied with NIS impact on appropriateness of care related to increased time at the bedside documenting and decreased time spent providing direct patient care. Related to Organizational/social quality, the potential to realize team communication among the clinical roles and disciplines was not always realized as evidenced by duplicate documentation and redundant questions posed to the patient [10].

The hospital nurses commented on the following 8 HITREF components within 3 *HITREF concepts*:

- *Structural Quality*: Organizational support/capacity, Hardware, Software;
- *Quality of Information Logistics*: Completeness/correctness of data, User satisfaction; and

- *Effects on Quality Processes*: Efficiency, Appropriateness of Patient Care, Organizational/social quality (team communication).

Across both studies, respondents commented on 12 HITREF components across 5 HITREF concepts. All themes that emerged from either study matched a HITREF component.

Table 1 - Examples of HITREF Concepts/Components Occurring in Each Study

HITREF Concept	**HITREF Component**	**Home Care**	**Hospital**
Structural Quality	Organizational Support/capacity	-Field Support, Training	- Training; Communication
	Hardware	- Reliability	- Computer placement
	Software	- Usability: Navigation	- Usability: Navigation; Mismatch screenflow/ workflow; Documentation fatigue
	Functionality	+Memory prompts	-Absence of needed functionality
Quality of Information Logistics	Completeness/ correctness of data	+ Timely, complete	+ Accessible, Complete
	Costs of information processing	NA	NA
	User satisfaction	+Overall satisfaction	+Overall satisfaction
	Patient privacy	NA	NA
	Patient satisfaction with EHR	NA	NA
	Diffusion	NA	NA
Unintended Consequences/Benefits	Unintended Consequences/Benefits	- EHR problems interfere with patient care	NA
Effects on Outcome Quality of Care	Patient outcome	NA	NA
	Costs of patient care	NA	NA
	Patient satisfaction with care	NA	NA
	Patient related knowledge	NA	NA
Effects on Quality Processes	Efficiency	- Increased documentation	- Bottlenecks; Redundant documentation; Many checkboxes
	Appropriateness of patient care	-Patient rapport	+ Time at bedside - Patient time, more NIS time
	Organizational or social quality	+Team communication	-Potential for increased multidisciplinary team communication not realized
	HIT Selection/ Development/ Implementation/ Training	- Clinician involvement	NA
Barriers or Facilitators to Adoption	Barriers or Facilitators to Adoption	- Interoperability	NA

Note: + indicates satisfactory attributes; - indicates dissatisfactory attributes; NA indicates not applicable

Discussion

The HITREF was designed to be used to evaluate a broad range of HIT. To date, the framework has been used to assess two types of HIT in three different settings, [6, 8, 10]. In addition to being evidence-based, a HITREF advantage is the inclusion of organizational, systematic and environmental, and professional criteria to evaluate whether the HIT was used as intended [5]. Across the two evaluations described in this manuscript, [8, 10] these three levels of criteria had one or more components with matched themes (e.g., Organizational support/capacity, Barriers/facilitators to adoption, User satisfaction, respectively). The emergence of these themes underscores the HITREF's value as an evaluation tool that includes contextual concerns in addition to technological capabilities. The initial study in which the HITREF was assessed [5] and the two studies described in this manuscript [8, 10] were similar in the inclusion and exclusion of HITREF components in the evaluations, despite differences in settings and HIT evaluated. The absence of new components missing from the HITREF indicates that the HITREF is a comprehensive evaluation framework.

Overall, 60% of the HITREF components emerged in the two recent studies across all but one of the HITREF concepts, as shown in Table 1. The excluded concept, *Effects on Outcome Quality of Care*, contains four patient-focused components without related themes that emerged in the evaluations. The constituent component, Costs of patient care, is an issue not usually encountered by front line clinicians. Two components that address the patient perspective (i.e., Patient satisfaction with care; Patient related knowledge) may be more likely to emerge in evaluations of patient-facing systems such as personal health records, EHR patient portals, or mobile health applications. Notable is the presence of patient outcomes in this group of unmatched components. Possibly clinicians did not see a relationship between their use of the point-of-care documentation system and the organization's goal of system implementation to improve patient outcomes. Similarly, the component Diffusion in the *Quality of Information Logistics* concept has a focus on an issue not usually encountered by front line clinicians: whether the system is universally used. Two additional components in the *Effects on Outcome Quality of Care* concept that addressed the patient perspective (i.e., Patient privacy concerns; Patient satisfaction with EHR) did not have themes emerge, probably because the studies did not assess patient-facing systems.

The 60% component match and lack of new components support the applicability of HITREF in evaluations with a range of HIT, settings, and users. Although the framework was

drawn from literature mostly focused on physician HIT use in hospitals [5, 7], the studies involved nurses in hospitals and multi-disciplinary teams in community settings, and focused on both EHRs and NIS. However, it is possible that HITREF use in evaluations of other HIT may identify new components to be added to the HITREF.

The two evaluations also provided support for another aspect of HITREF applicability: its use by informatics evaluators. While the first author (PS) developed the HITREF and conducted the studies, other members of the research team (KB, MR) successfully used the HITREF in their analyses (8, 10]. Use by informatics researchers other than the HITREF developer is evidence that the HITREF belongs in informatics evaluators' toolboxes.

As suggested in our initial study, because the HITREF is relatively large, the evaluator may choose to select HITREF components related to the questions being asked. For example, an evaluator could include questions about patient care and efficiency in evaluations of HIT intended to improve the clinical process or exclude questions about patient perspective from a point-of-care documentation system study.

A research opportunity previously identified that is yet to be addressed is increased knowledge about the relationships among the HITREF evaluation components. This exploration will be possible by using the HITREF in evaluation studies of larger sample sizes.

Conclusion

The HITREF fulfills the purpose of a framework: to ensure a study is comprehensive in terms of inclusion of stakeholder concerns to promote engagement and obtaining full information, and improve decision-making. HITREF use in evaluations with a range of HIT, settings, and users, by researchers new to the HITREF, demonstrates that it can be used as intended. Therefore, we continue to recommend the HITREF as a comprehensive, research-based HIT evaluation framework to increase the capacity of informatics evaluators' use of best practice and evidence-based practice to support the credibility of their findings for fulfilling the purpose of program evaluation.

Abstract

Despite the fast pace of recent innovation within the health information technology and research informatics domains, there remains a large gap between research and academia, while interest in translating research innovations into implementations in the patient care settings is lacking. This is due to absence of common outcomes and performance measurement targets, with health information technology industry employing financial and operational measures and academia focusing on patient outcome concerns. The paper introduces methodology for and roadmap to introduction of common objectives as a way to encourage better collaboration between industry and academia using patient outcomes as a composite measure of demonstrated success from health information systems investments. Along the way, the concept of economics of health informatics, or "infonomics," is introduced to define a new way of mapping future technology investments in accordance with projected clinical impact.

Keywords:

Economics of health information systems; health information technology; research informatics; health outcomes research; integration of academia and industry.

Introduction

As relatively young niches of information technology (IT) in the process of maturation, health information management (HIM) and health information technology (HIT) have gone through several stages of (first) chaotic and (later) systematic development. In some countries such as the United States, much of the growth is encouraged by government subsidies and legislative changes penalizing healthcare organizations for failing to invest in HIT. Early skepticism regarding benefits of digitization of medical records and computer-assisted clinical workflow turned into excitement regarding HIT's ability to drive quality improvement efforts resulting from electronic medical records (EMR) installations and streamlining ordering process via computerized physician order entry (CPOE) applications. In response to subsidies, large metropolitan healthcare systems in the United States championed HIT investment. The rate of adoption was closely associated with large size, urban location, and health maintenance organizations (HMO) penetration [1]. HMOs rely, in part, on health outcomes of the populations they serve in order to remain financially solvent. Therefore, association of HIT with quality of patient care puts technology investment on the central stage for organizations interested in generating income through advances in health outcomes.

Early documented and perceived gains from EMR and CPOE systems in the processes of clinical workflow enhancement, quality improvement, and reduction of medical errors, led to further development of disciplines that relied on the marriage of information and medical sciences. Examples of such disciplines are "big data" analytics, population health, predictive analytics, clinical decision support systems (CDSS), natural language processing, mobile health, health information exchanges, and even social engineering. In the United States, EMR adoption was systematized and documented in several widely referenced models, such as HIMSS EMR Adoption Model [2] and the Meaningful Use provision of the Accountable Care Act. The latter model is a government legislation that mandates interoperability of disparate HIT applications.

Despite massive investments into HIT by healthcare organizations and software vendors worldwide, as well as significant growth in the biomedical informatics research and education in academia, there remains a large gap between industry and academia. Moreover, some of the massive commercial investments into HIT, fueled by industry standards modeling and government subsidies, have yet to provide direct link between technology growth and actual patient outcomes. Seemingly, healthcare organizations, software companies, and universities are interested in similar goals – error prevention, quality improvement, enhanced clinical workflows, predictive analytics, and breakthroughs in knowledge processing and management. In reality, industry focused on digitizing medical records and streamlining orders (EMR/CPOE), while academia emphasized new methods of disease management and surveillance, as well as specific applications of medical knowledge via informatics for targeted disease treatment. This paper is aimed at exploring shared goals potentially leading to transformation of HIT and closer collaboration between industry and academia to achieve common objectives.

Patient Outcomes Focus as a Common Goal for Industry and Academia

On the industry side, transition from paper records to EMR and subsequent automation of clinical workflows and communication processes via CPOE and unified communications achieved a plateau in the past few years. At this level, a majority of the most successful organizations have already implemented these technologies and look to capitalize upon them in order to achieve more advanced clinical objectives. These massive investments travel through the process that Gartner calls the Hype Cycle – transitioning

through trigger, peak, disillusionment, enlightenment, and plateau of productivity [3]. As HIT travels through the hype cycle, and billions of dollars are invested into it, it becomes apparent that the HIT outcomes measurement process needs to be centered around clinical outcomes, especially in the absence of real productivity gains [4] expected of initial technology investments. While technologies such as CDSS have demonstrated success in driving effectiveness of specific process measures [5], HIT research remains in the early stage of demonstrating measurable clinical impact [6].

It is apparent that technology by itself will not positively impact safety. Instead, technology supported clinical workflow changes could hold the biggest promise of making measurable impact on quality and safety of patient care [7]. Massive and frequently chaotic investment in HIT needs to be replaced by targeted clinical problem definition that initiates the process of technology investment [8], followed by routinization – the process by which using innovation becomes regular organizational practice [9]. But why does the process of routinization remain so painfully slow in transition from biomedical informatics to HIT? It is due to mismatched effectiveness evaluation measures: while HIT focuses on operational measures and return on investment (ROI) from infrastructure and applications, the research side emphasizes patient outcomes over cost and operations.

The Evolving Role of HIT and Its Effectiveness Evaluation Criteria

Biomedical informatics research of health outcomes resulting from information technology development has remained separate from "field" investments at hospitals and medical practices that were largely driven by either government spending and/or perceived expectations of quality and productivity gains. As healthcare cost pressures rise and the healthcare delivery model shifts from volume to value based reimbursement [10], physician to patient centered care (Figure 1) and physician oriented to consumer oriented communication model (Figure 2), simply running an efficient information technology organization is not satisfactory. Providing customers with appropriate technology services, fitting within budget, maintaining up-to-date infrastructure, and timely completion of projects become secondary measures of HIT performance.

Figure 1 – Patient centered care model

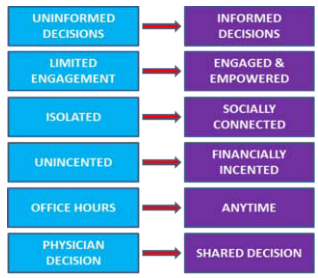

Figure 2 – Consumer oriented care model

A common denominator rises between HIT and research informatics, and that is health outcomes orientation. The primary goal of every healthcare organization is patient services, and so every process needs to be streamlined and oriented at achieving patient satisfaction. In turn, healthcare organizations' ability to deliver the most effective care at the lowest cost with the best clinical outcomes is a must in the new business of medicine environment where health outcomes and reimbursement are tied together. This applies to healthcare models in both private and public sectors, as ultimately no matter who controls reimbursement, the goals of achieving effective care at the lowest cost are the same. Patient outcomes orientation offers industry and academia a unique common perspective that could spawn new collaboration projects aimed at increasing the pace of translating discovery into industry implementation.

Health outcomes focus leads to emergence of a new discipline – let's call it economics of health informatics, or simply "health infonomics." The health infonomics science would merge biomedical informatics research with health economics and HIT investment mechanisms to generate new models of targeted selection and measurement of information technology aimed at reaching specific clinical and productivity goals. Health infonomics would also help construct instruments of innovation and operational effectiveness, in terms of impact on clinical outcomes.

The Evolving Model of HIT Effectiveness and Performance Evaluation

Changes in perception, evaluation, and measurement of the effectiveness of healthcare information systems are likely to lead a change in expectations and assessment of IT operations in healthcare organizations. Three traditional measures of IT effectiveness – service, quality, and cost – will be tied to patient-centric outcomes (Figure 3). This structure mimics industry service model change from physician-centric to patient-centric processes aimed at delivering accessible high-quality care.

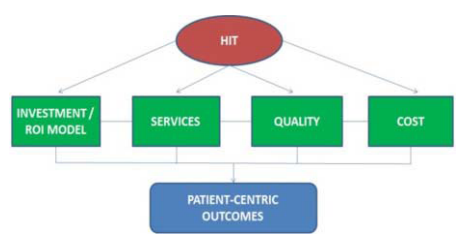

Figure 3 – Patient centric orientation of HIT

In accordance with this patient-centric care impact measure, future HIT investment, as well as operational effectiveness and customer satisfaction, will require a new inclusive measure of success represented by combination of clinical, technology, and cost factors. Patient Care Index (Figure 4), aimed at measuring the overall effectiveness of HIT investment and operations, would link technology to patient outcomes, removing separation between technology acquisition and enterprise clinical goals of the healthcare organizations. Such fundamental shift to tying success of information technology to clinical outcomes would drive re-evaluation of existing ROI models to tie them to core clinical and cost objectives of healthcare organizations.

Figure 4 – Patient care index as a central measure of HIT success

The patient care index (Tables 1 and 2) is a composite statistical score that includes a multitude of factors ranging from clinical outcomes, directly linked to specific technologies, to operational effectiveness in terms of systems stability and availability to customer satisfaction scores. Factors would be ranked and assigned statistical weights in accordance with clinical impact and the potential of HIT to impact patient and/or hospital operations outcomes. Factors listed in the tables below are organized by clinical and non-clinical items.

Table 1 – Example of the patient care index factors: Clinical

Health Outcomes	Quality	Safety
Mortality	Core measures compliance	Unassisted falls percentile
Preventable readmissions	Corrected reports	Orders placed via CPOE sets
Length of stay	Ambulatory patient lab redraws	Transfusion safety
ICU ventilator days	Acute care hospitalization rate	Infection control chart
NICU mortality index	Management of oral medications rate	Adverse drug effects (ADE) rate
Pediatric surgery mortality index	Improvement in dyspnea rate	Lab identification errors
	Improvement in ambulation rate	Mislabeled pathology slides
	CPOE utilization rate	Serious safety event rate

Table 2 – Example of the patient care index factors: Financial, operational, and technology

Cost	Patient Engagement	Technology
Cost per inpatient discharge	Patient satisfaction survey rate	Total critical care systems uptime
Cost per outpatient visit	Percent of (online) socially engaged patients	Total financial systems uptime
Total ED visits	Number of patient portal users	Number of downtime events
Total outpatient visits	Number of unique patient portal logins	Associate and provider IT services satisfaction score
Cost per ED visit	Health and wellness index	IT operating cost
Inpatient admissions	Public Wi-Fi uptime score	CPOE adoption rate

Project management and selection of computer applications to meet the needs of a clinical enterprise would undergo changes in accordance with health outcomes orientation of the technology selection process. Instead of identifying technological needs and subsequently evaluating technology's potential to bring desired benefits to the organization, the process would reverse to identification of a specific clinical problem – leading to a technology solution (Figure 5). Should there be no existing solution to a clinical problem, it is potential for collaboration with academia, leading to not only breakthrough innovation but also quick translation to industry oriented solution and implementation in patient care settings, using common goals between HIT and academia models.

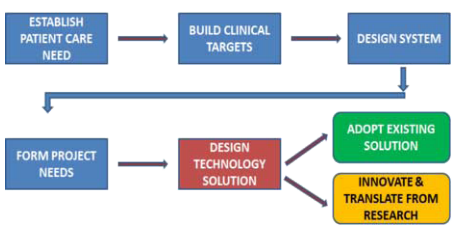

Figure 5 – Health outcomes oriented project selection and management

Infonomics, Health Outcomes, and Research/HIT Collaboration

The first two steps in the health outcomes oriented project management model described in Figure 5 - establishing patient care need and building clinical targets – are rooted in evidence based clinical practices. The figure can be adjusted based on clinical specialty and target patient population. For example, geriatric medicine would pose unique challenges and needs for patients who require physical and cognitive interventions aimed at improving and maintaining their health [11]. Establishing patient care need would represent a

complex process of determining the most critical factors affecting geriatric patients and subsequent opportunities for computer-assisted interventions. The outcomes based project management process would require detailed investigation of clinical needs, followed by setting quantitative targets for potential HIT interventions, and analysis of the current and potential options for implementation. This model brings HIT practitioners and researchers together to solve clinical problems. In another example, a post facto study investigated effectiveness of pneumonia CPOE order sets measured by such health outcomes as mortality, readmission, comorbidity, and length of stay [12]. The patient outcomes tied technology selection and management model would require preliminary investigation of expected health outcomes prior to system implementation and performing post-implementation analysis of the outcomes to determine clinical effectiveness of the HIT initiative.

Conclusion

Reevaluation of HIT goals, expectations, and measurement processes would initiate changes in the healthcare technology market, as well as investment selection and allocation processes at the healthcare provider organizations. Ultimately, providers, patients, and suppliers are expected to benefit due to renewed focus on patient care quality and targeted healthcare technology spending. Such collaboration could also have a profound positive impact on cost, as a secondary measure of industry/academia partnership success. But ultimately patients and providers would benefit most from integration of goals that could help bring industry and academia closer together in search of common scientific outcomes in line with business objectives. Academia is already focused on patient outcomes and has been for a long time. Industry's profit and operations models included a large variety of performance measures, not all leading to improved patient outcomes. Realignment is a great way to streamline the path from innovation to industry implementation.

Abstract

Liver cancer, the fifth most common cancer and second leading cause of cancer-related death among men worldwide, is plagued by not only lack of clinical research, but informatics tools for early detection. Consequently, it presents a major health and cost burden. Among the different types of liver cancer, hepatocellular carcinoma (HCC) is the most common and deadly form, arising from underlying liver disease. Current models for predicting risk of HCC and liver disease are limited to clinical data. A domain analysis of existing research related to screening for HCC and liver disease suggests that metabolic syndrome (MetS) may present oppportunites to detect early signs of liver disease. The purpose of this paper is to (i) provide a domain analysis of the relationship between HCC, liver disease, and metabolic syndrome, (ii) a review of the current disparate sources of data available for MetS diagnosis, and (iii) recommend informatics solutions for the diagnosis of MetS from available administrative (Biometrics, PHA, claims) and laboratory data, towards early prediction of liver disease. Our domain analysis and recommendations incorporate best practices to make meaningful use of available data with the goal of reducing cost associated with liver disease.

Keywords:
Liver cancer; liver disease; metabolic syndrome; economics.

Introduction

The availability of research, clinical and billing data provides an opportunity for the surveillance and management of chronic diseases and may lead to a reduction in associated costs. However, informatics challenges such as data accessibility, validation, integration, and lack of appropriate analytic tools inhibit progress. One such disease of interest that may benefit from domain analysis and data integration is liver disease.

Liver cancer is the fifth most common cancer and the second leading cause of cancer-related death in adult men worldwide [1]. The incidence of liver cancer in the United States has been rising slowly for the past few decades. According to estimates from the American Cancer Society, 33,190 new cases will be diagnosed and 23,000 people will die of this cancer in 2014 [2]. With an overall five-year survival rate of only ~16% [3], the mortality rate of liver cancer mimics its incidence rate. Unlike the decrease in mortality rates of other malignancies, mortality related to liver cancer has increased over the past two decades [4]. Late-stage detection, ineffective therapy, and other liver co-morbidities contribute to low survival and high mortality. Liver cancer is not only a public health burden, but also presents a significant fiscal burden on individuals and health plans with an estimated average first-year cost of more than $62,000 for treatment. The average first year post-transplant cost for liver transplant, currently the only potentially curative option for liver cancer and liver failure due to end-stage liver disease (see below), ranged from $158,274 - $248,358 for Medicare patients in 2008-09 [5].

Of the various types of liver cancer, hepatocellular carcinoma (HCC), involving uncontrolled proliferation of hepatocytes, is the most common, deadly, and costliest form of liver cancer accounting for ~80% of adult primary liver cancer [6]. The cost and associated poor prognosis of HCC make the cancer a prime candidate for early detection and intervention. HCC usually arises due to complications from underlying liver disease [7]. Therefore, using administrative and clinical measurement guidelines to characterize metabolic syndrome has the potential to offer a gateway to early liver disease detection and possible improvements in cost and patient outcomes related to HCC.

Liver cancer is one result of liver disease. The focus of this study is on a liver disease called cirrhosis, where cells become damaged and are replaced by scar tissue. Cirrhosis contributes as a major risk factor (condition that increases your risk of developing a disease) for HCC [4] in addition to demographic characteristics like age, gender and race/ethnicity. Current key causes of cirrhosis in the US include, but are not limited to: 1) *Alcohol abuse (alcoholic liver disease, ALD):* Chronic exposure to high levels of alcohol causes liver diseases ranging from simple hepatitis (inflammation) to steatohepatitis (fatty liver with inflammation) and consequently to cirrhosis; 2) *Chronic viral hepatitis:* Chronic infection of the liver with hepatitis B or hepatitis C virus causes chronic hepatitis that progresses to liver damage, which in turn leads to cirrhosis. In the US, 50% - 60% of HCC cases are infected with HCV, 10% - 15% are infected with HBV, less than 5% are infected with both, and 30% - 35% are not infected with any virus (cryptogenic HCC) [8]; and 3) *Non-alcoholic fatty liver disease (NAFLD):* NAFLD, like ALD, also refers to a spectrum of diseases that ranges from simple steatosis (fatty liver) to steatohepatitis (non-alcoholic steatohepatitis, NASH) and ultimately cirrhosis. However, unlike ALD, these diseases occur in the absence of exposure to excessive alcohol. The majority of cryptogenic HCC is thought to arise from NAFLD [9].

Understanding cirrhosis and its prevailing causes in the US is an important step in understanding and developing risk prediction models. Such models enable: (i) decisions regarding earlier or frequent screening; (ii) counseling for behavioral changes to decrease risk; (iii) designing chemoprevention and screening interventions; (iv) planning of

resource allocations for preventive measures; and (v) early disease management decisions. Thus, risk prediction models have the potential to aid individuals and their healthcare delivery in multiple ways.

During the past decade, several risk prediction models for HCC have been developed. A vast majority of these models are specifically applicable to those infected with either HBV or HCV. Different models of HCC prediction in HBV-infected individuals evaluate distinct combinations of factors like age, gender, HBV e antigen (HBeAg), HBV genotype, serum alanine transaminase (ALT), HBV DNA and HBV surface antigen (HBsAg), family history of HCC, alcohol consumption, albumin levels, bilirubin levels, and cirrhosis, core promoter mutation [10-13]. In contrast with the inclusion of virus-related measures for the prediction of HCC in HBV-infected individuals, factors associated with the prediction of HCC in HCV-infected individuals do not include virus serostatus or any other virus-related measures. Instead, unique combinations of factors like age, gender, platelet counts, albumin, aspartate transaminase (AST), liver stiffness (measured by transient elastography), and alpha-fetoprotein (AFP) concentration can predict risk of HCC in chronic HCV patients [14, 15]. A very recent study aimed at developing a risk prediction model for HCC in the general population has incorporated the etiology of cirrhosis as part of their model [4]. This model, called ADRESS-HCC, generates a risk score from the six factors: age, diabetes, race, etiology (autoimmune, alcohol/metabolic, viral), sex, and severity of liver dysfunction as measured by Child-Turcotte-Pugh (CTP) score. The resulting models are primarily restricted to individuals with HBV and HCV. However, about 65% of HBV- and 75% of HCV-infected individuals, respectively, are not aware of their infection status [16] precluding the assessment of their risk for liver cancer. Thus, risk of HCC in the general population needs to be better characterized. Further, these models have a tendency to largely neglect NAFLD, which is an emerging disease of importance.

The importance of NAFLD is evident from several facts [17]. NAFLD, which is associated with obesity and metabolic syndrome, is becoming epidemic with 31% of US population estimated to have this disease [18]. Approximately 1.5-2% of the US population has cirrhosis due to NAFLD. As a result, the burden of cirrhosis caused by NAFLD is twice as much as that caused by HCV. It is anticipated that within the next 5 years, NAFLD-related cirrhosis will surpass HCV-related cirrhosis as the leading indicator for liver transplant [17]. Liver cancer can develop in individuals with NAFLD in the absence of cirrhosis [19]. Presence of fatty liver increases risk of HCC associated with other liver diseases like chronic HCV and alcoholic liver injury. For example, risk of HCC in HCV infected individuals is 2-3-fold higher with coincident steatosis compared to those without steatosis [17]. It is unclear whether the process of neoplastic transformation is initiated after establishment of cirrhosis or during the early stages of liver disease, especially since steatosis (the earliest manifestation of NAFLD) has carcinogenic potential [7]. As a result, NAFLD could potentially be a more common predictor encompassing other liver diseases including ALD and HCV.

From the increasing prevalence of NAFLD and its association with hepatic and non-hepatic related mortality, it is apparent that screening and diagnosis of NAFLD is important for public health. Currently, liver biopsy is the gold standard for accurate diagnosis after suspected NAFLD to determine histological severity and prognosis of liver damage [20, 21]. Even though liver biopsies are the gold standard, they are performed with a particular set of risks [22]. While rare, complications of bleeding, infection and injury to nearby organs do exist with this invasive test and as such preclude its use as a screening tool in otherwise healthy individuals. Alternative methods of diagnosing NAFLD include ultrasonography, computed tomography and proton magnetic resonance spectroscopy (^{1}H-MRS). These techniques either lack sensitivity or are expensive and time-consuming [21]. To overcome these limitations, several prediction scores have been developed to encourage non-invasive assessment of NAFLD [21]. Current prediction methods and basis for their scores are:

1. *SteatoTest:* This test is a biochemical assessment of steatosis grade providing a numerical estimate ranging from 0.00 - 1.00 that corresponds to steatosis system of grades S0 -S4. It combines the six components of FibroTest/ActiTest [23] [alpha-2-macroglobulin (A2M), haptoglobin, apolipoprotein A1 (ApoA1), gamma-glutamyl transpeptidase (GGT), total bilirubin and ALT] with body mass index (BMI), serum cholesterol, triglycerides (TG) and glucose adjusted for age and gender.

2. *Fatty Liver Index (FLI):* The algorithm for FLI was developed based on the variables BMI, waist circumference, TG and GGT. The FLI ranges from 0 - 100. A FLI of less than 30 rules out fatty liver whereas FLI above 60 rules in fatty liver for further investigation by ultrasonography. It is thus a continuous measure that identifies the binary condition of fatty liver.

3. *NAFLD Liver Fat Score (LFS):* Among the many variables associated with increased liver fat content, metabolic syndrome (diagnosed according to the criteria defined by the International Diabetes Foundation [24]), increased fasting serum insulin, type 2 diabetes, fasting serum AST and decreased AST/ALT ratio were found to be independent predictors of NAFLD. These variables were used to calculate the NAFLD risk score. Since prediction of NAFLD is based on a specific cut score instead of a range of continuous values, this score does not reflect the severity of the liver disease.

4. *Lipid Accumulation Product (LAP):* This scoring mechanism, based on waist circumference and fasting TG, was originally used to detect prevalent cardiometabolic risk factors and diabetes [25, 26]. Since these two variables are common to FLI, LAP was tested for its ability to detect liver steatosis. Further, to avoid loss of information due to binary classification (as done in FLI), liver steatosis was evaluated as an ordinal 3-level variable. Nomograms depicting the probability of liver steatosis as a function of log-transformed LAP (lnLAP) indicated that the odds of more severe steatosis increased with increasing values of lnLAP.

5. *Hepatic Steatosis Index (HSI):* Lower BMIs and waist circumference in the Korean population compared to the Caucasian population precludes the application of FLI in this population. As a result, this novel index of NAFLD presence was devised by deriving an equation incorporating BMI, ALT/AST ratio and diabetes. A HSI of less than 30.0 rules out NAFLD whereas HSI of higher than 36.0 rules in NAFLD suggesting further screening. Due to the differences in BMI, waist circumference and susceptibility to insulin resistance between Korean and Caucasian populations, the cut-off values need to be reassessed for use of HSI in the US.

Independent development of these models limited generalizability of conclusions concerning superiority. Thus, a recent study was undertaken to compare the performance of these prediction scores on a single population in the US. For this purpose, data from the National Health and Nutrition Examination Survey (NHANES) conducted from 1988 to 1994 and subsequent follow-up data for mortality up to December 2006 were used [21]. According to this study, the performance of LFS for predicting NAFLD was superior to LAP, FLI or HSI. Further, LFS scores were also associated with outcomes. Higher LFS scores were associated with all-cause mortality. The high LFS group had a 31.25-fold and 30.3-fold increase in risk of liver mortality compared to the low and intermediate LFS groups, respectively. Cheung et al., 2014, suggest that the LFS model performs better than the others because it was derived using NAFLD cases diagnosed with ^{1}H-MRS, which is a very sensitive and quantitative imaging tool for identifying hepatic steatosis compared to ultrasonography that was used to derive the other three models. A difference noted in this method was the inclusion of metabolic syndrome in the algorithm, which is not a component of the other methods. It remains unknown whether or not the inclusion of metabolic syndrome creates a superior algorithm when compared to others.

Metabolic syndrome (MetS) is a cluster of risk factors that increases a person's risk for heart disease, stroke and NAFLD [46]. Three different organizations, the US National Cholesterol Education Program Adult Treatment Panel III (NCEP-ATP III), the World Health Organization (WHO) and the American Association of Clinical Endocrinologists (AACE), had initially recommended criteria for the diagnosis of MetS [27]. Subsequently, the International Diabetes Federation (IDF) and the American Heart Association/National Heart, Lung and Blood Institute (AHA/NHLBI) attempted to reconcile differences in clinical definitions of the recommended criteria but in turn outlined separate recommendations [28]. In general, the conditions that comprise metabolic risk factors include: 1) Obesity: large waistline (abdominal obesity) or high body mass index (BMI), 2) High TG level or on medicine for treatment of high TG, 3) Low high-density lipoprotein (HDL) or on treatment for low HDL, 4) High blood pressure or on treatment for high blood pressure, and 5) Insulin resistance: high fasting blood glucose, impaired glucose tolerance, type 2 diabetes or on treatment for high blood sugar.

Although the ideal thresholds and cut-off values differ between the different recommendations, the presence of three or more of these factors is required for the diagnosis of MetS [28]. According to the National Health and Examination Survey (NHANES) III (1988-1994) and NHANES 1999-2000, the age-adjusted prevalence of MetS was 24.1% and 27%, respectively [29]. It is now recognized that, in addition to MetS-associated risk of cardiovascular events and diabetes, MetS also impacts the liver in deleterious ways:

1. NAFLD is often associated with the individual components of MetS: ~90% of NAFLD patients have more than one feature of MetS and >33% have more than three criteria [30]. Further, a prospective cohort study conducted in Japan demonstrated that those with metabolic syndrome have a 4-11 times higher risk for future NAFLD [31] suggesting that NAFLD is a hepatic manifestation of MetS. Importantly, the presence of MetS is associated with progression of NAFLD to NASH and cirrhosis that may lead to HCC [32].
2. MetS is associated with faster progression of HCV-induced liver damage and decreased response to anti-viral therapy [32].
3. Obesity and overweight, components of MetS, are risk factors for the progression of ALD [33].
4. Risk of HCC is directly proportional to the number of MetS components present [34]. Importantly, HCC can develop even in the absence of cirrhosis when MetS and NAFLD are present [32, 35].

These relationships of MetS with liver disease and HCC strongly suggest that MetS can serve as an important predictor of liver disease (including NAFLD) and the probability of liver disease progressing to more complex conditions like cirrhosis and HCC.

Methods

We employed domain analysis of both research and disparate sources of data to develop recommendations for future directions towards cost reduction. We examine the informatics landscape from which these disparate data are generated to characterize MetS.

Results

We discovered that certain biomedical sources of data used to characterize MetS are not often used to screen for liver disease.

Current methods and uses of screening for MetS include:

1. *Data extraction from electronic medical records (EMRs):* A prospective cohort study developed an algorithm to identify patients at risk for cardiovascular health disease (CHD) or diabetes using data from EHRs [36, 37]. A validation study that compared electronic data extraction with manual chart review demonstrated substantial agreement between the two methods for identifying MetS. The prevalence of MetS determined by these methods was much higher than that determined from ICD-9 diagnosis code for MetS [38]. This is consistent with an earlier finding that metabolic syndrome is rarely coded in claims data using the designated ICD-9 code (dysmetabolic syndrome: 277.7) [39]. An internal analysis of claims data from The OSU Health Plan echoed this finding (where a 2013 incidence rate was calculated as 0.6 per 1,000).
2. *On-site health risk appraisal data of employed population:* A large study conducted on employees of a multistate financial services corporation used on-site health risk assessment that included a biometric screening by nurses and a questionnaire covering biological, psychological, and lifestyle health risks as well as presence of chronic diseases and health conditions and treatment for various medical conditions. Using this information, MetS (determined from biometrics data and treatment information) was found to be associated with poor perceived health, increased illness days and an increased trend of short-term disability incidence [40]. In a similar study conducted on employees of a manufacturing company, MetS was found to be associated with an increase in self-reported diseases (arthritis, chronic pain, diabetes, heartburn, heart disease and stroke) [41], and increasing healthcare and short-term disability cost [42].

Here, healthcare claims data was used to derive cost for the employees.

3. *Combination of multiple sources of information:* A retrospective analysis of a national EHR database containing clinical data, medication lists and prescriptions, and diagnoses or problems showed that clinical data identified more patients with cardiometabolic risk factors than either treatment- or diagnosis-based information [43]. Birnbaum et al. (2011) demonstrated that the use of claims or laboratory-based MetS patient identification alone underestimated MetS prevalence rates in comparison with an integrated data approach.

Recommendations: Screening

According to the claims data from The OSU Health Plan, HCC and end-stage liver diseases are among those conditions that consume the highest amounts of fiscal resources. A limitation of previous research is that despite the relationship between MetS and liver disease, no known studies have attempted to use MetS screening in a large population for understanding the risk of liver disease and HCC. Since risk factors for MetS are modifiable, identifying individuals with MetS and consequently, those at high risk for the liver diseases (including HCC), may facilitate intervention measures to alter these risks. Such early interventions at the MetS stage can prevent negative patient outcomes thus reducing the costs associated with treating the disease and continued monitoring for disease progression.

Next steps thus include screening and characterizing MetS for a population to encourage early interventions that can prevent or delay the onset of liver disease. Biometrics data for the past seven years (2008-2014), personal health assessments (PHAs) for the past two years (2013-2014), medication information from claims data for the past eight years (2007-2014), and laboratory values that are available through the Health Plan will be invaluable resources in the proposed screening of Health Plan members. Possible algorithms that might be developed using this data include:

1. *MetS risk prediction:* By restricting MetS characterization by yearly increments, we are able to determine incident rates based on clinically measured guidelines. Incident MetS cases can be determined from biometrics, PHA, laboratory test results, and medication data. Past data for matching individuals may be used to determine differentiating markers predicting risk by comparing data for those individuals without MetS. Those at risk for MetS can be referred to payer care-coordination programs for recommendations to control these risk factors.
2. *Liver disease risk prediction in presence of MetS:* MetS cases with or without subsequent ICD-9 diagnosis of liver disease can be identified using data from biometrics, PHA, laboratory tests and medications (for MetS diagnosis) as well as ICD-9 codes (for liver disease diagnosis). Differentiating features between these two groups can help to develop appropriate risk prediction algorithms. MetS has the potential to be measured as a continuous variable with specific cut-offs determining severity and risk of liver disease (similar to the algorithms developed for predicting NAFLD). Since there are different types of liver disease (viral, alcoholic and non-alcoholic), this analysis can be performed independently and collectively followed by testing to determine differences in performance of the prediction algorithm. Individuals identified to be at risk for liver disease can be followed-up with non-invasive tests (biochemical and image-based) to determine the presence and severity of the disease [44] in addition to referral to care coordination programs.
3. *HCC risk prediction in presence of MetS:* Similar to the above, retrospective data from identified MetS cases and/or those at risk for liver disease with subsequent ICD-9 codes for HCC can be compared with data for those without diagnosed HCC to determine differences in features. These features can be used to develop an algorithm that can accurately predict an individual's risk of HCC. Individuals identified at risk for HCC can be referred for liver biopsy for further confirmation of disease state.

The established chain of liver disease progression, presents a unique opportunity for informatics solutions to address results of this domain analysis and towards intervening in the resulting continuum of cost.

The Case for Conceptual and Computable Cross-Fertilization Between Audit and Feedback and Clinical Decision Support

Abstract

Many patients do not receive care consistent with best practice. Health informatics interventions often attempt to address this problem by comparing care provided to patients (e.g., from electronic health record data) to quality standards (e.g., described in clinical guidelines) and feeding this information back to clinicians. Traditionally these interventions are delivered at the patient-level as computerized clinical decision support (CDS) or at the population level as audit and feedback (A&F). Both CDS and A&F can improve care for patients but are variably effective; the challenge is to understand how the efficacy can be maximized. Although CDS and A&F are traditionally considered separate approaches, we argue that the systems share common mechanisms, and efficacy may be improved by cross-fertilizing relevant features and concepts. We draw on the Health Informatics and Implementation Science literature to argue that common mechanisms include functions typically associated with the other system, in addition to other features that may prove fruitful for further research.

Keywords:
Medical Audit; Quality Indicators; Healthcare Quality Improvement; Clinical Decision Support Systems.

Introduction

The prominence of evidence-based medicine has led to widespread acceptance of what consitutes good care. Implementing this evidence in clinical practice, however, is challenging – often referred to as the "second translational gap" Such problems lead to adverse outcomes for patients. For example, in the UK alone there are thought to be over 3,000 unnecessary strokes per year because patients with atrial fibrillation do not receive anticoagulant medication [1]. Barriers to implement evidence-based care may occur at different levels: individual patient-practitioner; provider team; provider organisation; and health system policy [2]. Health informatics interventions often attempt to address these barriers by highlighting to clinicians when patients may not receive care consistent with best practice evidence (e.g., in clinical guidelines) through analysis of patient data (e.g., from electronic health records [EHR]). When these interventions are delivered via computers during clinical encounters with patients, the interventions are called clinical decision support (CDS). When delivered outside clinical consultations and at the population-level, they are are typically described as audit and feedback (A&F). Systematic reviews of both types of intervention suggest they are moderately effective at ensuring patients receive improved care [3–5]. However, the reviews also suggest interventions are highly variable: sometimes the interventions work very well, and sometimes they do not [3–5]. The current challenge is therefore to understand how to maximize the efficacy. Although they are traditionally considered separate approaches, in this paper we suggest that computerized CDS and A&F share common mechanisms, and that their efficacy may consequently be improved by cross-fertilizing relevant features and concepts between each other.

To build our argument, we draw on literature from Health Informatics and from Implementation Science. Despite our focus on computer-based tools, we also draw on relevant evidence from non-computerized interventions. First we examine computerized CDS and A&F seperately: their functions, mechanisms and features associated with success. Next we consider their common aspects and provide a rationale for cross-fertilization. Finally, we provide examples of how this could be achieved both with functions typically associated with the other, in addition to other features that may improve their success. We end with a discussion on implications for future research and other tools that facilitate human interpretation of patient data.

Computerized Clinical Decision Support

CDS (both computerized and non-computerized) refers to a heterogeneous set of tools that can be broadly defined as "active knowledge systems which use two or more items of patient data to generate case-specific advice" [6]. This definition contrasts with passive knowledge systems, in which the user themselves must search the system [6]. Musen et al. classify CDS in three basic varieties [7]:

1. Patient-specific, situation-specific alerts, reminders, physician order sets, or other recommendations for direct action;
2. Information about the current clinical context to retrieve highly relevant online documents (e.g., *infobuttons*);
3. Organisation and presentation of information in a way that facilitates problem solving and decision making (e.g. graphical displays, documentation templates, structured reports).

We equate *computerized* CDS with the first variety. These are considered classic computerized CDS systems [7], and are arguably the most common [8,9]. Such systems provide custom-tailored assessments or advice based on patient-specific data (e.g., from EHRs or order entry systems) in consultation with a knowledge-base (usually best-practice evidence e.g. clinical guidelines), delivered via a computer to professionals at the point of care. Examples of these systems include [7,8]:

- Alerting clinicians if they are about to perform an action that may have adverse consequences (e.g., prescribing a macrolide antibiotic in a patient taking a statin);
- Reminding clinicians to perform a task (e.g., that a patient requires a cholesterol blood test);
- Suggesting management options for a particular patient based on their specific circumstances (e.g., suggesting changes in cholesterol-lowering treatment for a patient with high cholesterol).

Computerized CDS typically employs event-condition-action rules such as those in Arden syntax [7]. If a patient's data (the "event"; e.g., cholesterol level), meets criteria in accordance with the knowledge-base (the "condition"; e.g., >5mmol/L), then the CDS is trigerred (the "action"; e.g., suggestion of options for intensification of statin treatment). We exclude probabilistic CDS tools (e.g., Bayesian diagnostic systems) from our argument because they are usually not based on predefined clinical standards such as clinical practice gudelines.

We can surmise that computerized CDS attempts to improve compliance with best practice evidence by addressing barriers at the individual (patient-practitioner) level [2]. These include the health professional's lack of awareness or familiarity with the evidence, or their inertia of previous practice [10]. CDS works by making information available and visible to the health professional during the clinical encounter when action can be taken. However, CDS only works for patients that are encountered, and it is often ignored during time-pressured clinical encounters, or when a patient has an over-riding competing clinical priority. As a result, the efficacy of CDS is modest and highly variable. A recent Cochrane review of "on-screen, point of care computer reminders" demonstrated they improved processes of care by a median of 4.2% (interquartile range [IQR], 0.8% to 18.8%) [11]. Another review found only 58% of trials demonstrated an improvement in either processes of care or patient outcomes [3]. This review also demonstrated that CDS is more likely to be effective if it is delivered outside the EHR or order entry system, provides advice to patients as well as health professionals, and requires the user to articulate why they ignored a recommendation [3]. It has also been suggested that CDS may be variably effective because it does not target organisation-level barriers [12].

Audit & Feedback

A&F (both computerized and non-computerized) can be defined as "any summary of clinical performance of health care over a specified period of time" [13]. Other names for A&F include "clinical performance feedback," "performance measurement," and "quality measurement."

The audit part of A&F involves analysing data to produce a summary measure of clinical performance (interchangeably called a *quality indicator*, *performance measure*, or some combination of the two). Data may be obtained from medical records, computerized databases, or observations from patients [13]. Clinical performance is judged for a specified population according to accepted best practice (e.g., clinical guidelines). Quality indicators usually quantify clinical performance in a Donebedian classification as:

- Structural measures (e.g., number of nurses on a ward);
- Process measures (e.g.,proportion of eligible atrial fibrillation patients on anticoagulation); or
- Outcome measures (e.g., proportion of diabetic patients with good glycemic control (intermediate outcome) or number of myocardial infarctions per year per unit of population).

These indicators are generally calculated as proportions by comparing individual patients' data to the performance standard: the number of patients meeting the criteria form the numerator (e.g., number of children given a vaccination), and the total number eligible to meet the criteria form the denominator (e.g., number of children in the population eligible to receive the vaccine).

Feedback of audit results takes place after the clinical encounter, generally outside the clinical environment, and may target an individual, team or organisation. It may be delivered in a written, verbal or computerized format, and may include supporting materials, such as suggestions for improvement [5,13]. Feedback may also include *benchmarking* – comparison of recipients' performance with colleagues.

Traditionally, A&F was laboriously undertaken by the health professionals using paper medical records. However, widespread use of EHRs and web-based technologies means it is now much easier to undertake across multiple providers by external agencies such as governments or health service managers. As a result there is now an abundance of *computerized* A&F tools in healthcare systems around the world, variably termed *dashboards*, *benchmarking tools*, or *report cards*. Some are crude implementations of generic business intelligence software, others are more carefully developed for healthcare. These tools present information to health professionals (and often other audiences such as patients) via websites, computer applications or e-mail. Unlike non-computerized A&F, computerized A&F tools rarely make suggestions for improvement action to be taken by recipients.

Like CDS, A&F addresses barriers on the individual (patient-practitioner) level by making health professionals cognisant of their performance. As feedback is delivered outside the clinical encounter, it provides space and time for reflection and self-awareness, which ideally leads to behavior change. However, A&F also has the potential to address team and organisation-level barriers too, such as lack of resources and structural constraints [10] through the following ways:

- Feedback may be delivered to teams of clinicians and health care managers in addition to individual practitioners;
- Feedback provides recipients with a systematic and comprehensive view of entire patient populations served by a team or organisation, rather than only focusing on individual clinical encounters.

In addition to the space and time for reflection afforded by A&F, these factors encourage the formulation of service re-design plans for quality improvement. A limiting factor of A&F is that these plans must be formulated and undertaken, for which there must be sufficient time and resources. Consequently, like CDS, the efficacy of A&F is also modest and highly variable. The most recent Cochrane review of A&F demonstrated a median improvement in processes of care of 4.3% (IQR 0.5% to 16.0%) [5]. This review also demonstrated that A&F is more likely to be successful if the recipient is not performing well at baseline, and if feedback is

provided by a supervisor or senior colleague, regularly, in multiple formats with clear targets and an action plan [5]. It has also been suggested that A&F may be more effective if it includes individual patient-level data (in addition to population summaries) [14–16], individual clinician-level data (in addition to team- or organisation-level) [16,17], and if it is provided in a timely manner [17,18].

Rationale for Cross-Fertilization

Although computerized CDS and A&F have traditionally been considered separate approaches to quality improvement, we argue the above evidence (summarized in Table 1) suggests they are in fact highly related for the following reasons:

1. **They use the same substrates**: Both interventions use EHR data and compare the observed clinical workflow against a clinical standard (e.g. guidelines).
2. **They use analogous analytic methods:** The number of event-condition-action rules triggered in computerized CDS systems for a specific patient population are equivalent to the numerator value of quality indicators in a computerized A&F system. The total number of patients for which the event-condition-action rules could be applied is equivalent to the denominator.
3. **They use similar methods to effect behavior change:** Both feed back to recipients assessments of observed care versus a clinical standard.

As described above, it is established that CDS and A&F are moderately effective at improving patient care. The current research challenge is to therefore understand how their efficacies can be maximized [3,19]. We argue that given their similarities, there is a need to explore potential, systematic cross-fertilization and learning between them. In the following section we present evidence that cross-fertilization of their associated functionalities could increase their associated effectiveness. We therefore argue that this relationship should be exploited in systematic, computable ways.

Suggestions for Cross-Fertilization in Practice

Evidence-based Synergies of Typical Functions

Computerized CDS is more effective if delivered seperately from the EHR or ordering system [3], and may also be improved if it targets team and organisation-level barriers [12]. Both these are features typically associated with A&F (Table 1). For example, a computerized CDS system may only remind a user to order an annual thyroid function blood test for someone on long-term thyroxine if their EHR is opened during a clinical encounter. However, this only works for patients that are seen, and the reminder may be ignored in a time-pressured clinical environment. If this system was delivered outside the EHR, it would be possible to see all the patients who needed the blood test (like A&F), which may provide the time and space to formulate a plan to ensure they all had the blood test. Furthermore, providing this more population-based information may also help address some of the team and organisation-level barriers (like A&F), such as understanding that additional services may be needed to facilitate all the patients receiving the blood test e.g. providing additional phlebotomy clinics or new phlebotomy staff.

Computerized A&F is more effective if provided in a timely manner [17,18], with suggested action plans [5], individual patient-level data [14–16] and individual clinician-level feedback [16,17]. These are features typically associated with CDS (Table 1). For example, a computerized A&F system normally only highlights the proportion of hypertensive patients who have uncontrolled blood pressure. This requires searching for the patients and formulating action plans to improve performance, for which there may not be the resources or skills. Computerized A&F may therefore be improved if the summary also provides individual-level data on which patients have uncontrolled blood pressure, in addition to suggestions for improvement action (like CDS). This may include individual patient actions such as choices for medication optimization, but also team and organisation-level changes such as introducing a home blood pressure monitoring service or installation of a blood pressure machine in the clinic waiting room. Some computerized CDS systems already have similar functions to this termed “population registries”, however they are uncommon in practice [8] and only provide suggestions for individual patient actions. Furthermore, to address barriers at the individual patient-practitioner level, such as health professional’s lack of awareness or familiarity with clinical guidelines, requires knowledge of which clinicians need targeting. This is facilitated if feedback reports specify individual clinician performance in addition to their team or organisation (like CDS). This may also be more effective if provided close to the time of the clinical encounter (like CDS), when the experience is fresh in the clinician’s mind and the patient’s care is amenable to action, for example they have not left the hospital or moved address.

Conceptual Extension to Synergies of Other Functions

The evidence above suggests that functions typically associated with A&F are likely to improve the efficacy of computerized CDS, and vice versa, which re-inforces our argument that the two interventions are related. It also suggests that cross-fertilization of other features, for which there may not currently be supporting evidence, may be worth investigating. For example, computerized CDS may be more successful if it also provided population-level summaries like A&F *during* clinical encounters. One may hypothesize that when a computerized CDS system is triggered (e.g. for raised cholesterol), knowing the proportion of the eligible population for whom the alert would also fire (e.g. proprtion of patients with high cholesterol) will put the information in a broader context of clinical performance, re-inforcing the alert’s importance. This may more effectively motivate the recipient to take action, reducing alert fatigue [20].

This principle may also extend to other features that are not necessarily considered typical of either CDS or A&F, but that have been shown to improve their efficacy (Table 1). For example, computerized CDS is more effective if it provides advice for patients and if it requires a reason for over-riding its advice [3]. To our knowledge these features have not been investigated extensively in computerized A&F, though may improve its efficacy: providing advice to patients may improve adherence to medication and engagement with healthcare in the same way as CDS; and requiring users to justify why feedback is ignored may improve cognitive engagement with the quality improvement process. We suggest these and other areas in Table 1 may prove fruitful areas for further research.

We acknowledge there may be other features of computerized CDS and A&F interventions that are associated with improved efficacy, which have not been mentioned above. This may include features for which there are currently conflicting opinions or evidence, such as the use of benchmarking in A&F [15,19,21,22], or other features not yet

discovered. The application of behavioural change theory and use of qualitative evaluations in future research may help identify these additional features. This idea is beginning to gain traction in the A&F literature [19,22], but to our knowledge has not yet been mirrored in the CDS literature. We suggest that when new theories or features are discovered for either computerized CDS or A&F, they should be inclusively applied to both and their influence on efficacy assessed.

Table 1 – Comparison of computerized CDS and A&F

Feature	CDS	A&F
Data source	EHR	EHR
Analytic method	Event-condition-action rules	Quality indicators
Unit of analysis	Individual patient	Population
Delivery	During clinical encounter	Outside/after clinical encounter
Users	Individual clinicians	Individual clinicians, teams, organisations
Recommends improvement actions	Yes	No
Features associated with success	Delivered outside EHR Providing advice to patients Requiring over-ride reasons Targeting organisation-level barriers	Low baseline performance of recipient Feedback provided by supervisor/senior Regular feedback Multiple formats of feedback Clear targets and action plans fed back Individual level information (patient and clinician) Timely information

Discussion

We have studied the features of computerized CDS and A&F and argued that they they should be considered as related, rather than separate, approaches to healthcare quality improvement. In doing so, we have suggested their efficacy may be improved through the cross-fertilization of features typically associated with the other, and that future research should explore linking the two in a computable synergy.

Previous attempts to increase the understanding of (the effectiveness of) CDS and A&F have largely been limited to bottom-up aggregation of empirical evidence concerning a hetereogeneous set of intervention studies, with little success to date. Our approach advocates consideration of the mechanisms that underpin how they work and what they are trying to achieve, which we think will be more successful.

Our argument is not that computerized CDS and A&F should be used as 'multifacted' or 'co-' interventions; these terms suggest separate tools glued together. Our vision is that given their similarities these interventions should seamlessly incorporate successful features and other learning from each other. Interestingly, in support of this assertion, merely adding reminders to A&F has not been shown to impact efficacy [5], nor adding summary feedback to CDS [3], and there is little support from systematic reviews for multifaceted over single-component interventions in general [23]. Furthermore, we do not advocate that the empirical evidence relating to computerized CDS and A&F be simply combined to increase the power of meta-regressions in systematic reviews, as this belies the clear differences between them. Our argument is rather that a shared conceptualization can strengthen the generation and testing of specific hypotheses that draw on their shared mechanisms. We believe our understanding of both interventions can be advanced by considering the empirical evidence across them and borrowing evidential strength from adjacent areas where appropriate.

In addition to improving the efficacy of both computerized CDS and A&F, there are corollary benefits to their cross-fertilization. For example, the cross-fertilization encourages the development of common technical standards, which promises to save implementation time and effort [24]. Linking quality indicators to possible improvement actions also provides a more accurate measure of care quality, which is important if used for accountability purposes (e.g., performance-based payment). For example, it is more accurate to know the proportion of uncontrolled hypertensive patients prescribed suboptimal medication, rather than simply the proportion of uncontrolled hypertensives.

Although we have limited our discussion to CDS and A&F, our argument may well extend to a broader set of computerized interventions that facilitate clinician interpretation of patient data. Examples include range checks for laboratory test results, electronic checklists, and risk prediction tools. And although we excluded probablistic CDS systems from our discussion, they may also be relevant. For example there are arguments for the application of risk prediction tools in A&F [14] and a need for actionable suggestions (like CDS) in risk prediction [25]. Furthermore, there may be implications for non-computerized interventions too, as there are suggestions that A&F is most effective when there is external facilitation [26], which may be considered an 'educational outreach' feature [13].

A limitation of our argument is that the argument has occasionally drawn on evidence from non-computerized CDS and A&F, in addition to their computerized counterparts. This was necessary because some of the literature (particularly regarding A&F) does not distinguish between these two modes of delivery [5,6]. We believe our assertions transcend the distinction between computerized and non-computerized versions of these tools. Nevertheless, future research should empirically test whether our hypotheses regarding cross-fertilization hold in solely computerized settings. Our group has already started to do this by developing experimental computerized interventions [27,28].

Conclusion

We argue that computerized CDS and A&F systems are not separate but highly related approaches to quality improvement. We suggest that cross-fertilization of features and learning betweem them may improve their efficacy. We

have provided examples of how this may be achieved in computable ways, along with suggestions for future research.

Inside the Black Box of Audit and Feedback: a Laboratory Study to Explore Determinants of Improvement Target Selection by Healthcare Professionals in Cardiac Rehabilitation

Abstract

Audit and feedback (A&F) is widely used to aid healthcare professionals in improving clinical performance, but there is little understanding of the underlying mechanism that determines its effectiveness. The aim of this paper is to investigate the process by which healthcare professionals select indicators as improvement targets based on A&F. We performed a laboratory study among 41 healthcare professionals in the context of a web-based A&F intervention designed to improve the quality of cardiac rehabilitation care in the Netherlands. Feedback was provided on eighteen quality indicators, including a score and a colour (representing a recommendation for selection (red and yellow) or non-selection (green)). Indicators with more room for improvement were more likely to be selected, although this varied substantially between participants. In more than a quarter of the cases, participants did not select indicators with obvious room for improvement (yellow or red colour), or selected indicators without apparent room for improvement (green colour). We conclude that personal preferences and beliefs concerning quality and performance targets may dilute the efficiency of A&F.

Feedback, Psychological; Medical Audit/standards; Heart Diseases/rehabilitation.

Introduction

Healthcare organisations increasingly adopt audit and feedback (A&F) strategies to monitor and improve their quality of care. A&F provides healthcare professionals with an objective summary of their clinical performance over a specified period of time.[1] Clinical performance is typically measured by a set of quality indicators derived from clinical guidelines or expert opinion–each indicator representing a quality aspect of care (e.g., proportion of patients receiving a treatment according to guideline recommendations, or mortality rates). Despite the widespread use of A&F and the inherent efforts and costs put into their development and application, A&F interventions show variable effectiveness on improving quality of care. A recent Cochrane review of 140 randomised trials of A&F interventions reported a median 4.3% absolute improvement (interquartile range 0.5% to 16%) in quality of care, with a quarter of the studies showing a strong positive effect, but with another quarter showing a negative or null effect.[1]

Previous studies have attributed much of the observed variability in effect of A&F interventions to feedback design characteristics and contextual factors. They suggested A&F to be most effective if provided by a supervisor or colleague, more than once, both verbally and in writing, if baseline performance is low, and if it includes explicit targets and an action plan.[1–4] Other suggested effect modifiers are the perceived quality of the data underlying the feedback, motivation and interest of the recipient, organisational support for quality improvement (QI),[5] and how performance targets or benchmarks are derived.[6] However, whereas these studies contribute to our knowledge about what factors may influence the impact of feedback, they do not help us understand the underlying mechanisms of how A&F interventions affect the quality of healthcare.[7] Little progress has been made on this matter because most randomised controlled trials (RCTs) on A&F interventions did not explicitly build on previous research or extant theory.[8,9] Instead, they treated the intervention as a 'black box', focusing solely on outcomes (i.e., a change in quality of care) while ignoring the mechanism inside.

Control Theory is an increasingly recognised theory in A&F literature that offers an explanation of how this feedback mechanism works. It starts from the assumption that healthcare professionals are prompted to improve practice when observing a discrepancy between their own performance and a certain target (e.g., peer performance).[10] Feedback reports will continue to prompt improvement actions until the discrepancy has been solved, i.e., denoting target achievement. However, if professionals disagree with the target or observe a discrepancy that is too great, or professionals lack skills, motivation or resources for action, they may decide against selecting particular indicators as targets for improvement.[10,11] Herewith, Control Theory reveals two steps in the feedback mechanism essential to improving upon indicators: (i) healthcare professionals must recognise achievable room for improvement on indicators before selecting them as QI targets, and (ii) they must formulate and perform effective improvement actions. Understanding how these steps work is imperative for designing successful A&F interventions [12]; in this paper we investigate the first step.

The aims of this study were thus to determine (i) how healthcare professionals select quality indicators as targets for improvement based on reports of performance feedback, and (ii) what are reasons to disregard feedback's recommendations for selecting indicators. The study was conducted in a laboratory setting among cardiac rehabilitation professionals.

Methods

Study context: the audit and feedback intervention

The context of our study was the CARDSS Online A&F intervention, which was developed to improve concordance with guidelines and facilitate organisational change in cardiac rehabilitation (CR) in the Netherlands.[13] CR is a multidisciplinary therapy designed to support coronary heart disease patients recovering from a cardiac incident, and aims to improve their overall physical and psychosocial condition.[14] It is offered by multidisciplinary teams which generally include cardiologists, physical therapists, nurses, psychologists, dieticians, and social workers. A cluster-randomised trial among eighteen CR clinics in 2013 and 2014 evaluated its effectiveness [15]; the results will be published elsewhere. In the trial, local QI teams – consisting of CR professionals from various disciplines – received four quarterly feedback reports and educational outreach visits. During these four visits, the teams used CARDSS Online to select indicators as targets for improvement and to establish a QI plan consisting of concrete improvement actions and goals that were linked to the selected indicators. In follow-up visits, the teams assessed the new feedback and updated the QI plan accordingly. An average QI team consisted of 7 members (range 3 to 13). They were always part of a clinic's larger CR team, which consisted of a total of 6 to 16 professionals.

The feedback reports generated by CARDSS Online consisted of performance scores on eighteen structure, process, and outcome indicators for CR, combined with coloured icons to represent the objective room for improvement and a recommendation for selecting (red and yellow) or not selecting (green) an indicator as a target for improvement (see example feedback report in Figure 1). In the current study we focused on process and outcome indicators that reflected a dichotomous measure at the patient level (e.g., percentage of patients who quit smoking after CR). The indicator set was developed in close collaboration with CR professionals using a modified RAND method; the complete set is available in reference.[16] To determine performance scores for the indicators, all data were automatically derived from an electronic health record at the point of care. The coloured icons were assigned to an indicator based on the clinic's performance score and the average score across all clinics. Green was assigned if the clinic's score was ≥ 66%, except if the average score was ≥ 66%. Then the threshold for assigning a green colour was the average score minus 10%. If green was not assigned, yellow was assigned if the clinic's score was ≥ 33% or less than 10% below average. All other scores resulted in assignment of a red colour. In the case that a CR clinic submitted insufficent data to determine the score on a specific indicator, the feedback report lacked a score and showed a grey colour.

Study design and participants

We conducted our laboratory study among individual CR professionals from the eighteen CR clinics that were enrolled in the CARDSS Online trial. The 132 members of all local QI teams in the trial were invited by e-mail with up to two reminders (after 2.5 and 5 weeks).

All invited CR professionals received a personal account for CARDSS Online. For each professional, we randomly selected two real performance feedback reports from a report database containing all 50 reports that were previously generated for CR clinics participating in the CARDSS Online trial. We presented them as if they concerned reports of a 'virtual' CR clinic. Respondents were asked to select the quality indicators that they thought should be improvement targets in the QI plan of the virtual clinic. We did not set a limit on the number of selectable indicators, but encouraged respondents to compose a feasible QI plan that was to be evaluated after three months.

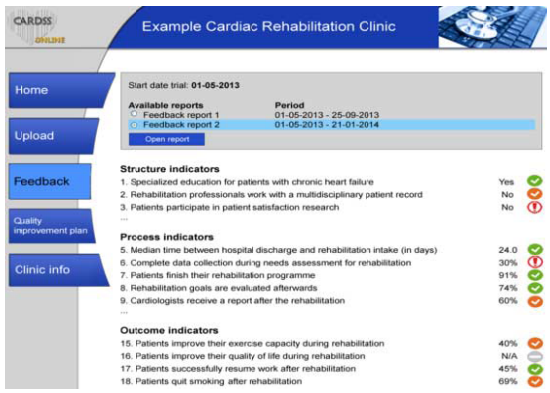

Figure 1 – Example feedback report in CARDSS Online

Data collection

Per quality indicator in each feedback report we collected the type of indicator (process or outcome), reported score (0 to 100%), reported colour (red, yellow, green, or grey), and whether the respondent selected the indicator as target for improvement (yes or no). To determine reasons for disregarding feedback's recommendations for (not) selecting indicators as improvement targets, we asked respondents to explain their choice if they chose not to select an indicator with a red or yellow colour by selecting one of the following statements: "not a relevant aspect of quality of CR", "improvement is not feasible", or "indicator score is high enough".[11] Similarly, we asked them to explain their choice if they did select an indicator with a green colour, using one of the following statements: "essential aspect of quality of CR", "easy to improve", and "indicator score is too low". If no statement applied, respondents could explain their choice in a text field.

At the level of the CR professional, we collected gender, age, years of clinical experience, discipline, whether they occupied a coordinating function in CR care, percentage of their time they spent on direct patient care, and how many educational outreach visits they attended in the CARDSS Online trial.

Statistical analysis

We performed three separate mixed-effects multivariate logistic regression analyses to determine which factors influence the selection of quality indicators by CR professionals. First, to test whether increased room for improvement was associated with higher chance of indicator selection (as posed by Control Theory), we used 'indicator type', 'reported score', and all collected professional-level factors as fixed covariates. Second, to determine whether the reported colour had additional or stronger influence, we performed another analysis by extending the model with the covariate 'reported colour'. Indicator values for which no score was available due to insufficient data (grey colour in feedback report) were left out of both analyses. Finally, to determine the impact of lacking feedback (grey colour) on indicator selection, we performed a third, similar analysis on the complete set of indicator values while leaving out the covariate 'reported score'. To account for clustering effects due to correlations between observations on the same quality

indicator (some indicators may be generally preferred to others), the same CR professional (some professionals may select more indicators than others), and the same clinic (professionals from the same clinic may have similar preferences), we added random intercepts for (i) indicator, (ii) respondent, and (iii) CR clinic to our regression models.

Following Nakagawa et al.'s [17] recommendations for reporting explained variance in mixed-effects models, we calculated two values of R^2: marginal and conditional R^2. Marginal R^2 describes the proportion of variance explained by the fixed effects alone, whereas the conditional R^2 describes the proportion of variance explained by both the fixed and random effects. For all fixed effects, we calculated the odds ratios (ORs) and 95% confidence intervals (CIs). To quantify how much of the explained variance could be attributed to each random effect, we substracted for each random effect the conditional R^2 of a model with only that single random effect from the marginal R^2 of the full model. All analyses were performed using R version 3.1.1 (R Foundation for Statistical Computing; Vienna, Austria).

Results

Fourty-one individual CR professionals (response rate, 31%) accepted our invitation; Table 1 summarises their characteristics. The majority of respondents were CR nurses and physiotherapists, had a coordinating function, and reported to spend more than half of their time on direct patient care. On average they attended approximately two educational outreach visits in the CARDSS Online trial. Two of the eighteen CR clinics from the clinical study were not represented in the study sample.

Table 1 – Participant characteristics (n=41)

Characteristic	Value*
Male gender	19 (46)
Mean age in years (SD)	45.6 (10.7)
Mean clinical experience in years (SD)	23.3 (10.5)
Mean visits attended (min-max)	1.83 (0-4)
Discipline	
CR nurse	18 (44)
Physiotherapist	13 (32)
Psychologist	3 (7)
Social worker	2 (5)
Dietician	1 (2)
Sports physician	1 (2)
Cardiologist	2 (5)
Manager / head of CR department	2 (5)
Coordinating function	22 (54)
Time spent on direct patient care	
Less than 25%	6 (15)
25% to 50%	9 (22)
50% to 75%	14 (34)
More than 75%	13 (32)
Mean no. of participants per clinic (SD)	2.7 (1.9)

* Values are numbers (percentages) unless indicated otherwise

In total, participants evaluated 82 feedback reports (two each). These evaluations concerned 40 unique reports (out of the 50 reports in the database), which were evaluated by one to four participants. The 82 reports contained a total of 767 patient-level dichotomous indicator values. 437 indicator values (57%) were assigned a grey colour due to a lack of data in calculating a score. Of the remaining 330 values, 287 (87%) were process indicators and 43 (13%) concerned outcome indicators. On average, participants selected 75% (range 52% to 100%) of all patient-level dichotomous indicators presented within the two feedback reports as targets for improvement. Participants most frequently selected the following indicators: proportion of patients who finish their relaxation and stress management training (process indicator; n=35, 100%), proportion of patients whose cardiovascular risk factors are evaluated after rehabilitation (process indicator; n=41, 100%), and proportion of patients who successfully resume work after rehabilitation (outcome indicator; n=39, 95%). These were also the indicators that most often showed a grey colour. Least frequently selected indicators were process indicators: proportions of patients for whom all data are collected during the needs assessment concerning lifestyle factors (n=5, 19%), psychological functioning (n=7, 26%), and proportion of patients that were offered a complete and tailored CR programme (n=30, 37%). These were also the indicators that most often showed a green colour.

Determinants of selecting quality indicators as targets for improvement

In the first analysis (Table 2), we found the reported performance score to be a significant determinant of selecting indicators as targets for improvement (OR 1.50, 95% CI 1.28 to 1.76; per 10% decrease in score). We found no association between the indicator type nor any of the professional-level factors and the selection of an indicator as target for improvement. The model explained 50.6% of the total variance (conditional R^2), where 20.8% was explained by the fixed effects alone (marginal R^2). Selection of indicators depended significantly on the participant, with its random effect accounting for 17.7% of the variance explained. Random effects of the CR clinic and quality indicator showed no significant influence on the selection of indicators.

In the second analysis, we found a significant influence of the reported colour on indicator selection, whereas the influence of the reported score was no longer significant. Red and yellow indicators were more often selected compared to green indicators (red: OR 10.42, 95% CI 1.28 to 84.85; yellow: OR 17.44, 95% CI 5.92 to 51.32). The total explained variance increased to 58.0% (conditional R^2), where 31.9% was explained by the fixed effects alone (marginal R^2).

The third analysis revealed that grey indicators were selected 100% of the time.

Reasons to disregard feedback's recommendations for selecting quality indicators

For the 330 of 767 quality indicator values with a reported score and colour, respondents deviated from the feedback's recommendation in 88 (27%) cases; they either did not select indicators showing a red or yellow colour (n=55, 34%), or they selected indicators showing a green colour (n=33, 19%).

Respondents' main reasons for not selecting red or yellow indicator values were that they reckoned the reported score to be high enough (n=16, 29%; fourteen yellow and two red indicators), and that improving the indicator was not feasible (n=14, 25%; in particular outcome indicator 'proportion of patients that quit smoking' [n=4] and process indicator 'proportion of patients whose rehabilitation goals are evaluated after CR' [n=3]). Further, they thought that improving the indicator lacked priority (n=11, 21%), or that the indicator did not represent a relevant quality aspect of CR (n=8, 15%).

The main reason for respondents' selecting green indicator values was that they considered the indicator an essential aspect of the quality of CR care, and should thus belong in every quality improvement plan (n=27, 82%; e.g., process indicator 'proportion of patients that were offered a complete

and tailored CR programme' [n=8]). All other reasons were selected in less than 10% of cases.

causes, making it more challenging to formulate effective improvement actions.

Table 2 – Determinants of selecting indicators as targets for improvement by CR professionals

Variable		p-value
Fixed effects	*Odds ratio (95% CI)*	
Quality indicator level		
Outcome vs. process indicator	1.01 (0.30, 3.39)	0.955
Reported score (per 10% decrease)	1.50 (1.28, 1.76)	<0.001
CR professional level		
Male vs. female gender	2.16 (0.42, 11.09)	0.363
Years of clinical experience (per 10 years)	1.10 (0.60, 1.99)	0.764
Spends more than half of the time on direct patient care	1.64 (0.53, 5.14)	0.393
Number of educational outreach visits attended in trial	1.03 (0.64, 1.65)	0.903
Discipline		
Physiotherapist vs. CR nurse	1.03 (0.13, 8.35)	0.969
Other vs. CR nurse	0.86 (0.18, 4.12)	0.848
Coordinating function	1.27 (0.45, 3.63)	0.650
Random effects	*Explained variance*	
CR clinic	4.4%	0.501
CR professional	17.7%	0.002
Quality indicator	7.7%	0.071

Discussion

We explored CR professionals' decision-making behaviour with regard to selecting quality indicators as improvement targets when confronted with performance feedback. Based on Control Theory, this is the first and essential step in the feedback mechanism to enable effective A&F. Professionals were more likely to select an indicator if there was more room for improvement, and they were more strongly influenced by the reported colour (red, yellow, green) than by the reported performance score. Still, they ignored more than a quarter of the feedback's recommendations for (not) selecting indicators based on the reported colours. Indicators for which insufficient data were available to calculate a score (indicators with a grey colour) were always selected. In addition, the number of selected indicators varied strongly between individual participants.

Relation to other studies

Although we are the first to have empirically investigated step 1 in the underlying feedback mechanism, earlier studies aimed at identifying design characteristics and contextual factors that influence the outcome of the mechanism (i.e., change in quality of care). A Cochrane review [1] concluded that low performance scores increased A&F effectiveness. The authors attributed this to greater intention to take action, or absence of ceiling effects [12]; our findings seem to support the first. Two reviews [2,3] found that feedback is more effective when accompanied by explicit performance targets. Supporting those results, our study revealed that CR professionals act more strongly upon colours, which served as a graphical representation of whether a target was achieved, than upon their absolute performance scores. Another review [5] suggested that A&F is more likely to improve process indicators compared to outcome indicators. However, our study found no effect of the type of indicator on the selection process. This implies that feedback's limited effect on outcome indicators may be explained by factors related to subsequent steps in the feedback mechanism outside our scope. For example, suboptimal scores on outcome indicators may require further drilling down to understand the underlying

Meaning of the study

A&F interventions often achieve only limited improvement of quality of care, for which current scientific knowledge fails to offer a satisfactory explanation. Our findings suggest that one of the reasons could be that feedback may not always convince healthcare professionals that certain aspects of their practice require improvement. In one third of the cases where quality indicators showed room for improvement (by showing a red or yellow colour), professionals did not select them as targets for the QI plan; they either disagreed with the performance target (they thought their score was high enough, thus not acknowledging room for improvement), deemed improvement unfeasible or lacking priority, or did not consider the indicator an essential aspect of care quality. Moreover, as this study was conducted in a laboratory setting amongst individual professionals, we expect that contextual factors in clinical practice (e.g., organisational constraints within a clinic, or social context within care teams) may further distort the process of selecting improvement targets based on performance feedback.

Nevertheless, our results show that using colours to represent the extent to which performance targets are achieved can be a useful means to guide healthcare professionals in selecting those indicators that require most improvement. This was illustrated by the fact that in our study red and yellow indicator values were much more often selected than green ones. Professionals also always selected indicators for which no feedback was available due to insufficient data. A possible explanation is that professionals seek to optimise data collection in order to draw a more complete picture of their clinical performance.

The number of selected indicators differed substantially between CR professionals. Our analysis did not reveal any systematic professional-level factors that may offer an explanation for this phenomenon. Instead, part of the explanation may come from individual professionals having personal preferences and beliefs concerning which indicators constitute care quality, and about what are achievable performance targets. Hence, accompanying feedback with explicit performance targets or colours may not always succeed in influencing the process of selecting improvement targets.

Limitations

Our study found reported colour to be a powerful tool to persuade healthcare professionals into selecting an indicator as target for improvement. Although there are various ways to derive colour thresholds for reported performance scores (such as based on peer performance, expert knowledge or clinical practice guidelines), the A&F design in our study used a relatively simple colour assignment scheme. This might partly explain why professionals in our study ignored a third of the feedback's recommendations for selecting indicators, in particular for the reasons "indicator score is high enough" and "improvement is not feasible" (both stated in almost one third of cases). In case our A&F design would have used a more sophisticated method for assigning colours, this proportion may have turned out smaller.

Furthermore, due to practical reasons, we only analysed the selection of indicators that reflected a dichotomous measure at the patient level; thus leaving out continuous measures and clinic-level dichotomous measures. Therefore we do not know whether the type of measure plays a role in professionals' selection of indicators as targets for improvement.

Future work

Currently we are conducting a clinical study to investigate how teams of CR professionals participating in the CARDSS Online trial select indicators as targets for improvement in clinical practice. Comparing the results of the clinical study to those in our laboratory study will provide insight as to the impact of real-world barriers on selecting indicators. Further research may also focus on investigating the second step in the feedback mechanism to explore determinants of actual change in performance.

Conclusion

CR professionals presented with indicator-based performance feedback were more likely to select indicators if there was more room for improvement, and they were more strongly influenced by the reported colour (red, yellow, green) than by reported performance score. Still, in more than a quarter of the cases they ignored the feedback's recommendations for (not) selecting indicators based on the reported colours. We conclude that personal preferences and beliefs concerning quality and performance targets may dilute the efficiency of performance feedback. A follow-up study will be conducted to investigate the same step in clinical practice among CR teams.

Using Patient Journey Modelling to Visualise the Impact of Policy Change on Patient Flow in Community Care

Rosemary Sayvong[a], Dr Joanne Curry[ab]

[a]*University of Western Sydney, New South Wales, Australia*
[b]*CSC, Australia*

Abstract

Health policy plays a crucial role in community care, particularly within care programs such as ComPacks. ComPacks is a short-term care program administered by New South Wales (NSW) department of health which runs for up to 6-weeks and its goal is to prevent or minimise hospital readmission. Compliance to the ComPacks health policies is required in order to gain financial support from overnment bodies, however when the Government makes changes to service policies, this may potentially cause ripple effects to the workflow of the service and increase pressures on care providers, which in turn may affect the patient. Utilising a multi-layer visualisation tool can help identify whether changes made to policy are impacting patient flow in a positive or negative way. This research study investigates the use of an emerging patient journey modelling technique to better understand service design in a community care setting, whilst also determining the impact of State-level policy interventions.

Keywords:

Patient Journey Modelling; Essomenic; Health Policy; Community Care; ComPacks.

Introduction

The increasing prevalence of hospital readmissions and the subsequent impact on acute care services cannot be easily ignored. Easing the burden on acute care services can be managed through efficient and effective service delivery of community care services [1, 2]. *C*ommunity care programs have been initiated by Local and State government as a means to addressing community health issues. Such examples can be exemplified through programs such as Home Aged Community Care (HACC), Hospital in the Home (HITH), and Community Packages (ComPacks) in which patient care is transitioned from hospital to home and assistive services are provided to patients, post-discharge [1, 3, 4]. These programs in particular are driven by a focus on reducing the probability of readmissions due to post-discharge complications, thus reducing the pressures on hospital services. In understanding that state and local governments administer most of these care programs and services, policies and guidelines are developed and implemented as a directive measure in achieving an effective service delivery for care. These documents dictate service delivery processes and also indicate performance areas that are to be measured [5]. When changes are made to policy, it is difficult to examine whether the impacts of these changes are affecting service workflow, patient flow and patient outcomes without understanding the concepts of policy analysis. The following study examines the use of a healthcare-oriented service redesign technique as a tool to visualise the impact of policy change on service workflow, patient flow, and outcomes within community care.

Health Policy Development

Health policy is an essential component of the delivery of care services. It establishes a plan describing the courses of action or intended actions to be taken by institutions or organisations that have an impact on health [6–8]. Health policy is developed based on informed values and reasoning [5]. It is formulated, proposed, and evaluated using evidence-based methods to ensure successful implementation. Therefore, policy changes must undergo comprehensive analysis and evaluation. Analysis and evaluation have the potential to (1) increase policy impact and (2) provide evidence for future policy amendments [9, 10]. Based on literature surrounding existing theoretical frameworks for policy analysis, it is generally agreed that the policy development environment comprises several interconnecting elements; policy-makers, processes and outputs. These elements interact through the 5 stage Health Policy Development Cycle (HPDC) (Figure 1).

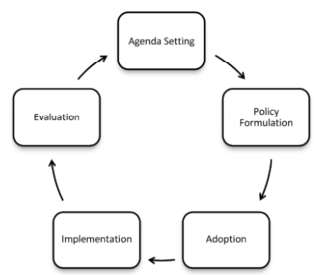

Figure 1 – Key Stages in the Health Policy Development Cycle [8]

Stage 1 – Agenda Setting: Identifies and defines the current policy issues and sets an agenda as to what problems need to be addressed [7, 8, 11].

Stage 2 – Policy Formulation: Sets policy boundaries between State and Federal health authorities and creates and/or changes actual policy content [8].

Stage 3 – Adoption: Sees the policy amendments brought to attention of policy approval bodies and put into force by State or Federal legislative measures [8, 12].

Stage 4 – Implementation: Action is taken to officially put approved policy changes into practice – more particularly formalising these actions by writing and documenting them into legislation.

Stage 5 – Evaluation: Involves the process of monitoring, analysing, critiquing and assessing existing or proposed policies. It is designed to help governments implement these policies in an effective and efficient manner through heavy examination of their policy content and their effects [11, 12].

Tools

Policy developers use a range of tools during the various stages of the HPDC. Stakeholder Analysis is used during Stages 1 and 2 to analyse the behaviour, responsibilities, interests, agendas, and common resources or interactions between different stakeholders and how these impact the policy process [11, 12].

Stage 3 may include the use of policy evaluation software, such as Policy Maker. These types of software focus on analysing the political dimensions of adopting public policy and decision making around such changes. They can also assist stakeholders in determining the feasibility of the policy to be implemented. Outputs are in the form of graphs, statistical charts and opportunity/obstacle narratives [11].

Tools used in Stage 5 (Evaluation) include document analysis and stakeholder mapping. Document analysis involves a systematic review of existing policy documentation and determining the clarity and comprehensiveness of the internal statements in alignment to the reflection of intended outcomes [9]. Stakeholder analysis has also been applied to the latter stages of the policy process. By deconstructing political dimensions, linkages can be made to stakeholders and objectives particularly between the distinct micro, meso and macro policy levels [14]. Further analysis on the level of control each stakeholder has in relation to proposing new agenda items can also trigger recommencement of the policy development cycle.

Issues

The current tools and approaches to policy analysis present several limitations. In document analysis, there a disregard to other contributing factors which are generally involved with the policy process such as stakeholders, resources and monitoring processes. Application of stakeholder analysis/mapping within a healthcare context has also proven difficult in drawing proper conclusions in relation to policy assessment. With the continuous changes occurring within health environments, it is difficult to easily gather information which is "cross-sectional" or "static" to a particular period of time [13, 14]. The timeframe for which health policy data is collected and analysed can also affect the relevance of analysis that informs decision-making. When using computer-aided policy tools, the quality of the assumptions and judgments made by the analyst can affect the validity of the results produced by the application [11, 15, 16].

This suggests there is a major deficit between the formulation stage and the implementation stage [9] as those that formulate the policy are usually not involved in the implementation of resulting policy changes at the operational level [9, 17]. In addition, current methods and tools used for evaluating and analysing policy within particular stages of the policy cycle are isolated to a singular perspective potentially resulting in an incomplete understanding of workflow, impact and outcomes. This deficit can be overcome by introducing visual patient journey modelling to the early stages of the HPDC to provide evidence to policy developers and help them to understand the potential impact of policy changes on patient flow and service delivery at an operational level.

Research Setting & Design

This research study utilises a multi-method approach for visualising the impact of policy changes particularly in a community care setting. Participatory Action Research is used to gather healthcare stakeholder input. The aim of the research is to better understand service design in a community care setting, whilst also determining the impact of State-level policy interventions through the application of an emerging patient journey modelling technique known as Essomenic. Document analysis and healthcare provider focus groups also contributed to the development of the resulting models.

Research Setting

The study examines the process flow and service design of a six-week short-term post-discharge care program known as ComPacks (Community Packages). ComPacks is a non-clinical care program initiated by NSW Department of Health that promotes a safe transition of patients from hospital to home. Services include: meals on wheels, mobility and transport, assistive care and home nursing. The main focus of ComPacks is to reduce the probability of hospital readmissions caused by post-hospital complications, as well as provide an interconnecting pathway for on-going services for longer-term care and management. There are currently several community care sites across New South Wales that deliver ComPacks Services to eligible patients in their local communities. One such site, Liverpool Catholic Care is part of a major non-profit organisation, which is responsible for the delivery of 120 programs in areas such as ageing, disability care, youth and family, education, training and support services.

Participatory Action Research

Participatory Action Research (PAR) involves all relevant parties actively examining together, current action (which they experience as problematic) in order to change and improve it. Research is designed to address specific issues identified by local stakeholders, and the results are directly applied to the problems at hand [25]. Staff from the local ComPacks office were included in a number of group workshop sessions. They described the flow according to the old policy (pre) and as per the latest policy changes (post).

Patient Journey Modelling

Patient journey modeling (PJM) visually describes the journey of patients as they transition through the system of care [18], [19]. It is an improvement tool used to represent the healthcare system as a whole and identify the areas in which service delivery can be improved [18–24]. This study focused on the application of an emerging healthcare redesign technique known as Essomenic. Essomenic is a patient journey modelling technique that has had successful applications within the healthcare domain, in areas such as oncology, ambulatory care, indigenous maternity care and mental health [18–24]. Essomenic patient journey modelling, uses the principles of patient centered care and drives the redesign activity from a patient viewpoint identifying items of value to the patient and placing them at the forefront of the modeling process [18]. It incorporates additional factors that contribute to the overall quality and delivery of care including patient needs, policies and guidelines, staff roles, information needs and provides considerable measurement capabilities [18]. Modelling syntax puts patients, shown in red, at the top of the model with each type of staff role involved in the patient flow allocated a unique colour.

Other key syntax includes:

- Blue oblongs = processes
- Green documents = paper-based information
- White system icons = electronic information supported by ICT
- Pink documents = clinical guidelines/policies
- White metrics boxes = measurement criteria

By including care providers in the model development process and producing visual outputs, stakeholders exhibit higher degrees of understanding and engagement [25]. The models also provide evidence on the impact of policy change pre- and post-implementation of the amendments.

Facilitated Patient Journey Modelling Sessions

Throughout the duration of the study, several facilitated PJM sessions or workshops were conducted with the purpose of gathering first-hand evidence of perceived impacts made to ComPacks workflow and service design. These modelling sessions/workshops serve as an informal collaborative environment aimed to educate participants of the methods used (PJM), whilst also encouraging and empowering them to be part of the problem solving process. As was previously addressed, the workshops emphasise visually representing the personal experiences of ComPacks staff members during the delivery of ComPacks. The ComPacks staff members are also included in the validation process of the models produced. This is to ensure that models produced accurately depict workflow and service design of ComPacks services.

ComPacks Patient Journey Models

As compliance to policy is an important part of the ComPacks funding model, document analysis and modelling were undertaken to examine the impact of policy changes implemented in 2012. The ComPacks policy was analysed to produce two viewpoints.

1. Patient flow prior to policy changes made in late 2011. This model visually represents the normal course of events as per the previous (2005-2006) ComPacks policy.
2. Patient flow post-policy changes.

   This model visually represents the current patient flow as per the latest policy implemented in 2012. See Figure 2.

Production of models pre- and post-policy changes provides evidence as to the impact of policy changes on patient flow into, through and out of the ComPacks program, and highlights if service delivery processes have been improved as a result of the decreed State-level policy changes. The scope of each model begins with an in-hospital eligibility assessment until their exit from the ComPacks program. Figure 2 shows the first page of the post-policy change Essomenic patient journey model.

Comparative Analysis Between Pre and Post Policy Change Models

Comparative analysis of both models was conducted to determine how ComPacks was impacted by the dictated policy changes. The Essomenic modelling technique allows for the easy identification of factors that may potentially affect the overall service design and workflow of ComPacks. These factors include:

- Change in total number of processes
- Repetition of tasks or duplicated processes
- Introduction of new staff roles

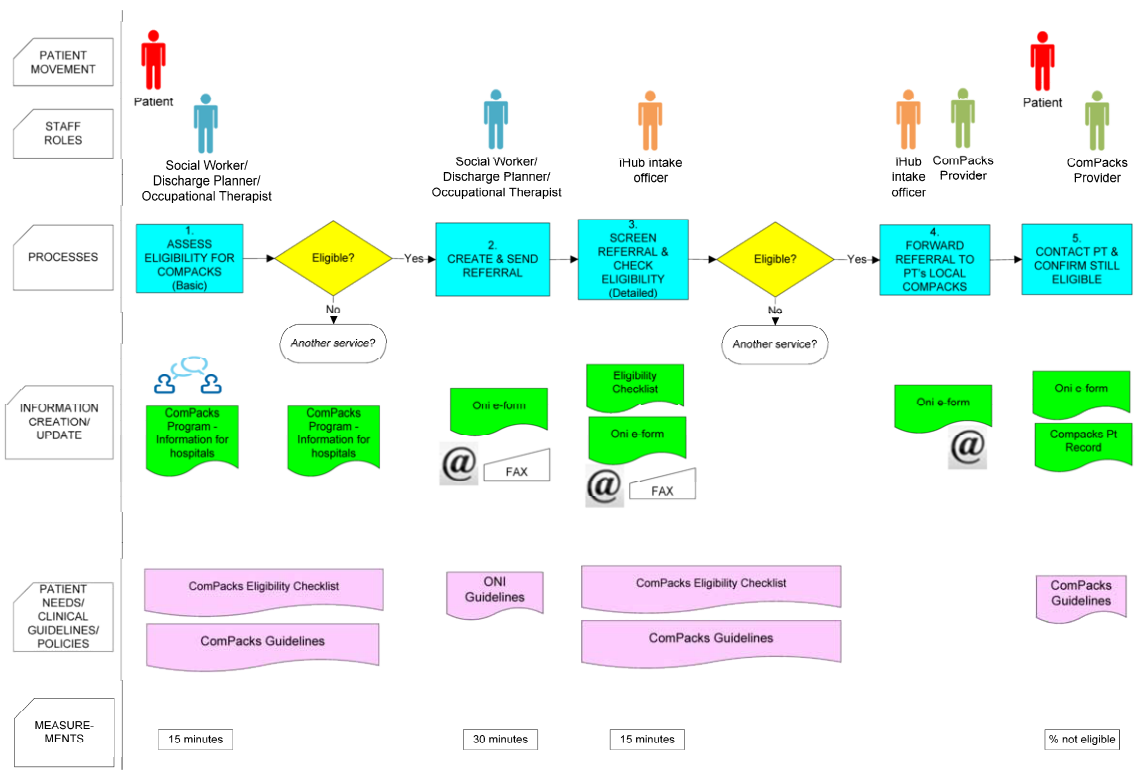

Figure 2 – Page 1 of post-policy change (Essomenic patient journey model)

Results and Discussion

Due to space restrictions the **pre-change policy model** has not been included in this paper however the description of an excerpt of the patient flow, **post-policy change** (see Figure 2) is as follows:

1. The in-hospital team discusses patient assistance requirements and performs a basic ComPacks eligibility check;
2. If eligible, the in-hospital team creates a referral and transmits this to Triple I Hub by email or fax (Triple I Hub is the centralised intake and intervention centre for the Local Health District);
3. The referral is screened for validity and a detailed eligibility assessment is performed by the Triple I Hub intake officer;
4. If eligible, the referral is forwarded to the patient's local ComPacks provider;
5. The ComPacks provider contacts the patient and confirms the patient is still eligible for an assistance package.

The journey continues on from this point and each individual service provider also checks the patients' eligibility for their particular service prior to commencing service delivery.

From the preliminary analysis conducted, two key policy impacts were identified between the pre and post change patient flow: the number of processing steps in the new policy has increased by over 44% and the number of service eligibility assessments have increased by 100% (see Table 1).

The increase in the number of processes is mainly due to the introduction of a centralised referral centre known as Triple I Hub. This centre receives all referrals from hospitals in the Local Health District, screens them for validity and performs a detailed eligibility check.

Table 1: Key preliminary findings of impact Pre- and Post-policy changes

Item	Pre-policy change	Post-policy change	% change
# of processes	18	26	44% increase
# of eligibility assessments	2	4	100% increase

The impact of the introduction of the Triple I Hub is a delay in the time taken to commence service delivery to the patient post-discharge and a number of processing duplications around eligibility assessment.

Eligibility is in fact checked four times in the new patient flow as shown in Figure 3.

Figure 3: Eligibility checkpoints as per latest policy changes

The visual representation of the patient flow readily identifies the increase in the number of processing steps, as each process is numbered.

The duplication in eligibility checking is also easily identifiable due to the decision points which are shown as yellow diamonds (See decisions between processes 1 and 2 and then processes 3 and 4 on Figure 2).

The Essomenic method of visual patient journey modelling provided ComPacks management with clear evidence on how they have been negatively impacted by State-level decreed policy changes at a operational patient flow level.

As a result of this study, it has been demonstrated that patient journey modelling can be used to visualise the impact of policy changes in community care services. There is high value in utilising Essomenic type models to illustrate suggested policy amendments prior to and after the implementation of policy changes.

Conclusion

Health policy plays an important role in the delivery of healthcare services. Policy guides providers during care processes whilst ensuring consistent service delivery and compliance to service criteria needed to secure government funding. Policies for care services are often amended by government bodies with the aim of enhancing and optimising services provided. However, it is perceived that changes made to policy can negatively impact workers, resources and workflow as well as the patient outcomes during service delivery. Therefore, it is imperative that all involved stakeholders understand and comprehend the impact of such changes and the ripple effects they may have on service delivery. This will not only allow for better decisions to be made on current and future policies but it will generate basic understanding for all those involved with the policy development process. In this study, focus was placed on utilising patient journey modelling, more specifically Essomenic, as a tool to visualise the impact of policy change on patient flow and service delivery in community care. There is value to be seen in using patient journey modelling as a tool to visualise impact of changes made to policy. It is a visual overview with representation of all elements that contribute to the policy process and provides solid evidence on the impact of changes on patient outcomes during service delivery.

Future work will investigate using Essomenic as a tool to evaluate and assess the impact of proposed policy changes to provide new value evidence to feed into the earlier stages of the health policy development cycle.

Abstract

Health informatics has the potential to improve the security and quality of patient care, but its impact has varied between developed and developing countries. Related to this, the objective of this study is to identify the challenges and hurdles to improve eHealth in developing countries. We surveyed experts to discover their opinions about five general questions: economic support by Government for eHealth, Government education or training projects in the field, issues related to cultural or educational problems for the implementation of eHealth, policies in terminology or messaging standards and eHealth status policies for long periods. The respondents answered affirmatively in these proportions: 1. Economic support policies 58%, 2. Training policies 25%, 3. Cultural and educational problems 95%, 4. Standards policies, 38%, 5. Policies for long periods, 50% Conclusion: Our survey has shown that the important problems that need to be addressed in order to implement e-Health in developing countries are firstly, cultural and educational, secondly, economic resources and thirdly policies for long periods.

Keywords:

Computer system; eHealth; Medical Informatics; Cultural; Educational.

Introduction

eHealth is the transfer of health resources and health care by electronic means. It involves three main parts: the delivery of health information, for health professionals and health consumers, through the Internet or telecommunications. It is using the power of Information Technology (IT) and e-commerce to improve public health services, e.g. through the education and training of health workers [1].

eHealth has a great importance in the management of health care services. There is no doubt about the advantages of information technology applied to health [2], but in most developing countries there are serious barriers to its effective implementation [3]. Information technology may allow significant improvements across various aspects and has the potential to benefit both developed and developing countries. The World Health Organization (WHO) identified the use of eHealth as a priority skill in the development of human resources in health (human resources in eHealth requires people with knowledge in medical informatic and standard terminology (e.g., ICD-10, SNOMED and HL7 messaging standards.)) Furthermore, it is increasingly recognized as a crucial piece to improve health systems to achieve the WHO Millennium Development Goals [4].

Poor strategic planning and a lack of international standards consume government budgets without reaching good results [5]. Beginning to develop systems without having a defined framework means implementations might fall into serious common mistakes. Without first identifying standards policies, network connectivity and Internet access, master files and unique identifiers it could lead us to waste time and resources. Even though experience and resources for early implementation projects in developed countries are available, in many developing countries there are still barriers and difficulties to access these resources.

eHealth care is a challenge that all countries face today, irrespective of their development status [4]. Some aspects that threaten system implementation in the health sector involve economic resources [6], income disparities, exorbitant costs of usage fees, excessive costs for even rudimentary health information systems [7], lack of human trained resources [8], lack of governmental policies that address a well-defined health system that incorporates eHealth [9], cultural aspects [10] and some resistance to the use of computers for health care processes. Also, standards policies have the potential to play a major role in system interoperability. Ensuring standards, generating guidelines, and introducing essential policies based on effective and efficient evidence could be necessary [11].

The aim of this work is to identify the main challenges and hurdles for the eHealth maturity of economically developing countries, located in Asia and South America.

Materials and Methods

In order to collect data about challenges and hurdles for eHealth implementations, we conducted a survey. A short, semi-structured, confidential interview was conducted by one physician trained in the field with special care to query respondents to answer about their spontaneous perception or personal knowledge.

Setting: Data collection was carried out among those attending INFOLAC 2014 the Latin American Conference on Medical Informatics organized by the Uruguayan Society of Health Informatics in Montevideo Uruguay from 16th to17th October 2014 [12] and APAMI 2014, the Asia Pacific Association for Medical Informatics Conference organized by the Indian Association for Medical Informatics (IAMI) in New Delhi, India from 30th Oct to 2nd November 2014 [13].

Design: The design of the study is a cross-sectional descriptive study.

Sampling strategies: From the meeting attendees, consecutive convenience sampling was performed on

attendees until three participants from each country participating in the events had responded to the survey.

The number of participants proposed for this study was 60 surveys in total.

Inclusion criteria: Individuals carrying out activities in the field of medical informatics in their country attending either INFOLAC 2014 or APAMI 2014.

Exclusion criteria: Those who could not answer more than two questions will be excluded.

Attendees will be able to add comments and suggestions that will be used in future studies.

To determine the obstacles to implementing eHealth in developing countries, we first identified the elements necessary to develop eHealth according to other studies, mainly in developing countries [14]. These variables are: 1) Economic support by the government for eHealth, 2) eHealth training, 3) Cultural or educational problems for implementation of eHealth, 4) Standards policies in terminology or messaging, 5) Polices in eHealth.

Questions for INFOLAC 2014 were made in Spanish and in English for APAMI 2014.

The questions for the anonymous survey were:

1. Is there any economic support by Government for eHealth?
2. Does Government organize eHealth courses or training?
3. Do you consider that there are cultural or educational problems for the implementation of eHealth?
4. Does your country have any standards policy in terminology or messaging in eHealth?
5. Does your country have eHealth status policies for long periods?

Results

All respondents agreed to participate in the study. Personal information was kept confidential. From the 60 proposed surveys, 27 were from South America and 33 from Asia. Four surveys were excluded due to not fitting the inclusion criteria.

The results of the survey showed the following:

1. "Is there any economic support by Government for eHealth?" Answer was 'Yes' in South America 33% of the time (Table 1 and Figure 1) and in Asia, 79% (Table 2 and Figure 2). The result across all countries was 58% (Table 3 and Figure 3).
2. "Does Government organize eHealth courses or training?" Answer was 'Yes' in South America 15% of the time (Table 1 and Figure 1) and in Asia 33% (Table 2, Figure 2). The result across all countries was 25% (Table 3 and Figure 3).
3. "Do you consider that there are cultural or educational problems for the implementation of eHealth?" In South America, respondents answered 'Yes' 100% of the time (Table 1 and Figure 1), and 91% in Asia (Table 2 and Figure 2). Considering all countries, 'Yes' was selected 95% of the time (Table 3 and Figure 3).
4. "Does your country have any standards policy in terminology or messaging in eHealth?" The answer was 'Yes' in South America 33% of the time (Table 1 and Figure 1), and in Asia 42% (Table 2 and Figure 2). There was a positive answer across all countries 38% of the time (Table 3, Figure 3).
5. "Does your country have eHealth status policies for long periods?" Answer was 'Yes' for this question in South America for 41% (Table 1, Figure 1) of respondents, and 58% in Asia (Table 2 and Figure 2). The results for all countries was 50% (Table 3, Figure 3).

Table 1 - South American respondents

			%
1	Economic support	9	33
2	Training	4	15
3	Cultural or educational problems	27	100
4	Standards policy	9	33
5	Policies for long periods	11	41
	Total	27	

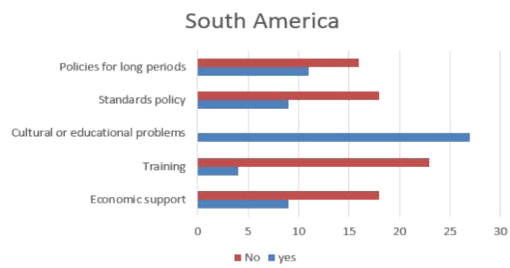

Figure 1 - South America respondents

Table 2 - Asia respondents

			%
1	Economic support	26	79
2	Training	11	33
3	Cultural or educational problems	30	91
4	Standards policy	14	42
5	Policies for long periods	19	58
	Total	33	

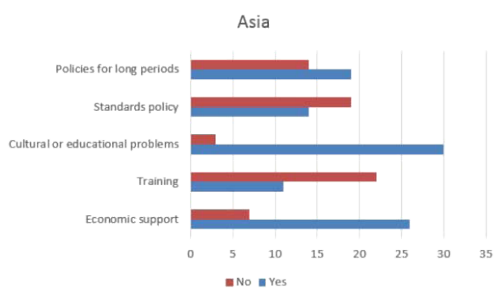

Figure 2 - Asia respondents

Table 3 - All respondents

			%
1	Economic support	35	58
2	Training	15	25
3	Cultural or educational problems	57	95
4	Standards policy	23	38
5	Policies for long periods	30	50
	Total	60	

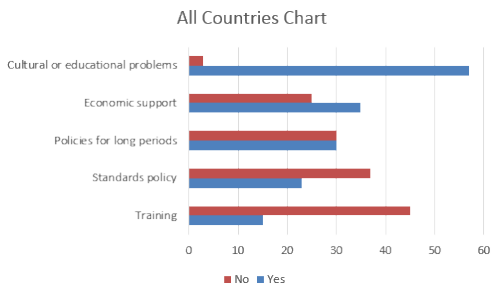

Figure 3 - All respondents

Table 4 - All respondents, comparison by region in %

	Asia	S.America
Economic support	79	33
Training	33	15
Cultural or educational problems	91	100
Standards policy	42	33
Policies for long periods	58	41

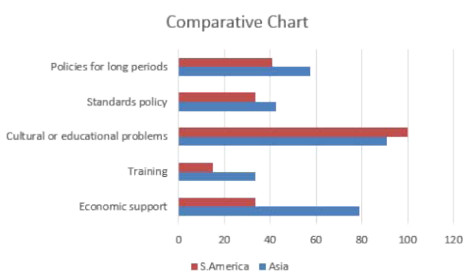

Figure 4 - All respondents, comparison by region

Results shown in both regions were very similar about the role of the states in relation to national policies for long projects, standards policies, cultural issues and education for eHealth. The role of the state in relation to training and economic support in eHealth was perceived differently in the analyzed regions, being more intense in Asia than in South America. (Table 4 and Figure 4).

Discussion

This was a preliminary survey to get an overview of the situation in our region and pave the way for more complex studies.

Training of human resources in eHealth is critical, because we think it is one of the limiting steps of high impact, not only from a technical standpoint, but as a change management tool.

It is interesting to note that participants agree that eHealth development will require more universal eHealth interoperability standards and strategies to overcome technical infrastructure barriers and address privacy, security, and other legal requirements [15]. We should take advantage of the lessons learned in developed countries in order to optimize the strategies to achieve this goal.

Concerning regulatory legal and policy framework, it is difficult, in most of our countries to find clear policies and coordination between state or governmental agencies and eHealth initiatives. This is a huge obstacle to implementing eHealth in developing countries.

Instability in politicals issues make it really difficult to find policy governance for long-term projects. Governments want centralized systems instead of dictating long-term policies that enable the local developers to interoperate with other regional developments through clear policies standards. In many of our countries there are no state policies, and if there are, they often change when the government and projects fall or are changed by others. Developing policies for eHealth requires long-term political times exceeding consensus and projects [16].

One of the limitations of this study is the sample. We collected the data at only two events in South America, during INFOLAC 2014 conference and during APAMI 2014. It could be necessary to extend the coverage of the sample for our next studies. Even so, our results are consistent with the work of Lacroix and colleagues that report that one of the main problems has to do with the educational training [17].

Conclusion

eHealth is a promising concept to achieve better health for all. The present study suggests there is a huge gap in cultural and educational issues regarding eHealth. Also, according to our results, we must take into consideration long-term eHealth projects. It is very important to consider interoperability and standards in eHealth as well. We have to work hard to solve the obstacles presented to achieve health for all and not settle for anything less.

On the Development of a Hospital-Patient Web-Based Communication Tool: A Case Study From Norway

Conceição Granja[a,b], Kari Dyb[a], Stein Roald Bolle[a], Gunnar Hartvigsen[a,b]

[a] *Norwegian Centre for Integrated Care and Telemedicine, University Hospital of North Norway, Tromsø, Norway*
[b] *Department of Computer Science, UIT – The Arctic University of Norway, Tromsø, Norway*

Abstract

Surgery cancellations are undesirable in hospital settings as they increase costs, reduce productivity and efficiency, and directly affect the patient. The problem of elective surgery cancellations in a North Norwegian University Hospital is addressed. Based on a three-step methodology conducted at the hospital, the preoperative planning process was modeled taking into consideration the narratives from different health professions. From the analysis of the generated process models, it is concluded that in order to develop a useful patient centered web-based communication tool, it is necessary to fully understand how hospitals plan and organize surgeries today. Moreover, process reengineering is required to generate a standard process that can serve as a tool for health ICT designers to define the requirements for a robust and useful system.

Keywords:

Elective surgery cancellations, pre-operative planning, web-based communication, process optimization, Norway.

Introduction

Considering the trends of healthcare, hospitals today have an extended focus on reducing costs [1]. Surgery is one of the most costly services provided by hospitals [2, 3]. However, elective surgeries are still regularly cancelled; in western countries, cancellation rates between 10 and 40 % have been reported [3-5]. Furthermore, up to 20 % of elective surgeries are cancelled on the day of surgery [6-8] and it is also identified that 50 % of these cancellations might be avoided [3, 9, 10]. Evidence [7, 11] points to lack of information as being the main cause for elective surgery cancellations, referring to information that existed but was not available when required for surgery planning. In line with what is reported in the literature, our site of research, the University Hospital of North Norway (UNN), has identified that 50 % of all cancellations are related to inadequate planning due to lack of information [12]. In the described health scenario, health ICT emerges as part of a discourse that emphasizes cost-effectiveness and active involvement of patients as a policy to meet the growing demand of care and the expected shortage of health care professionals [1].

The aim of the research project "eTeam-Surgery" is to reduce the number of elective surgery cancellations at UNN. In today's surgical process, the information required for anesthetic evaluation is gathered after the patient admission, based on a health assessment questionnaire. eTeam-Surgery will provide a digitalized tool for two way communication between the hospital and the patient prior to hospital admission. Such a tool will enable the hospital to collect the missing information from the patient at home and at an earlier stage in the pre-operative planning process.

The development of an efficient and functional web-based tool for hospital-patient collaboration is not an easy task, and it has not always been successful. As the development of health ICT grows, there are also an increasing number of reports on unsuccessful implementation projects, challenges and unforeseen consequences of ICT in health care, particularly in hospitals [13-24]. A contributing factor to such results may be found on the focus of health ICT on improving individual tasks rather than supporting value added care processes. By supporting individual tasks, ICT is focusing on the provider. This is a significant contribution to a lower quality and high cost health care. On the other hand, process focused care is centered on the patient. It integrates the teamwork (e.g. patients, physicians, nurses, caregivers, managers, and administrative personnel) to provide high quality and efficient care throughout the process. Value added care processes are the goal of the patient centered health care. However, few health care processes have been modeled comprehensively enough to provide a basis for specifying software requirements to health ICT designers. Thus, health ICT designers have focused on supporting the work of individual care team members by taking existing paper-based tools, as their models. The result is that most health ICT systems do little to support care teams. Hence, prior to development, eTeam-Surgery carried out an in-depth study of the pre-operative planning at UNN.

In this paper, is described an in-depth study of the pre-operative planning at UNN. The aim of this study was to describe and understand the process to define the requirements for a hospital-patient web-based communication tool. The paper is divided in four sections. In the first section, the health ICT limitations are introduced, and the aim of the study is described. In the second section, a brief introduction to the existing process modeling tools is presented. The methodology to model health care processes is described and explained in the third section. In the last section, discussion and conclusions, the authors elaborate on the need to understand care processes in order to define the requirements for a hospital-patient web-based communication tool.

Background

Workflow modeling is the basis for process optimization, and exists in a wide range of modeling languages. Graphical modeling languages can be divided in languages oriented to: (a) information flow, (b) control flow, or (c) objects [25]. In this work the modeling languages applied to the control flow are considered for a better accommodation of health care specific workflow.

Petri nets are a formalism of graphical modeling, with application in systems description and in the study of information processing, characterized by being asynchronous, parallel, non-deterministic and/or stochastic [26]. This formalism was applied to several problems in the healthcare field, such as the evaluation of patient monitoring systems [27, 28], the modeling of patient flows in progressive systems [29-31] or the modeling of logistic processes in hospitals [32].

Apart from the Petri nets, process chains oriented to operations, denoted Event-driven Process Chains (EPC) is another modeling formalism widely used in the healthcare field. EPC is presented as a modeling concept of logical and time dependencies of processes, and was applied to the information flow management between the different systems [33].

Materials and Methods

The eTeam-Surgery project group has developed a three-step methodology to gather the knowledge required to model the pre-operative planning process. In order to keep this paper self-contained, the empirical methodology will be described briefly hereafter, for further information please refer to [34].

1. Gather data on the hospital's representation of the elective surgery cancellation problem;
2. Observations and interviews at the hospital, related to the pre-operative planning processes at the department level;
3. Individual, in-depth interviews with all professional groups involved in pre-operative planning at a specific hospital department.

In Stage 1, the aim was to gather knowledge on UNN's understanding of the elective surgical cancellation problem, and the hospital representation of the pre-operative planning process. One document, containing information on the use of resources involved in surgery at the hospital was identified and studied [12]. In 2012, UNN initiated a Lean project in order to optimize the elective surgical process. Researchers from the eTeam-Surgery group followed this project.

In Stage 2, the pre-operative planning process at different departments at UNN was investigated. This comprised three weeks of fieldwork at the Surgery and Intensive care clinic, doing interviews while following an anesthesiologist and an anesthetic nurse. In addition, thirteen interviews with physicians, nurses and administrative personnel were conducted, at six different departments. The interviews were semi-structured, done at the workplace, and lasted between thirty minutes to two hours.

During the first two stages, two departments were described to be more efficient. However, these departments still evidenced a representative number of cancellations. One of the departments was chosen to proceed with an in-depth study in Stage 3. The chosen department is not revealed due to ethical reasons. In Stage 3, representatives from all the professional groups involved in the pre-operative planning process at UNN were addressed. At this specific department, extensive knowledge on the pre-operative planning process was collected. The department-specific interviews were semi-structured, conducted at the workplace, and lasted between one to two hours.

Results

The observations of, and interviews with, the health professionals at the chosen department at UNN, described in the previous section, allowed the definition and mapping of the generic pre-operative process model shown in Figure 1 and Figure 2. (For further information on the interviews, refer to [35].) A process model facilitates a systematic description of the events permitting the identification of each decision activity and the health worker responsible for that activity. In addition, it allows us to learn about the information flow, and allows the opportunity to identify the underlying processing issues that may be compromising the availability of vital patient assessment information.

At UNN, as seen in Figure 1 and Figure 2, the final pre-operative planning is often done after the patient has arrived for the scheduled surgery, which means, the final pre-operative planning might be completed the day prior to, or even on the day of the surgery. During this final planning process, new information, which may lead to cancellations, is gathered from the patients. Figure 1 and Figure 2 show additional steps when supplementary / new information might be necessary. The first step is in the beginning of the pre-operative planning process during the referral evaluation. A descriptive comparison of the referral evaluation process in both figures also evidences the ambiguity of the resources' role on the process. For example, as depicted in Figure 1, the task of quality assessment and subsequent referral, or request for additional information, is performed by the secretary. Figure 1 also portrays identified telephone calls between the surgeon and the patient as an additional alternative to collect lacking information. None of these tasks are described in Figure 2.

Discussion and Conclusions

As explained in the Introduction section, Health ICT orientation to individual tasks reflect the focus of health care itself: The majority of clinical departments behave as discrete and independent sets of physicians, nurses, and other health personnel instead of a single team [36]. This is partly due to the autonomy of most clinical departments.

eTeam-Surgery started by mapping and evaluating the pre-operative process at UNN, and explored a system for gathering information from a patient on his/her condition through a personal health assessment questionnaire. This process facilitated the evaluation as to whether if, and how, part of the process could be migrated from the hospital to the patient at home through electronic collaboration.

The comparison of the pre-operative planning process models, shown in Figure 1 and Figure 2, evidences the heterogeneity of work patterns at the individual level. The narratives of the different health professions describe different patient pathways for the same process. This analysis of hospital workflow evidences the superfluous work required by hospital personnel to develop and document the information required for the patient to move forward in the EHR pathway. In such an environment, it is very difficult to develop a Health ICT system that both supports the full process and is useful for each member of the care team. Therefore, we argue that in order to develop a useful patient centered web-based communication tool, it is imperative that the processes by which hospitals plan and organize surgeries are fully understood, and that process reengineering be employed in the generation of standard processes of robust Health ICT system.

Abstract

Cellular pathologists are doctors who diagnose disease by using a microscope to examine glass slides containing thin sections of human tissue. These slides can be digitised and viewed on a computer, promising benefits in both efficiency and safety. Despite this, uptake of digital pathology for diagnostic work has been slow, with use largely restricted to second opinions, education, and external quality assessment schemes. To understand the barriers and facilitators to the introduction of digital pathology, we have undertaken an interview study with nine consultant pathologists. Interviewees were able to identify a range of potential benefits of digital pathology, with a particular emphasis on easier access to slides. Amongst the barriers to use, a key concern was lack of familiarity, not only in terms of becoming familiar with the technology but learning how to adjust their diagnostic skills to this new medium. The findings emphasise the need to ensure adequate training and support and the potential benefit of allowing parallel use of glass slides and digital while pathologists are on the learning curve.

Informatics; Pathology; Microscopy; Qualitative Research; Learning Curve.

Introduction

While traditionally health informatics focused on the consulting room and the use of electronic patient records (EPRs) and computerised decision support systems, recent years have shown an interest in broader range of settings. Not only is the spread of EPRs and mobile technologies into secondary care leading health informatics researchers to explore ward settings, but we are gradually learning more about those areas of medicine whose work patients may not see but which play a key role in diagnosis, determining treatment, and assessing response to treatment, such as the work of clinical pathology laboratories [1]. This has led to studies of diagnosis around imaging systems, such as use of Picture Archiving and Communication Systems (PACS) in radiology [2,3]. At the same time, we are seeing interest in a broader range of technologies for diagnostic imaging, including increasingly pervasive wireless and sensor-based technologies [4,5]. In this paper, we turn to the underexplored area of cellular pathology: the diagnosis of disease through microscopic examination of tissue.

Cellular pathologists diagnose cancer and other diseases using a microscope to examine glass slides containing thin sections of human tissue. The tissue will have been stained using a chemical or immunologically based method. Haematoxylin and Eosin (H&E) is the most common stain and it highlights the most significant tissue structures well, while special stains use histochemical reactions to identify specific tissue components or organisms, that are less easily identifiable with an H&E stain.

It is now possible to digitise glass slides so that they can be viewed on a computer; the field of digital pathology is concerned with the development and evaluation of technologies that support this. Digital pathology promises a number of benefits, both in terms of efficiency and safety. Advocates of digital pathology highlight the potential for improved workflow; a digital system would allow the pathologist to be alerted to when new cases are ready to be viewed, as well as allowing the pooling of cases, resulting in a revolution of the workflow similar to that seen in radiology [6]. There is also the ease of obtaining second opinions electronically from a national or international source rather than having to send the glass slides through the post with the delay and the risk that they will get broken or lost in transit [7]. Slides can be simultaneously sent to several people for second opinions, which is not possible with glass slides. There is the reduced risk of getting slides mixed up so that a patient receives the wrong diagnosis, something that happens rarely but can have devastating consequences when it does [8], and there is the option to integrate decision support technology [9, 10].

Despite this potential, uptake of digital pathology for diagnostic work has been slow. While there have been positive reports about the use of digital pathology within education and training [11,12] and for teleconsultation [10], in relation to routine diagnostic work, research suggests scepticism and uncertainty amongst pathologists [13,14]. In a recent survey conducted in the United States, while 59% of respondents agreed that the benefits of digital pathology outweigh concerns, 78% perceived digital slides as currently being too slow to view for use in routine diagnostic work [15]. This fits with the findings of experimental studies which have found that it takes significantly longer to make a diagnosis on a digital slide compared to a glass slide [16,17]. A study of barriers and facilitators to the use of digital images in clinical practice that involved interviews with two radiologists and three pathologists, found a key barrier in pathology to be the perception that diagnostic performance is inferior with digital slides [9].

As part of a larger study concerned with the design and evaluation of a digital microscope for use in routine diagnostic

work [18-21], we undertook an interview study to better understand the barriers and facilitators to the introduction of digital pathology. In this paper, we present the findings of that study and discuss the implications of these findings for the implementation of digital pathology.

Methods

Data collection

Semi-structured, face-to-face interviews were conducted with nine consultant pathologists within our institution, a large teaching hospital. The interviewees were from a range of subspecialties and had varying levels of experience of digital pathology: two had almost no experience of digital pathology, three had used it for External Quality Assessment (EQA) schemes, one had used it for obtaining a second opinion, and two had experience of using it for research and/or teaching.

Interview questions explored what participants saw as the benefits and limitations of the conventional microscope and current workflow, benefits, limitations, anticipated impacts of digital pathology, and willingness to move to digital pathology. All interviews were audio recorded and later transcribed.

Analysis

An iterative approach was taken to data collection and analysis, to allow the collection of further data on emerging themes in subsequent interviews. Anonymised transcripts were entered in NVivo, software for qualitative data analysis. Data was analysed using thematically [22], with codes developed inductively.

Results

Here we present the findings from the interviews organised according to key themes. While interviewees discussed the benefits of digital pathology for multidisciplinary team meetings and teaching, we focus on attitudes towards digital pathology in the context of diagnostic work.

Benefits of digital pathology

The most commonly mentioned advantage of digital pathology was the ease of sharing digital slides in order to get second opinions, mentioned by eight of the nine interviewees:

'I have sent slides to others for second opinion and it works brilliantly. First of all we don't have to pack slides. Recently I had to send a case to Boston [...] and I didn't have to pack any slides. The main problem was packing slides across to America, it's so difficult now. So I scanned the slides […] and sent it across and within half an hour I got the reply. So he emailed me saying yeah the report I think it's fine. And the thing is we don't choose any particular area as when you take images and send it to another person […] This is you're sending the entire slide as you would be seeing down the microscope. So that is a big advantage.' (HC6)

While most comments were about the ability to share slides with other sites, a couple of interviewees also mentioned benefits in terms of being able to look at slides with colleagues:

'When you're getting a second opinion, it's much much easier if you're all looking at a screen, you can all point at it and know you're all looking at the same thing. Um, and that you can all point at it whether you're steering or not, whereas on this [microscope] the only person who can point really very easily is the person steering it.' (HC5)

Interviewees were also very positive about the idea of having remote access to slides, both for on call work but also to allow more general flexibility:

'The scope for it is for the very specialised stuff, if you're looking to get cover for cases around the country, that sort of thing, that's the one diagnostic role I can see.' (HC3)

Another perceived benefit, mentioned by four of the interviewees, is the ease of access to slides, so that previous slides can easily be viewed:

'The nice thing about electronic images is that you can store them, you can access them rapidly, so if I needed to go back to look at something I don't have to go back to the file to get it out. In theory. If there's a secure server, I could go straight to it and find the one that I want with some rapidity. […] that would be grand. […] it would allow laboratories to store large amounts of glass off site. Rather than having to keep it all on the premises. So that people can review stuff very quickly, scanned images, and very rarely have to go back to the original bit of glass, which is quite labour intensive.' (HC4)

The interviewees mentioned the benefit of being able to have multiple people using the slide at the same time, mentioned by one interviewee when discussing EQAs but also by two interviewees in the context of diagnostic work:

'I suppose now I have to complete a case and then give it to a colleague because then as long as a colleague is working on it I can't look at it, so I suppose that would be an advantage, […] it's more easy to share cases.' (HC7)

Two interviewees mentioned the durability of digital slides, that they do not get broken or lost, while also mentioned by two interviewees was the removal of 'glass work':

'You don't have all the glass work, filing, you don't have to constantly file loads of glass work and pull it out and refile it and so on.' (HC2)

Two interviewees also mentioned that the ability to have an overview of the whole slide which is not possible with the microscope:

'I like the way it can be navigated where you can see in a wider view the entire biopsy or pieces of tissue that you see on the glass slide. That is definitely an advantage.' (HC6)

Limitations of digital pathology

The most commonly mentioned disadvantage, mentioned by three of the interviewees, was the lack of familiarity with digital slides:

'It just takes a bit of getting used to, open it up, zooming in and out and going round. And sitting at a computer screen as opposed to looking down a microscope.' (HC2)

One interviewee felt that it was not just a case of learning to use the technology but also adapting her diagnostic skills:

'I can't imagine someone who's so used to this as me would want to change for my routine work to a digital way of reporting. [...] Because, yeah, I'd be relearning a lot of diagnostic skills but wouldn't have the time to do it. I wouldn't see any need to do it.' (HC3)

While the ability to share slides with other sites was seen as a benefit, one pathologist was concerned that digital slides could result in less interaction amongst pathologists within the department.

An issue which came up in the first two interviews and which we explored further in subsequent interviews was the impact digital pathology would have on the sense of 'immersion' that some pathologists report experiencing when working at the microscope. One of the interviewees felt that a move to digital pathology would have a negative impact on the sense of immersion. However, two of the interviewees were unsure whether or not the loss of immersion would have a negative impact:

'I think when you're starting with something new, you've got the distraction of the vehicle which it's presented in and so you're not immersed because you're also worrying about, 'Am I doing it right? Is it the right way round?' And the immersion's all about being able to focus on the thing that you're interested in and that's because you're not having to worry about other things [...] I think people would feel more immersed if they did it more often because they would start to be familiar with it and they then wouldn't notice.' (HC4)

Interesting in the interviewees' comments was the different ways in which they conceptualised the sense of immersion – whether it comes from having all visual attention focused on the slide, or from the physical connection with the microscope, or simply from familiarity with the technology of the conventional microscope, so that the user does not have to think about what they are doing. However, five of the interviewees did not present this as a concern.

Perceived impact on efficiency

When asked whether they thought that the introduction of digital pathology would have an impact on efficiency, three interviewees said that they felt the impact on efficiency would be a positive one, although all three identified different sources for this improvement. One interviewee talked about efficiency in terms of not having to wait for referred cases (assuming that the referring site also used digital slides), while another talked of removing the physical transfer of slides. Another focused on the benefits of looking at a screen as opposed to looking down a microscope:

'So [the microscope] is a […] kind of tunnelled vision or tunnelled thinking process which could be easily distracted. Whereas if […] you're looking down the screen, even if for a moment I want to look out of the window you can still come back and that is still there in a wider view staring at you.' (HC6)

Willingness to move to digital

There was huge variation in interviewees' enthusiasm for digital pathology in relation to routine diagnostic work. While most could be described as open to the idea, one interviewee rejected the idea strongly:

'We haven't got enough money to do what we're doing now. And the investment that you'd need to really make digital pathology taken on as for routine I think is unjustifiable.' (HC3)

At the other extreme, we had one interviewee who was very keen to move to using digital pathology as soon as possible:

'These [gesturing to microscope] can all go in the scrap heap. I just think it liberates us so much as well. […] I think it's just going to be revolutionary actually, quite frankly, I really do.' (HC9)

One interviewee acknowledged that there would be a learning curve but did not see this as a problem:

'So if you are going to give a diagnosis to a patient, are you ready to sign out on the screen? I said yeah, maybe if I start using it, it's only a question of getting used to it, I can't see any great difficulty there.' (HC6)

Generally, the impact on safety was not a concern amongst the pathologists that we interviewed. Four of the interviewees felt that there would not be a negative impact on safety, with three of the four saying that safety might be improved by reducing the risk of mixing up slides, while one interviewee was unsure what the impact on safety would be. There was little concern regarding image quality:

'An image on a computer if it's high quality is no more or less real than you know a section that's been stained and has light shone through it really, […] it's just a representation of what was happening in life anyway, isn't it? Not really live tissue, just a thin slice of it that's been stained.' (HC5)

Concerns regarding safety related to lack of familiarity with the technology:

'There's the patient safety from getting it wrong using a system you're not used to or haven't been trained in and therefore there could be some drawbacks which we're just not used to. […] Stain deposits, dodgy staining, […] how does dodgy staining look? 'cos we're so used to looking down the microscope. And you've been looking at it for like 10 years.' (HC2)

Three of the interviewees said that they would want the opportunity to try it out for themselves:

'I'd just have to had seen quite a number [of digital slides] I think, probably in parallel [with glass slides], or alternate, or something like that. Just to see if you would have made the same diagnosis. And er, yeah, just to get a feeling for it, 'cos it's a different system. The trouble is, with the glass, you've been doing it for so long you're used to all the flaws and you compensate for all the flaws. Whereas with the computer system, you haven't used it, you might not know all the niggles and glitches and flaws.' (HC2)

One interviewee said that he would like to see data regarding the time it takes to become familiar with the system:

'I think the kind of data to be after would be, that would be worth getting, would be to be able to demonstrate to people who have not used it very much that there is a learning curve and that people can approach the diagnostic speeds that they are used to.' (HC4)

One interviewee was more concerned about the processes surrounding the technology, in terms of the training and support that would be provided. This seemed to be influenced by their experience of other IT systems within the hospital:

'I just think you've got to have that IT support to sort it out straight away. [...] and you need to pay people proper money to support it. And our IT guy's just had a 20% pay cut because he's been down-banded, you know? [...] That's going to impact on how well your system works. [...] That's the other thing, we get [lab system] or whatever and you start learning new things about it years later. 'Oh I didn't know you could do that.' Quite earth shattering things that can drastically reduce your amount of time. So, you know, people need to be trained properly in it...' (HC5)

Robustness was an issue mentioned by three of the interviewees, two of whom explicitly linked this to their experience of hospital IT systems:

'I think that's probably my main concern. […] They're very good at being optimistic but the delivery's always a major disappointment.' (HC7)

Discussion

Interviewees were able to identify a range of potential benefits of digital pathology in the context of diagnostic work, with a particular emphasis on easier access to slides and the efficiency gains this could bring. Amongst the barriers to use of digital pathology, a key concern was lack of familiarity, not only in terms of becoming familiar with the technology but learning how to adjust their diagnostic skills to this new medium. This reflects similar findings from radiology, where the reading of images takes place in light of readers' knowledge of the principles of the production of the image as well as specific local practices, allowing them to distinguish between artifacts of the screening process and those that have diagnostic significance [23]. Findings from the experimental studies we have undertaken suggest that pathologists need to relearn what they should expect to see at each magnification level, as it may be that it is necessary to view digital slides at a higher level of magnification than would typically be required for viewing glass slides on a conventional microscope [18].

Interestingly, interviewees did not express concern about diagnostic performance, in contrast to previous studies [9]. They also did not have concerns about the speed of digital slides, despite this being highlighted as an issue in previous studies [15-17], instead focusing on the potential efficiency gains of a digital workflow. This may be due to the interviewees' lack of familiarity with digital slides, their responses suggesting a belief that, with experience, the speed and accuracy of their diagnoses would increase. On this basis, we would suggest that the majority of the interviewees in this study were fairly positive about the idea of using digital pathology for diagnostic work but were rightly cautious about its impact on their work, wanting more opportunity to try the technology themselves, alongside the microscope so that they could judge for themselves the accuracy of their diagnoses, and aware that it is not just an issue of learning to use the technology but potentially has implications for how they make diagnoses.

Where negative attitudes to digital pathology were expressed, was on the basis that glass slides work adequately and so it may be difficult to justify the investment of money and time (in learning to use the technology) that a move to digital pathology for routine diagnostic work would require. Greater evidence of cost savings that digital pathology can provide may go some way to overcoming such concerns. However, challenges often arise in adoption of technology when the users of the technology are not those who will benefit most. The key benefits of digital pathology are currently predicted to be in workflow efficiency, which benefits the organisation, and potentially the patient, rather than providing any efficiency benefit to the individual. However, developments such as the integration of decision support could provide benefit to the user [9,10]. Perception of benefits is likely to vary according to organisational factors; our institution is a tertiary centre providing specialist expertise, and so pathologists do not often need to seek advice from pathologists at other institutions where digital pathology would provide a benefit.

Another challenge is that, while previous studies have compared adoption of digital images in radiology and pathology [9], in radiology the images begin as digital data, whereas for digital pathology the need to create the glass slide remains, so that digital pathology introduces an extra step into the process [10]. However, in the future it may be possible to produce digital slides without the need to first produce a glass slide, for example by using spectral domain optical coherence tomography (SD-OCT) to scan tissue blocks [24].

Implications for practice

The findings suggest, as with any health IT system, adequate training and support need to be in place for digital pathology to be effectively integrated into diagnostic work. Before transitioning to a totally digital workflow, pathologists may benefit from the opportunity to review glass slides alongside digital images as well as learn to use the technology, that can help to adjust their diagnostic skills and gain confidence in their ability to make a correct diagnosis with a digital slide. There is a need for further research on the learning curve associated with digital pathology, to reassure pathologists about the time investment required to work in this new way. This is work that we have begun to undertake [25].

Strengths and limitations

This is a small scale study, conducted within a single institution, so we cannot judge to what extent the findings reflect the attitude of pathologists in general. However, our participants were from a range of subspecialties and had varying levels of experience of digital pathology.

A strength of our study is that it provides detailed qualitative data on the barriers to integrating digital pathology into diagnostic work, with larger number of participants compared to previous studies, and provides guidance for those who seek to implement such systems.

Conclusion

Interviewees were able to identify a range of potential benefits of digital pathology in the context of diagnostic work, with a particular emphasis on easier access to slides and the efficiency gains this could bring. They were predominantly positive about the idea of using digital pathology for diagnostic work but rightly cautious about its impact on their work, aware that it is not just an issue of learning to use the technology but potentially has implications for how they make diagnoses.

Acknowledgements

We would like to thank those pathologists who have allowed us to observe their work and who have taken part in our evaluations of the LVM. Abstract

Electronic Health Records (EHR) promise improvement for patient care and also offer great value for biomedical research including clinical, public health, and health services research. Unfortunately, the full potential of EHR big data research has remained largely unrealized.

The purpose of this study was to identify rate limiting factors, and develop recommendations to better balance unrestricted extramural EHR access with legitimate safeguarding of EHR data in retrospective research. By exploring primary, secondary, and tertiary sources, this review identifies external constraints and provides a comparative analysis of social influencers in retrospective EHR-based research.

Results indicate that EHRs have the advantage of reflecting the reality of patient care but also show a frequency of between 4.3-86% of incomplete and inaccurate data in various fields. The rapid spread of alternative analytics for health data challenges traditional interpretations of confidentiality protections. A confusing multiplicity of controls creates barriers to big data EHR research.

More research on the use of EHR big data is likely to improve accuracy and validity. Information governance and research approval processes should be simplified. Comprehensive regulatory policies that do not exclusively cover health care entities, are needed. Finally, new computing safeguards are needed to address public concerns, like research access only to aggregate data and not to individually identifiable information.

Keywords:

Electronic Health Records; Clinical Research; Public Health; Health Services Research.

Introduction

The vast amount of clinical data accumulating in Electronic Health Records (EHRs), or big data EHRs, represents an unprecedented opportunity to discover unrecognized risk factors, study the epidemiology of diseases, calculate life expectancy, distinguish best practices from superior outcomes and recognize opportunities for better health care.

The review of patient charts has been the cornerstone of clinical research for centuries. Historically, many landmark discoveries have originated from analyses of retrospective data. The relationship between smoking and lung cancer was first discovered by Müller in 1941 based on an analysis of patient records [1]. From these simple beginnings, recognition of smoking as a health hazard continued to evolve, ultimately becoming one the greatest public health achievements of the 20th century [2]. More contemporary examples include the relationship between thalidomide and birth defects [3], cancer epidemiology and pathophysiology, and vaccine development [4-6].

Facilitating biomedical research is one of the most important, but unrealized promises of introducing EHRs [7]. Researchers interested in conducting needs analysis, process, and outcome evaluations utilizing EHRs often run into seemingly insurmountable barriers.

Extramural access to big data represents a particular challenge (e.g., researcher of institution A trying to study big data of institution B). An illustrative case from a recent personal communication:

> *A professor of one of the world's top ranked universities wanted to get a large EHR data set for research from a leading hospital nearby. The request for an anonymized data set and the study plan was approved by the institutional IRB. In spite of regulatory compliance, ethics clearance, and stellar personal scientific track record, the professor was unable to obtain the EHR data over a period of 18 months and finally gave up.*

With the advancement of computer hardware and software, access to and analysis of clinical data is no longer a primarily technical issue. Today, the principal obstacles to EHR use in research are essentially social, ethical and regulatory.

Significant gaps exist for researchers in requesting, accessing, analyzing, and applying EHR data [8]. The Institute of Medicine reports that disappointment in the lack of EHR improvements has tempered enthusiasm for continuing research efforts [9]. Patients/consumers are increasingly participating in their own care and in care decisions, and most report being open to sharing their data for research [10, 11]. Their priorities regarding use and re-use of data will need to be taken into consideration.

Ideally, EHR-based research should meet the simultaneous but somewhat conflicting requirements of both unrestricted extramural access to the EHR by meritorious, innovative biomedical researchers with minimal administrative requirements and guaranteed zero access to EHRs by unauthorized, unnecessary or potentially harmful users of health data. Obviously, unnecessary and unjustified limitations on the access to EHR big data also represents a serious ethics violation in terms of denied care, lost public health improvement, and unrealized research discoveries benefiting patients.

The purpose of this study is to identify rate limiting social factors and develop recommendations to facilitate research on EHR big data. This study focuses on three dimensions: validity, ethical considerations, and security risks of EHR data use in biomedical research, focusing on the US context.

Methods

The project explores relevant studies and methods originating in biomedicine, health informatics, historical research, bioethics, health administration, computer science, public health and other fields. Eligibility criteria: EHR-based original research project of at least 1000 records, or thematic exploration of EHR big data management in research. Peer reviewed literature and policy documents were explored along the following hierarchy:

1. Primary sources (data): original research publications in the peer-reviewed scientific literature on EHR projects, national and international statistical databases, national surveys, and historical documents illustrating important aspects of EHR use in research.
2. Secondary sources (management): thematic scholarly explorations in the scientific literature, critiques, pertinent scholarly books, government documents, and statements of national and international organizations on social actors in big data research.
3. Tertiary sources (pointers): newspaper articles, speeches, videos, encyclopedias, web pages and other popular publications that help to identify primary and secondary sources of information.

In processing and synthesizing the information, tertiary sources were used solely to identify primary and secondary sources of information, which serve as the backbone; meanwhile, secondary sources were used to elaborate and enhance the ideas and themes of the primary sources.

PubMed and Web of Science were utilized for full text searches. Search terms included: electronic health records (EHR), electronic medical record (EMR), retrospective health research, ethics of EHR data use, confidentiality of EHR data and HIPAA. We then investigated similar themes and ethical dimensions presented in the literature. A PRISMA framework was applied to the larger systematic review resulting from this analysis [12]. The comparative and discerning analyses generated the list of factors that create external and internal influences on big data EHR use.

Results

Patient data from large EHR databases are increasingly available from multiple sources and often for a price. Efforts to evaluate the availability of these data from a practical and ethical standpoint is ongoing (see Table 1).

Validity - Issues of data integrity

Data integrity is defined as the validity, accuracy, reliability, timeliness, and consistency of the data. It remains the first question of recorded EHR data use in biomedical research. Retrospective analyses need to consider the limitations and appropriate use of data, including potential risks of inaccuracies [8]. Retrospective data are collected in variable circumstances, recorded with inconsistent data definitions, missing data, and without standardized testing. Table 2 lists the frequency of some of the reported deficiencies in EHR-based research.

On the other hand, this patient care data represents the reality of actual practice, as opposed to results of sterile research protocols. In many cases, real data can fill gaps in current evidence and provide evidence in areas where clinical trials will never be carried out. Illustrative and appropriate research uses of retrospective clinical data include exploration of risk factors, cost-effectiveness of care, selection of best practices, and the epidemiology of diseases and health conditions.

Table 1 - Selected EHR data aggregators

Source	Type of Data
CMS	Medicare and Medicaid
Blue Health Intelligence	Claims data on 210 million individuals, available longitudinally
Aetna – Accountable Care Solutions	Claims data on Aetna subscribers
Validic	Commercial firm, data aggregator for physicians and health systems
Kaiser Permanente Health Connect (Northern CA)	9.1 million patients Subscriber health claims data
Massachusetts Health Quality Partners	Intramural, work with Department of Public Health and others
OCHIN	Members of 70 health system across 19 states
IMS® Disease Analyzer	EHR are contributed by a representative panel of more than 2.500 physicians in Germany
Humana Health Care – Anvita Health	11.2 million members health data
Cerner Health Facts	Since 2000, EHR collected from 480 contributing facilities throughout USA
Vestrum	EHR data from private physicians
MS HealthVault	Personal health information of "far more" than the tens of thousands of users
Express Scripts and CVS Pharmacies	Sale of prescription information which is “match-backed” by third parties, and linked to website databases

Table 2. – Frequency of deficiencies in EHR-based research

Source	Estimate	Reference
Incompleteness	24%	[11, 13, 14]
	86%	[15]
	65%	[16]
	86%	[17]
CPOE Errors	51.4-91.5	[18]
Inaccuracies, errors	4.3 %	[19]
Inconsistencies	variable	[11, 13, 14]

EHR-based analyses provide the opportunity to evaluate individual outcomes and compare results to larger populations [20]. Reduction in costs comes with streamlined processes and improved practice efficiency. The National Patient-Centered Clinical Research Network hopes to provide unparalleled access by producing national EHR data sets available to researchers [21].

Research on rare diseases is difficult because of small sample sizes, which may be geographically distant from each other. Expanded EHR networks would enable easier access for both patient and provider, and in turn increase opportunities for research [22, 23].

The gold standard of evidence based medicine, multi-center randomized controlled clinical trials (RCT), are enormously expensive and time consuming, particularly when the sample size is very large to support high power analyses [24]. Due to

special resources and arrangements, RCTs often represent centrally-controlled practices that are not representative of current practices; and also, may never be fully replicated in general use. Furthermore, prospective randomized studies can evaluate only beneficial interventions, as opposed to allocation of patients to a harmful intervention, such as smoking, which would be unethical.

In the assessment of biological phenomena and therapeutic potential, the multicenter RCT cannot be replaced by anything less methodologically rigorous. However, due to the very high rate of negative clinical trial results, the use of retrospective data from EHR is recommended for more effective filtering prior to the evaluation of safety and efficacy of new treatments in prospective studies [25].

The use of large databases requires special statistical techniques as enormous sample sizes can overpower results (i.e., practically meaningless minutia can appear statistically significant). Additionally, appropriate scrutiny of data quality and accuracy variability is needed with reasonable logistical and statistical checking prior to analyses.

Ethics: Issues of Privacy, Beneficence, and Non-maleficence

Ethics concerns in big data biomedical research are twofold: wrongdoing in research, and ineffective administration of human subject reviews. In this study, we referred to the DuBois taxonomy of misbehavior in medical research [26]. Out of 15 fundamental kinds of wrongdoings in medical research, two stand out as particularly relevant to big data research (Table 3).

Table 3. Taxonomy of Misbehavior in Medical Research

Application Area	Examples
Violation of privacy or confidentiality	• wrongful disclosure • wrongfully obtaining information • wrongful use of health information • failure to safeguard health information
Failure of informed consent	• no need for such consent regarding archived data • advance blanket research approval forms to facilitate future use

Privacy is the basic human right of limited access by others to aspects of their person, including thoughts, identifying information, and even information in bodily tissues and fluids [27]. Patients are increasingly playing an active role in their care and are often unaware that their health information, de-identified or not, may be used for clinical or community health research in the future. This directly impacts the autonomy of the patient, even if they would have given consent.

Confidentiality is the mandate to protect information that an individual has disclosed in a relationship of trust [27]. In certain circumstances, personal information may be analyzed without consent when the benefits to society outweigh the individual's interest in keeping the information confidential [28]. Typically, big data researchers are not involved in data collection and, therefore, confidentiality and security of protected data become the foremost concerns.

Extramural research is much harder to conduct than collaborating with an intramural colleague or being an inside user of local databases. Institutional Review Boards are tasked to protect human subjects in research. Unfortunately, variable interpretations and a lack of coordination among multi-site IRBs creates a challenging health research environment [7]. This has been recognized by the NIH as an area in need of improvement. The recently published draft policy for public comment noted "there is no evidence that multiple IRB reviews enhance protections for human subjects" [29].

Regulation: Data Security and Alternative Analytics

In the US, the Health Insurance Portability and Accountability Act (HIPAA) and subsequent regulations direct covered entities (e.g., a healthcare institutions) in the protection of individually identifiable protected health information in research. Violations of the Privacy Rule can become the basis for both civil and criminal penalties, including fines and possible time in jail.

A particularly controversial part of the HIPAA provisions is use of de-identified data in research. For facilitated research access, the Privacy Rule requires de-identification (i.e., removal of 18 identifiers including names, social security numbers, telephone numbers, and others). However, de-identification creates obstacles to many research projects, particularly cause-effect and time series studies.

Table 4. Examples of alternative analytics

Source	Type of Data	Alternative Use
28% of US hospitals	Patient wealth screening	Grateful Patient Program
Target	Consumer data	Use of shopping pattern identifies marketing strategies, including based on health behaviors: pregnancy, diabetes
Garmin Connect	Athletic performance data	4 billion miles of performance information
CRM Healthgrades	Aggregate health data	Sells patient lists based on diagnosis, evaluates hospital patient data for non-compliance and QC
Carolinas HealthCare	Consumer data on 2 million people	Identify high-risk patients. Data aggregated through public records, store loyalty program transactions, and credit card purchases.
LexisNexis	Medicaid recipients and consumer data publicly available (vehicle registration, property records, etc.)	Identify Medicaid Fraud and Abuse

Without an authorization, a covered entity can use and disclose protected health information for treatment, payment and health care operations (TPO). Recently, the American Medical Informatics Association started advocating for the inclusion of observational or non-interventional data research as an appropriate operational use of protected health information [30, 31]. Ultimately, EHR big data should be available not just in the present, but also for improved future decision-making.

The rapid spread of alternative analytics for health records also challenges traditional interpretations of covered entity and confidentiality protections. For example, the recently announced Qualcomm Tricorder XPRIZE is a $10 million global competition to accurately diagnose a set of diseases independent of a healthcare professional or facility. Corporations have discovered algorithms in shopping and browsing patterns, utilizing shopping cards and credit card transactions, to identify health diagnosis or needs – without the need to access a person's medical record (Table 4). While this is skillful marketing and consumer targeting, it appears that little thought has been given to the ethics of such analysis.

Data matching with publicly available records is also becoming possible [32]. While the use of this same consumer data when legitimately coupled with a person's health record may have genuine positive outcomes, such as warning that purchased food may interact poorly with current medications or reminders to refill prescriptions, the negative consequences are not far-fetched.

The "Grateful Patient Program" model is gaining more support across the country as a way to increase donations to both non-profit and for-profit hospitals [33]. Offices of giving or communication match EHR data with income/wealth data to identify prospective donor patients and families, and then send targeted information, or even organize special visits and contacts when the patients are admitted [34]. Currently, alternative analytics has far fewer regulatory obstacles than big data biomedical research.

In addition to the ever increasing flow of health information with data stored on hard drives and cloud computing, human tissues and cells also challenge the current system of protections as they are also carriers of personally identifiable health information.

The American Health Information Management Association recommends comprehensive information governance to ensure accuracy, reliability, integrity, timeliness, accessibility, and security of data and information impacting patient care, research studies and public policy. Health care data and information must be governed to meet these imperatives.

Discussion

Big data EHRs have proved to be not only an irreplaceable source of clinical, public health and health services research but also an epicenter of confusing expectations and restrictions. The balance between access to EHRs, validity concerns, ethics safeguards and regulatory protections remains elusive.

To unlock the full potential of big data EHR research, a series of actions are needed:

1) More research on the use of EHR big data is not only a matter of new scientific knowledge but also immediate public interest as more use is likely to discover more errors and stimulate corrective efforts [35]. More EHR big data research is likely to improve accuracy and validity through improved error detections and control mechanisms.

2) The confusing multiplicity of controls creates hindrances in big data EHR research (e.g., IRB for human subject protection, institutional privacy officers for regulatory compliance, multiple IRBs for inter-institutional collaborations). Therefore, information governance and the research approval processes should be integrated and streamlined to be a one-stop research approval process.

3) Considering the rapidly expanding array of health databases outside the health care system, and alternative analytics, there is the risk that academic research and also patient care by licensed clinicians will be outpaced and major ethical and security concerns will be unaddressed. Comprehensive policies are needed for secondary use of all electronic health data, not just those in currently covered health care entities.

4) The many rate-limiting privacy and information security requirements call for new computing safeguards to address public concerns (e.g., creation of access only to aggregate data but not to individually identifiable information, tools for matching big data from diverse sources without revealing individual data).

Trust in the protection and utilization of health data is essential to continued public support. The public must see and believe that their data security is taken seriously and used responsibly. It is reasonable to expect that the larger availability of EHRs and the opportunities to match data from multiple databases should lead to an accelerated rate of valuable research discoveries.

Abstract

High speed physiological data represents one of the most untapped resources in healthcare today and is a form of Big Data. Physiological data is captured and displayed on a wide range of devices in healthcare environments. Frequently this data is transitory and lost once initially displayed. Researchers wish to store and analyze these datasets, however, there is little evidence of any engagement with citizens regarding their perceptions of physiological data capture for secondary use. This paper presents the findings of a self-administered household survey (n=165, response rate = 34%) that investigated Australian and Canadian citizens' perceptions of such physiological data capture and re-use. Results indicate general public support for the secondary use of physiological streaming data. Discussion considers the potential application of such data in neonatal intensive care contexts in relation to our Artemis research. Consideration of the perceptions of secondary use of the streaming data as early as possible will assist in building appropriate use models, with a focus on parents in the neonatal context.

Keywords

Patient data privacy; Data collection; Medical device

Introduction

In recent research, there has been an increased interest in the analysis of physiological data, particularly in real-time. Many critical care and neurological monitoring applications capture physiological data. Examples include electrocardiogram (ECG), electroencephalogram (EEG) and pulse oximetry data [1].

High speed physiological data represents one of the most untapped resources in healthcare today and is a form of Big Data. In neonatal intensive care for example, a premature newborn infant's heart beats approximately 7000 times an hour and yet traditional charting on paper, or within an electronic health record (EHR), includes one number per hour of an indicative heart rate for that hour. The heuristics employed to determine the number to write are as much qualitative as quantitative and part of the function is to express overall stability or instability hour to hour. The potential for the use of high speed physiological data for earlier and potentially more reliable pathophysiological indicators have been presented for late onset neonatal sepsis [2], pneumothorax [3], intraventricular haemorrhage [4, 5] and periventricular leukomalacia [6]. Opportunities abound for the exploration of new pathophysiological indicators for many other conditions, but these are yet to be explored due to the absence of a collection of physiological data for patients developing such conditions. Analytics on high frequency physiological data, from both the perspective of retrospective knowledge discovery and real-time monitoring has the potential to be equally disruptive for healthcare as genomics research.

Within the Neonatal Intensive Care Unit (NICU), a variety of medical devices monitor the infant's vital organs while other equipment assist with breathing, maintains appropriate body temperature and provides necessary drugs and nutrients. Many of these devices continuously create physiological data second-by-second. Although many health care settings are in the process of transitioning from the use of paper to electronic for charting purposes, this does not include new approaches for new analytics derived from this sensor data. This leads health care professionals to rely on sharing clinical information in a qualitative manner [7]. Comparable to the concept of business intelligence and analytics, which stems from the prompt interpretation of large volumes of data for actionable information, there is a growing urgency for the health care sector to similarly adopt a notion of "health care intelligence" in (near) real-time [1]. There are limitations regarding the use of analytics in health care due to the time it takes to deliver predictions to healthcare providers and enable action [8].

The value of Big Data comes from the ability to make "connections between pieces of data, about an individual, about individuals in relation to others, about groups of people, or simply about the structure of information itself" [9]. An example of a Big Data platform that includes the use of physiological streaming data is Artemis. Artemis supports online health analytics that allows for concurrent multi-patient, multi-diagnosis and multi-stream temporal analysis of complex, high-frequency physiological data streams in real-time for purposes of clinical management and research. By comparing the analytical results that are gathered in the platform with current treatment practices, new patterns in real-time physiological data can be discovered, thus enabling earlier detection and possible prevention of various health conditions before clinical symptoms are visible. Artemis captures ECG data and ECG derived signals including the heart rate, respiration rate and chest impedance for purposes of breath detection. Other signals captured include blood oxygen saturation in addition to diastolic, systolic and mean blood pressure when such data is available [7].

Secondary usage of health data is defined as the use of personal health information collected for purposes unrelated to the initial purpose of providing direct delivery of health care to the patient/data subject. This includes activities such as research, analysis, quality and safety measurement, payment, provider accreditation and commercial activities [10]. The

secondary usage of personal health data plays an essential role in expanding current knowledge and understanding of health care and its delivery. Utilitarian motivations are strong in this research area, however, less utilitarian and more commercial focused and personally confronting issues are also significant. Privacy issues in this area are well documented and challenging [11-13]. Physiological data (e.g. ECG data) has the potential to reveal more information about an individual than what may be realized on first consideration. Nonetheless, it appears that many people are still willing to contribute the use of physiological data generated by themselves or even by their neonate(s) as a resource for the advancement of health research. Suitable privacy and governance frameworks are required in this fast moving domain. The potential for secondary use of physiological streaming data is clear and it is important for us to begin to understand what the public opinion is regarding the secondary use of their health data, specifically physiological data for health research purposes.

The remainder of this paper is structured as follows: The survey of Australian and Canadian citizens will be introduced and results pertaining to secondary use of data captured through physiological devices will be reported. This section is followed by a discussion about related work regarding neonatal contexts and associated issues surrounding the use of Big Data in health care. Prior research regarding parental attitudes towards research in the neonatal population and privacy concerns will be considered. Conclusions and future research are then presented.

Materials and Methods

The opinion of patients regarding the possibility of analytics on physiological data was explored, as part of a larger study, through a pilot survey deployed in Australia and Canada in 2009. The pilot survey included thirty attitudinal statements using a seven point Likert scale for responses and two open-ended questions. Focus groups reviewed the survey design before deployment. These groups included teenagers, aged pensioners, early school leavers, postgraduates and citizens with English as a second language. Between August and November, 482 self-administered surveys were distributed to residential blocks in regional New South Wales (NSW) and Darwin. During October and November, 250 surveys were distributed to sample populations in Ontario. The survey sampling strategy included high, medium and low socio-economic populations in regional and urban areas. Cronbach's Alpha results for reliability were in the acceptable range. Ethics approval was provided by the Research Ethics Board at the University of Ontario Institute of Technology and the Human Research Ethics Committee of the University of Wollongong.

The broader study that these questions are drawn from explored general public expectations and concerns regarding secondary use of their medical data, particularly pertaining to privacy matters [14, 15]. Constructs in the survey investigated the concepts underpinning the contemporary privacy theories of Restricted Access and Limited Control (RALC) [16] and a proposed framework for contextual integrity [17].

Results

The Australian and Canadian pilot surveys achieved response rates of 34.8% and 21.5% respectively. Question 26 in the survey explored the reuse of data captured through physiological devices: *If I was in hospital and a medical device was used to care for me – like a heart monitor or oxygen saturation monitor – I would agree for the information displayed on the screen to be saved in an anonymous way and used for medical research purposes.*

The stimulus statement used to capture feedback on physiological devices makes it clear that the data will be anonymized and used only for medical research purposes. Results for both Australians and Canadians indicate agreement with this type of secondary use of streaming data.

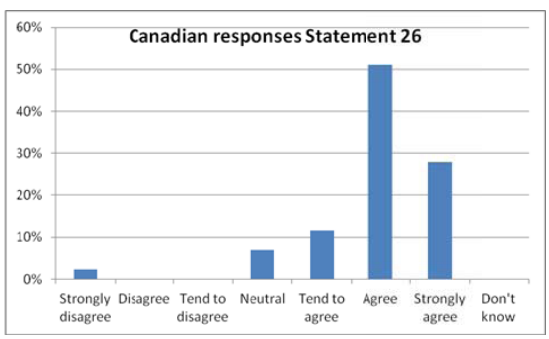

Figure 2- Frequency responses to Statement 26 on Canadian surveys

Discussion

The discussion here considers the secondary use of physiological streaming data within the neonatal intensive care context. It has been demonstrated that many parents are very willing to enroll their neonate in research studies [18, 19] even if it is known that there are significant gaps in knowledge about the study [18]. Many parents would also be willing to enroll their neonate again, if presented with the opportunity [18]. This is further supported by a study conducted by Morley et al. [20]. Parental opinions regarding the enrollment of their premature neonate(s) into several research studies in the days following birth were examined via the use of a questionnaire. Parents of preterm infants in the NICU who were invited to participate in two or more research studies were approached with this survey. Amongst the invited participants, 10% declined to allow their infants to join any studies. The majority of parents were willing to have their infant(s) be enrolled in multiple studies. In fact, 58% of the parents were willing to give their permission to enroll their infant(s) in three or more studies and 20% were willing to have their infant(s) participate in more than ten studies [20].

Many parents choose to consent for their neonate's participation in research studies because they are hopeful that it would somehow benefit their infant [18]. Many parents also want to contribute to the advancement of health research. According to findings by Morley et al. [20], 94% of the parents thought that if their baby joined a research study, the care of infants in the future would either be "better" or "very much better". Parental altruism was further demonstrated when parents were asked "Who will benefit from these studies?" in which 91% responded that "future babies", 67% said "researchers", 25% mentioned "my baby" and 2% said "no one". The insight provided by the Australian and Canadian survey results suggest that perhaps parents making decisions for neonates would also agree with the anonymised use of physiological streaming data for research purposes. This is an open research area where results could inform the governance and strategy surrounding deployment of data analytics platforms, utilizing physiological streaming data in neonatal contexts.

The issue of well informed consent arises, particularly in emotion charged contexts such as neonatal environments and the next section considers these issues.

Consent in the NICU context

The practice of acquiring informed consent is a crucial component of the research process for the protection of a neonatal research subject [21]. For consent to be considered valid, the following elements must be satisfied: full comprehension, information, and voluntariness. The participant must be mentally competent to make a free and adequately informed decision and must give their consent voluntarily and freely. Sufficient information, including the risks about the decision to be made must also be provided to the participant [22, 23].

The informed consent process is straightforward when it comes to dealing with a competent adult [24, 25]. Obtaining informed consent presents ethical and legal difficulties in certain groups of people who are considered to be part of vulnerable populations, often as a result of limited capacity or inadequate access to social goods such as rights, opportunities and power [26]. This includes but is not limited to minors and individuals living with mental disabilities or diminishing capacity [18, 22, 25, 26] as well as individuals in certain situations when one may be unable to consent for oneself. Proxy consent is therefore required for such groups of people and/or in such situations. Proxy consent is the process which occurs when individuals with the legal right to consent give advance permission to an authorized third party who is legally and competent to consent on their behalf when the individual is unable to consent for themselves. This adult may be designated through the power of attorney to consent or via a living will [22, 26, 27]. In the case of a newborn, the proxy consent at best represents parental discretion, preferences and family values [22, 25] as the neonate is incapable of communicating his/her own opinion about research and their willingness to participate [22].

It is well understood that the information provided regarding the details of a study should be sufficient enough for the reasonable parent to make an informed decision. Yet striking an ideal balance is easier said than done, since by providing too little information can render consent invalid, whereas providing too much information may consequently cause unnecessary distress. In addition to the emotional stress associated with the birth of a premature and/or critically ill infant, the mother may also have to deal with the physical stress related to the recovery period following the birth [22, 28]. The parents of such infants then face a multitude of complicated and urgent decisions while rapidly digesting new and changing information [29] in an unfamiliar environment. They are then obliged to take on the responsibility of being surrogate decision-makers on behalf of their infant. With no previous experience on which to turn, this can be a frightening experience as these parents are concerned with trying to make the right decision to benefit their infant or if they are unable to, at the very least, they want to make a decision that will benefit future infants [30].

However, it is difficult to test if parents truly understand what they are consenting their infant to when it comes to research studies [25]. Stenson et al. [31] conducted a survey that examined if parents of infants who entered into a randomized controlled trial of pulmonary function testing had any recollections about being asked to give consent for enrolling their infant in a research study and how they felt the research had affected their experience as parents of a sick infant. Although the parents were given a detailed verbal description and printed information sheet regarding the trial, of the 99 respondents, 12% could not remember being approached for consent and did not think that their infant had participated in a research study and 6% remembered being approached for consent but were unsure of whether or not their infant actually participated in a study. 89% parents who remembered being approached for consent felt that a full explanation of the studies they were enrolling their infant in had been provided to them; however only 27% and 42% of those parents felt that they understood the explanation completely and reasonably well respectively. The rest of the parents either understood a little of the explanation or not at all.

Ballard et al. [18] also examined the validity of informed consent obtained in the perinatal period in relation to their NEOPAIN study. To determine the level of parental understanding of the study, participating parents were asked open-ended questions that addressed the timing of consent, understanding of the study's purpose, benefits and risks, the voluntary nature of the project, and their willingness to enroll in future studies if applicable. Of the 64 parents who were interviewed, 5 parents (7.8%) did not remember the study or signing of consent. Of the remaining 59 parents who remembered the study, only 67.8% understood the study's purpose. It was observed that maternal understanding regarding the purpose of the study was greater than that of paternal understanding (73.3% vs 57.1%) which was particularly interesting as this study also evaluated the mother's medication effect on their memory. The medication given most frequently to the mothers in this study population was magnesium sulfate, a drug that can cause adverse effects on memory and mentation although in reality, the risks are minimal. At the time they signed their consent to enroll their infant in the NEOPAIN study, 37 of the 43 mothers were being treated with magnesium sulfate but it was noted that the administration of the drug in this case appeared to have minimal effect on the mother's ability to recall the study. It was proposed that despite exposure to labor and medication, mothers are better able to handle stress or process information more effectively. Involving the father in the consent process did not improve the overall understanding of the study or its benefits and risks.

Yet even with a double consent process, in which parents experience the consent process twice with the first time taking place before the neonate's birth and the second time occurring before the neonate's enrollment in a study, it has been found that these parents are no more likely to have given valid consent in comparison to those parents who consented only once. The reasons for this phenomenon is not well understood

although it has been suggested parental stress immediately following birth may play a role [18].

Privacy in the NICU context

Philosopher Herman Tavani provides an insightful phrase which is a useful starting point for considering privacy matters: "Privacy is a concept that is neither clearly understood nor easily defined" [32, p.11]. Within the scholarly literature, many have attempted and continue to attempt to provide the ideal definition of privacy. Some, such as Alpert (2000) see privacy as having the freedom to be whom and what one is as an individual while others such as Stephen (1873), Warren and Brandeis (1890), Westin (1967) and Gavison (1980) define it as "anything that offends decency", "being let alone", to "control over information" and "restricted access to persons and personal information" respectively, as cited by Allen [33]. There are also cultural dependencies with some cultures valuing privacy more than others [34].

Traditionally the privacy of medical patients' personal information has been protected through application of the 'limited access' theory of privacy. With the change of medium used for capture and storage of personal medical information from paper to electronic, the 'limited access' approach to privacy is under pressure due to the ease with which electronic information can be exchanged. This is an issue of growing importance with the emergence of Big Data, and the physiological streaming data available in the NICU would benefit from consideration against more contemporary privacy theories [16, 17] that go beyond the 'restricted access' or 'limited control' paradigms.

The NICU context, with volumes of streaming physiological data, is well described by Nissenbaum's definition of context:

Contexts are structured social settings characterized by canonical activities, roles, relationships, power structures, norms (or rules) and internal values (goals, ends, purposes) [17, p. 132].

The survey question regarding reuse of streaming physiological data provides context related insights. The goal-ends-purposes of the data reuse were clearly described as being 'for research purposes'. The role of the survey respondent as a patient was clarified. The power structures were considered with the patient given some power to make decisions regarding the re-use of their data. The wording of the survey question implied that the clinicians were seeking shared power over the streaming data.

The deployment of privacy frameworks within the NICU to explore: (1) the enhancement of consent and simultaneously (2) privacy as contextual integrity concepts is an open research area. The early survey results and NICU specific matters considered here are a useful launch-point for further work. The broader patient privacy study referenced here explored concepts of shared power involving clinicians and patients and results indicated there was an appetite for this type of arrangement from both Australians and Canadians surveyed. There is clearly a need for the development of an appropriate patient privacy/clinician engagement model.

Biometrics from the NICU

Biometric data is considered personal information when derived from an individual to determine or verify one's identity [35]. The term "biometrics" may refer to quantifiable characteristics or the automated methods that utilize the aforementioned characteristics to identify or confirm one's identity [36]. Any human behavioural and/or physiological characteristic has the potential to be utilized as a biometric identifier provided it satisfies the criteria of universality, distinctiveness, acceptability, collectability, performance, permanence and circumvention [37]. This may have implications for the secondary use of physiological streaming data – even when the data has been anonymized.

It is unclear how biometrics captured while an individual is a patient in a NICU environment could be exploited later in that individual's life. However it is noted here that the issues surrounding biometrics will influence the future directions of secondary use of streaming physiological data.

Conclusion

This paper highlights the important contributions that physiological data, as captured by Big Data platforms, brings to health research. To date there has been little research relating to patient engagement in matters related to secondary use of such data. Contemporary privacy theories may aid navigating the emerging privacy and ethical issues, including biometrics, regarding streamlining physiological data. The survey results presented here formed part of a broader study into Australian and Canadian citizens opinions regarding application of contemporary privacy theory in medical domains. The focus here has been on the NICU context and potential for collaboration with parents of neonates on matters pertaining to consent, privacy and streamlining physiological data. The Artemis platform has been considered as one Big Data platform providing technological support.

It is important to understand the perceptions of secondary use of data in this area as early as possible and build an appropriate use model. The initial patient perceptions presented here can inform the challenging privacy aspects of a future physiological data use model. Physiological data analysis could potentially be the path to the next major advances in healthcare thus serving as a motivation to our research on a parent engaged privacy model using Big Data.

Driving the Profession of Health Informatics: The Australasian College of Health Informatics

Christopher Pearce[a], Klaus Veil[a], Peter Williams[a], Andrew Cording[a], Siaw-Teng Liaw[a], Heather Grain[a]

[a] *Council of the Australasian College of Health Informatics*

Abstract

Across the world, bodies representing health informatics or promoting health informatics are either societies of common interest or universities with health informatics courses/departments. Professional colleges in Health Informatics (similar to the idea of professional colleges in other health fields) are few and far between. The Australasian College of Health Informatics has been in existence since 2001, and has an increasing membership of nearly 100 fellows and members, acting as a national focal point for the promotion of Health Informatics in Australasia.

Describing the activities of the college, this article demonstrates a need for increasing professionalization of Health informatics beyond the current structures.

Keywords:

Professional education; Professional Review Organisations.

Introduction

Health Informatics (HI) as a distinct entity is an evolving field [1], and has developed from a craft based solution to the problems of computerising the health sector, into a distinct field of practice. The next step is to understand HI as a profession, one in which a 'Health Informatician' can be seen as part of a specialised group, in the same way that, for example, surgeons identify as a professional group.

The beginnings of Health Informatics began in the 1960's with the development of the concept of information systems in medicine, both in the US and the UK. The International Medical Informatics Association was formed in 1989, and in 1994 the first MEDINFO was held [2]. It is therefore over this time that the discipline of informatics evolved, as participants grappled with the implementation of a game-changing technology in medicine [3].

In order to be considered a separate academic discipline, a field of study needs several characteristics [4], sufficient to be:

1. A particular object of research (e.g. law, society, politics), though the object of research maybe shared with another discipline;
2. A body of accumulated specialist knowledge referring to their object of research, which is specific to them and not generally shared with another discipline;
3. Have theories and concepts that can organise the accumulated specialist knowledge effectively;
4. Use specific terminologies or a specific technical language adjusted to their research object;
5. Have developed specific research methods according to their specific research requirements, and maybe most crucially; and
6. Must have some institutional manifestation in the form of subjects taught at universities or colleges, respective academic departments, and professional associations connected to it.

With the development of a significant research base, journals devoted to the discipline, Health Informatics qualifies on all these counts. Therefore, the academic basis for HI is relatively strong, particularly in the US.

Does the same apply for HI as a profession? The features of a profession have some similarities and some differences to academic standing. A profession must have [5]:

1. A systematic body of knowledge and theory: in other words have those features of an academic discipline outlined earlier;
2. Professional authority: which in turn derives from the first point. To have specialised knowledge and understanding allows a profession to have deemed or delegated authority over that body of theory;
3. The sanction of the community: a profession seeks to have control over aspects of its internal functioning – training, standards, and regulation – all of which must come from persuading the community that the profession can and should have control indeed, that it is in the communities (or the public) interest in having such control;
4. A regulatory code of ethics: where a profession exists, it effectively functions as a monopoly, or a dominating interest in the field. The profession activities must therefore be regulated, and self-regulation is first by a code of ethics, and second, by structures that mandate standards of entry; and
5. A professional culture: the establishment and maintenance of a professional community in which to set and monitor standards, maintain skill sets, and drive the growth of the profession.

It is in these latter areas that the ACHI as a professional college sits, and where ACHI derives its professional authority from – to drive the profession of HI in Australia.

Across the world, bodies representing health informatics or promoting health informatics are either societies of common interest, universities with health informatics courses/departments, or academic professional bodies. These societies of common interest are represented by organisations such as the American Medical Informatics Association (AMIA), the Health Informatics Society of Australia (HISA), or the Colombian Association of Health Informatics, for example. These organisations generally have no barriers of entry, and have as their purpose the promotion of activities within their members. The International Medical Informatics Association (IMIA) lists 57 such organisations in its membership.

Universities with health informatics faculties are characterised by their focus on research and teaching in that domain. Teaching staff are appointed for their demonstrated domain knowledge, researchers for their demonstrated publication outputs, and students for their demonstrated prospects in achieving health informatics competencies.

A third model exists, which is an academic professional body dedicated to standards and education. This model is common in medicine, and acts as a supplement to the other two. The Royal College of General Practice (RCGP) is an example: 'We are the professional membership body and guardian of standards for family doctors in the UK, working to promote excellence in primary healthcare'. The RCGP sits alongside the British Medical Association and works in conjunction with the various academic departments to further the discipline. Professions are ideally placed to work with government on matters of standards and training [6].

A defining characteristic of these bodies is a standard of entry, acquired by 'fellows' after an approved period of training and demonstrating the achievement of a certain standard. These bodies are then active in the defining of standards of practice, revalidation, and policy surrounding the scope of activities. Their main role is therefore to bridge the gap between academic practice and professional practice.

Such a model is rare in health informatics. The American College of Medical Informatics is an example for health biomedical informatics (http://www.amia.org/programs/acmi-fellowship). The ACMI model was used to guide the establishment of the ACHI.

This paper describes the Australasian College of Health Informatics (ACHI), a unique body in this area. ACHI is:

'*the professional body for Health Informatics in the Asia-Pacific Region. The credentialed Fellows and Members of the College are national and international experts, thought leaders and trusted advisers in Health Informatics. ACHI sets standards for education and professional practice in Health Informatics, supports initiatives, facilitates collaboration and mentors the community'*.

It is the only body of its type that is a member of the International Medical Informatics Association (IMIA). The ACMI is a member through its being an integral part of the AMIA.

The college was established according to a perceived need, to have a qualification of sufficient standard to demonstrate that the holder is an established professional, worthy of developing and implementing the evidence base in HI. Again, using the model of the medical colleges, a surgeon must have achieved the fellowship of the college of surgeons before being able to practice in that field.

In Australia, formal training in Health Informatics (HI) is rare, with few designated courses and variable support from universities. Many active in large projects have been either 'enthusiastic amateurs' who trained in another profession, or have learned on the job through a variety of methods. Fellows have come through the college with demonstrable Health Informatics PhD's, awarded through engineering departments, general practice, anaesthesia, and even business faculties. Others have come through paths involving mostly industry based training, with an emphasis on practical implementations.

A not unusual scenario is of a clinician thrust into an informatics role to help implement a new clinical system, and having to understand clinical coding, adoption and workflow theories, all in a rapid timeframe. Learning paths are therefore driven by interest and need, rather than following a formal path.

ACHI was founded in 2001. Professor Enrico Coiera was the first president. Enrico was an early champion of 'medical informatics' [7] in Australia. ACHI currently has 85 fellows and 11 members. The majority are from Australia, but ~10% are from New Zealand and another 10% are based overseas (Hong Kong, Japan, Malaysia, England, and Germany). The overall membership has doubled in the past 18 months, suggesting a significant demand for a professional body of this type, and 20% are female.

While many are in university departments with clear academic roles, the majority are in industry, working for government departments, hospitals, Medicare Locals (primary care support organisations), and companies. Many work in isolation, in that they are the only college fellow/member in that organisation or department.

Membership

There are two levels within the college: fellows and members. In the absence of a formal structured education program in Health Informatics, applicants have to demonstrate skills and expertise in the field, by applying to the membership committee. To join ACHI, an applicant must:

- Have made a (distinguished for fellows, measured for members) contribution to the field of Health Informatics;
- Have a minimum of eight years (for fellows) or five years (for members) of practical experience in Health Informatics (excluding time spent as an undergraduate student). For fellows, at least five must have been in a position from which the actions of the nominee have resulted in outcomes which can be seen to support the 'distinguished contribution' to the field in Australasia; and
- Be an ethical user of health information, demonstrate professional integrity, and have their academic documentation verified and accepted.

To achieve the required level, members must accrue 60 points, and fellows 100 points of recognised activities. As examples, a PhD in a relevant discipline is worth 50 points, a research paper 20 points, each year in a HI post 5 points, and chief investigator in a significant research project 20 points.

Governance

ACHI is governed by a seven member council, with four committees reporting to council. They are:

- Membership committee: receives and determines membership applications, and developing a reaccreditation program;
- Education committee: developing models of career pathways and course accreditation programs;
- Program evaluation committee: tasked with performing rapid evidence reviews to inform policy development. The last two areas have been on personal health records and consumer access to diagnostic testing results; and
- Professional standing committee: tasked with developing a plan to promote heath informatics as a discipline to potential stakeholders (government, health institutions).

Figure 1 – Governance Structure

Activities

The activities of the college for the next three years are guided by its strategic plan, focussed on several areas.

Figure 2 – Priority Areas

Education

Here, the objective is to see that the College sets the framework for education excellence in Heath Informatics in the Asia Pacific region. In addition to the education committee's role in developing a vision for a career path in Health Informatics, taking into account the diversity of entry points and education provision, including the Certified Health Informatician of Australia program (CHIA - an entry level practical qualification), the college will strengthen links with international organisations (including AMIA, IMIA, and EFMI) active in the area, particularly in the field of course accreditation.

At the moment, there is no national standard to inform course development, and therefore no driver for employing organisations to request appropriate skills.

Membership

Designed to foster a community of health informatics professionals, this inwards looking target is designed to increase membership, establish connections with international bodies, and develop a framework for revalidation. Revalidation is an essential feature of a professional college if it is to be able to demonstrate that its fellows remain skilled. In health, revalidation is now compulsory, and health informatics should be no exception.

An important advancement is the establishment of a mentoring program. Prospective fellows who do not meet the criteria can be allocated to a fellow to advise them on career development.

Advocacy

Crucial to the activities of a professional college is to be able to advocate on behalf of its members, and ACHI regularly contributes to the policy discourse on Health Informatics and is seen as an expert in the area. These papers are all available through ACHI's website <www.ACHI.org.au>. Despite having fellows who are national and international experts in various fields, their voice has often been silent in policy development in Australia, particularly at a time when, nationally, the government is embarking on an ambitious shared EHR project [8].

The increased activity of ACHI is correcting this balance. Governments develop stakeholder consultation plans, and the existence of a formal college has allowed fellows to be represented at the table alongside with other professional colleges.

The activities of the Program Evaluation Committee have been crucial in this area, allowing the college to present evidence based views to inform policy, rather than vested or stakeholder views.

Engagement

Alongside advocacy, engagement broadly across the professional spectrum is an activity designed to raise the profile of informatics as a profession. This means not only engaging with HISA and similar bodies, but also with the other health professional colleges – surgeons, physicians, and the like. Clinical engagement is crucial to the success of health projects, but that clinical involvement must be tempered by the appropriate level of Health Informatics professionalism [9].

Professional Recognition

The final piece of the puzzle, and underpinning all other activities, the role of ACHI is to see that the profession of health informatics be duly recognised by all, and that the College be seen as the standards and expert body in the field.

This area has many aspects, ranging from the bureaucratic to the broad. Health informatics is not represented in the statistical classification of professions, for instance [10]. Nor is HI and the presence of the college well understood by other bodies. Reconciling the definitional issues between the pragmatic, industry based definition of Health Informatics versus the academic definitions (biomedical informatics/medical informatics) [11] is another issue.

Discussion

For HI to be considered a true profession, there needs to be bodies worldwide such as ACHI to promote the profession. Associations, with no barriers of entry and no standards have a role in developing a community, but only a professional body can have the moral authority and standing to negotiate and maintain standards [12]. In this light, ACHI's role in supporting the profession becomes clear, revisiting Greenwood's criteria:

1. A systematic body of theory: well defined through existing academic work, but supported through the community created by ACHI, with meetings, the 'electronic Journal of Health Informatics' (www.eJHI.net), and other activities;
2. Professional authority: this is a key goal for ACHI. In an industry environment where HI is not necessarily recognised as such, the advocacy and engagement areas of the strategic plan are designed to develop and improve the authority held by the profession;

3. The sanction of the community: again, a key goal. In order to be able to influence the professional development, ACHI must persuade the 'community' that this is in the community's interest. Setting the educational and training standards is the essential function, as is the engagement and advocacy roles;
4. Regulatory code of ethics: ACHI has such a code. Designed to set out the standards of behaviour that are required of health informatics professionals in Australia. It deals with all aspects of professional activity including ACHI members' duties to patients, the public, employers and colleagues. Any ACHI member who fails to comply with these standards may be removed as an ACHI member. The code of conduct can be found at: <http://www.ACHI.org.au>; and
5. Professional culture: this is in many ways the most important, and the most complex one in the early stages of development of the profession. Fellows came from a wide variety of backgrounds and experiences. They can be medical professionals well steeped in medical ethics, or from other backgrounds with different ethical frames [13]. It is the most important aspect of creating the community of the profession. Approximately 15% of the college are active on committees and in developing positions, and the College has an active email group.

The progress of the college over the last twelve to eighteen months has been encouraging. Membership has doubled, engagement has increased both within and without. ACHI is poised to develop from a small group to a fully-fledged professional body influencing the development of the profession.

Challenges

ACHI is beginning to form an important role in developing the profession in the region. Although its main impact is in Australia, its role is developing outside the country, in particular in New Zealand. The challenges it faces are both internal and external.

Internal

The demands on the college far exceed its capacity to achieve them. Especially at this stage of development, the college employs no staff, and all work done is in a voluntary capacity by people who are already, by the very nature of the field, very busy. This limits the ability to deliver many of the required activities.

The heterogeneity of fellow development paths also means that there are a high variety of views existing within the profession. These vary from basic definitional issues mentioned earlier to discussions on appropriate role for the college.

External

The most significant issue for the college and its external relationships devolves primarily from the first challenge. As the presence of the college becomes more prominent, so does the external expectations of capacity and ability to deliver. In an all-volunteer body with a relatively small number of fellows many of them new to the profession, there is significant risk of failure to deliver on expectations, and for this reason, expectation management is an important area.

Conclusion

This paper has outlined the activities of ACHI, a professional body for health informatics. More importantly, it has outlined the framework for a profession, demonstrated Heath Informatics can be seen to be a profession. The growth of ACHI demonstrates an unmet need, not just in our local area, but one that needs to be replicated elsewhere for HI to achieve full recognition, and its practitioners to receive the recognition they deserve.

Acknowledgements

We acknowledge Associate Professor Chris Bain, for his thoughtful comments, and all fellows and members who have contributed to the college's development. We also acknowledge all previous presidents.

Person-Specific Standardized Vulnerability Assessment in Health and Social Care

Léa A. Deleris[a], Pól Mac Aonghusa[a], Robert Shorten[a]

[a] IBM-Research – Ireland, Dublin, Ireland

Abstract

We describe an integrated person-specific standardized vulnerability assessment model designed to facilitate patient management in health and social care. Such a system is not meant to replace existing health and social assessment models but rather to complement them by providing a holistic picture of the vulnerabilities faced by a given patient. In fact, it should be seen as a screening tool for health and social care workers. One key aspect of the modeling framework is the ability to provide personalized yet standardized multi-dimensional assessments of risk based on incomplete information about the patient status, as is the case in screening situations. Specifically, we integrate a Markov chain model describing the evolution of patients in and out of vulnerable states over time with a Bayesian network that serves to customize the dynamic model. We present an application in the context of elder care.

Keywords:

Comprehensive Health Care; Patient-Centered Care; Aging; Risk Factors; Vulnerability.

Introduction

Health and social programs represent a significant, and growing, proportion of the public sector budget across OECD economies. In fact, the OECD reported that public sector budgets devoted to social programs across OECD economies represented 22% of GDP [1]. In the US, Medicaid spending ($457 billion in 2014) is expected to almost double by 2020 [2]. As expenses continue to grow, it has become essential for sustainability to look into solutions for reducing health and social care expenses while possibly minimizing the effect on the support provided (if not to improve its quality at the same time). Such an objective is not necessarily as utopic as it sounds. Indeed, there remains ample room for improvement within the current delivery of health and social services that mostly operate as a set of side-by-side, one-size-fits-all processes (unemployment, child support, housing support…). In addition, those services have typically been designed to address simple situations and tend to be ill-suited for complex ones; i.e., when a person presents a variety of health and social needs. Unfortunately, such complex situations are often associated with high costs. In New York State (NYS), about five percent of Medicaid beneficiaries account for more than half of Medicaid spending [3] and in Camden, NJ, one percent of patients account for a third of the city's medical costs [4]. Hence, finding ways to (i) better coordinate the actions of social and health services across silos, and (ii) proactively identify situations that can become high-cost, high-need are promising avenues to address the health and social care spending challenge.

Our proposed model seeks to help in those two directions at an operational level. Specifically, the objective of our model is to assist care coordinators (whether healthcare or social care) as they receive new situations or update existing ones. The model provides them with a holistic high-level assessment of the clients' current needs, along with assessments of the vulnerabilities (upcoming problems) of those clients. With this decision support information, careworkers are able to effectively address current situations and to identify potentially complex and costly ones ahead of time.

Note that the benefits of looking at holistic assessment of needs, in particular across health and social issues, reach beyond the efficiency gains of improved coordination. In fact, the main reason for taking a holistic perspective is the existence of strong cross-influences between health and social factors, often termed as the social determinant of health [5]. For instance, research has shown that an additional four years of education, besides lowering mortality, reduces the risk of heart disease by 2.16 percent and the risk of diabetes by 1.3 percent [6]. Understanding and accounting for the cross-influences among domains is critical in the effort to better manage patients' wellness altogether and to reduce health inequalities that arise between people of different socio-economic or ethnic groups.

Methods

Our vulnerability modeling framework consists of a single integrated model that evaluates a set of vulnerability metrics across several domains; for instance, "Physical Health", "Mental Health", "Income", "Shelter", and "Fundamental Activities of Daily Living" in the context of eldercare.

Dynamic Model through Markov Chain

The heart of a vulnerability model is a dynamic model that represents the probabilistic evolution of a person over time. From that model, and given the current state of a person, we can estimate the chance of that person reaching a vulnerable state. Specifically, we use a homogeneous Markov chain to represent the transitions of persons through states, a subset of which have been identified as vulnerable states. A Markov chain is a random process that represents the sequence of states visited by a system over time. It is characterized by the Markov property (also called "memoryless") which stipulates that the evolution of the system only depends on its current state and not on how it reached that state. This property enables one to characterize the model with few parameters, and simplifies computations. In a simple two-state chain, for instance, "Employed" and "Not Employed", the only two parameters that need to be provided are (i) the probability of becoming unemployed in the next time period given one is currently employed and (ii) the probability of becoming employed given one is currently unemployed.

As our goal is to consider multiple dimensions of vulnerability at the same time, the Markov chain needs to consider state combinations, as in the example in Figure 1, which looks at Shelter and Employment vulnerabilities, albeit in a very crude way (modeling two states for each domain):

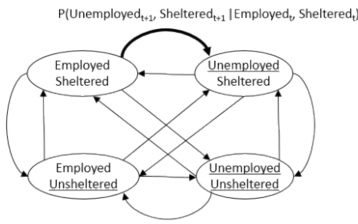

Figure 1– Simple Markov Chain Model to Represent Evolution of a Person over time

Note: To make the diagram readable, we have not represented the self-transitions. The transition probability that is spelled out is associated with the bolded arc.

Based on the Markov chain parameters, it is possible to compute future-behavior statistics aimed at characterizing vulnerability. We have chosen to rely on the mean first passage time (MFPT) to a vulnerable state conditional on the current state. In our example, assuming the person's current state is "Employed, Sheltered", then the Employment vulnerability would be the average time of the first "visit" to either the "Unemployed, Sheltered" or "Unemployed, Unsheltered" states. MFPT provides a characterization of the short-term behavior of the model and is thus particularly suited as a measure of immediate vulnerability of a person.

Mathematically, Let *d* index vulnerability domains and let D denote the number of such domains. Each domain is described by a state space $\boldsymbol{S^d}$ where $\boldsymbol{S'^d}$ is the subset of $\boldsymbol{S^d}$, which corresponds to those deemed vulnerable. In our preceding example, we would have D = 2. The first domain is "Shelter" with **state space** $\boldsymbol{S^1} = \{\boldsymbol{Sheltered, Unsheltered}\}$, **and vulnerable state set** $\boldsymbol{S'^1} = \{\boldsymbol{Unsheltered}\}$, and the second dimension is **"**Employment**"**, with **state space** $\boldsymbol{S^2} = \{\boldsymbol{Employed, Unemployed}\}$, **and vulnerable state set** $\boldsymbol{S'^2} = \{\boldsymbol{Unemployed}\}$. We denote by $\boldsymbol{S}$ the product space of each state space for each dimension. $\boldsymbol{S} = \boldsymbol{S^1} \times \cdots \times \boldsymbol{S^D}$. Let N denote the total number of states, $\boldsymbol{N} = \boldsymbol{card}(\boldsymbol{S})$.

Let $\boldsymbol{x_t^d}$ represent the state of a person at discrete time intervals *t* along vulnerability domain *d*. Thus, $\boldsymbol{x_t} = (\boldsymbol{x_t^1}, \cdots, \boldsymbol{x_t^D})$ captures the comprehensive state of the person at time *t*. We assume that there exists a homogeneous Markov chain with transition matrix $\boldsymbol{M}$ where $\boldsymbol{m_{ij}} = \boldsymbol{P}(\boldsymbol{x_{t+1}} = \boldsymbol{s_j} | \boldsymbol{x_t} = \boldsymbol{s_i})$ where $\boldsymbol{s_i}, \boldsymbol{s_j} \in \boldsymbol{S}$, which describes the evolution of a person across states. Finally, let $\boldsymbol{\mu_{ij}}$ denote the mean first passage time $\boldsymbol{\mu_{ij}}$ from state $\boldsymbol{s_i}$ to state $\boldsymbol{s_j}$, defined as the expected number of steps to arrive at destination $\boldsymbol{s_j}$ for the first time starting from state $\boldsymbol{s_i}$. For each domain *d*, we define the vulnerability index associated with current state $\boldsymbol{s_i}$ as follows:

$$\begin{cases} \boldsymbol{v_i^d} = \boldsymbol{\min}_{\boldsymbol{j}:\boldsymbol{s_j}^d \in \boldsymbol{S'^d}} \boldsymbol{\mu_{ij}} & \forall \boldsymbol{i}: \boldsymbol{s_i}^d \notin \boldsymbol{S'^d} \\ \boldsymbol{v_i^d} = \boldsymbol{0} & \forall \boldsymbol{i}: \boldsymbol{s_i}^d \in \boldsymbol{S'^d} \end{cases}$$

Indeed, if the current state does not correspond to a vulnerable state for domain *d* ($\boldsymbol{s_i}^d \notin \boldsymbol{S'^d}$), then we are interested in the mean first passage time to any destination state for which its *d*th component is deemed vulnerable, hence the need to use the minimization operator. When the starting state corresponds to a vulnerable state ($\boldsymbol{s_i}^d \in \boldsymbol{S'^d}$), the vulnerability index is is set to 0 to indicate current need. Finally, we call the vector $\boldsymbol{V_i} = (\boldsymbol{v_i^1}, \cdots, \boldsymbol{v_i^D})$ the vulnerability profile of the person corresponding to current state $\boldsymbol{s_i}$.

Bayesian network for standardised customization

Observe that if the parameters of the Markov chain are fixed, any person in a similar current state would have the exact same vulnerability profile, providing minimal differentiating information. To allow for model customization, we have chosen to let the parameters of the Markov chain depend on a set of relevant factors. Specifically, we assume that there exists an underlying Bayesian network that articulates the relationships among the factors themselves and also between the factors and the state of a person. Bayesian networks are graphical models that represent relationships among uncertain variables [7]. The nodes represent the variables and the arcs represent the conditional dependencies in the model. Markov chains and Bayesian networks are consistent modeling frameworks in the sense that they are both based on representing conditional probabilities.

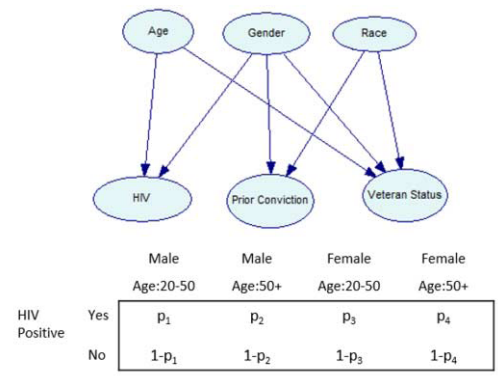

Figure 2 – Illustrative Bayesian Network

Figure 2 shows an example of such a Bayesian network with six factors. This model implies that *Age*, *Gender,* and *Race* are independent of one another but that *Veteran Status* is influenced by all three. In addition to the structure of the model, Bayesian networks are characterized by a quantitative layer that represents the distributions of the variables conditional on all possible parent scenarios. At the bottom of Figure 2, we present the conditional probability table for the variable *HIV positive,* where p_2 represents the probability of being HIV positive given one is at least 50 years old and male. Bayesian networks are especially efficient at computing inference queries; i.e., conditional probabilities involving the subsets of the variables in the network. In our example such a query could be asking for the probability of a person being *HIV positive* given *Gender* and *Veteran Status*.

Note that we can extend such a model to include variables corresponding to a Markov chain model as presented in Figure 3. By extending the Bayesian network so as to pair it with the Markov chain model, inference computations can provide personalized parameters for the Markov chain, accounting for the current knowledge of a person's situation, both current state and known factors, as large or limited as this knowledge may be.

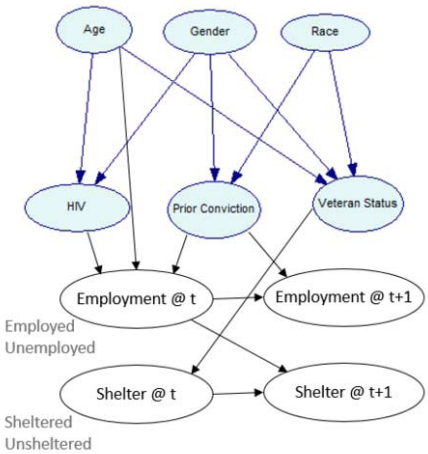

Figure 3– Illustrative Paired Bayesian Network

Mathematically, Let $\boldsymbol{\chi} = \{\boldsymbol{X_1}, \cdots, \boldsymbol{X_n}\}$ denote the set of all the variables represented in the Bayesian network. We decompose $\boldsymbol{\chi}$ into three groups:

- $\mathcal{F} = \{ x_k^F : k = 1, \cdots, K\}$: set of variables representing explanatory factors
- $\mathcal{S}_t = \{ x_t^d : d = 1, \dots, D\}$: set of variables representing the state variables at current time t
- $\mathcal{S}_{t+1} = \{ x_{t+1}^d : d = 1, \dots, D\}$: set of variables representing the state variables at future time t+1

The last two sets enable the pairing to the Markov chain model. Indeed, each element in the set $\boldsymbol{\mathcal{S}_t}$ corresponds to one of the vulnerability domains and $\boldsymbol{Val}(\boldsymbol{x_t^d}) = \boldsymbol{Val}(\boldsymbol{x_{t+1}^d}) = \boldsymbol{\mathcal{S}^d}$. Where in a Markov model a state s was represented by one (vector) variable, it is represented by a set of variables in the Bayesian network. For any observed evidence $\boldsymbol{\mathcal{E}}$ belonging to a subset of the state space of $\boldsymbol{\mathcal{F}}$, and any state $\boldsymbol{s_i}, \boldsymbol{s_j} \in \boldsymbol{\mathcal{S}}$, the Bayesian network model can provide through inference the value of the parameters of the Markov chain model :

$$\boldsymbol{P}\left(\boldsymbol{x_{t+1}^1 = s_j^1}, \dots, \boldsymbol{x_{t+1}^d = s_j^d}, \dots, \boldsymbol{x_{t+1}^D = s_j^D} \middle| \boldsymbol{x_t} \ = \boldsymbol{s_i} \ , \boldsymbol{\mathcal{E}}\right)$$

Therefore, when we let $\boldsymbol{\mathcal{E}}$ represent the observed information about a person related to factors in $\boldsymbol{\mathcal{F}}$, we can estimate the associated personalized Markov chain parameters and thus that person's vulnerability profile. Finally, as knowledge about a person's situation evolves, the vulnerability indexes evolve as well.

Characteristics of the modeling framework

This modeling framework presents several advantages. Through the Bayesian network model, the vulnerabilities across domains are made interdependent. In particular, in the context of health and social care, this means that the model can capture the *interactions* among social factors, health factors and vulnerabilities. The resulting vulnerability profile is *personalized yet standardized*. It is personalized as the Bayesian network provides a way to determine the parameters of the Markov chain model based on observed state of the person. It is standardized, as the same customization model is used for everyone. Note also that the vulnerability indexes are associated with a *physical* (thus interpretable) measure, in the form of average amount of time. This consistent use of one metric enables both within-subject and across-subject comparisons. Finally, the model is designed to function with *incomplete information* about a person's current state and profile, a key difference with assessment tools, making it a useful complement as a screening step.

In the presentation of the model above, we have focused on measuring vulnerability through the risk of occurrence of a vulnerable state. The model can be used at the same time to evaluate severity upon occurrence. Specifically, for a vulnerability domain d, for a state $\boldsymbol{s_i}^{\boldsymbol{d}}$ corresponding to a vulnerable state, the severity index $\boldsymbol{w_i}^{\boldsymbol{d}}$ is defined as the mean first passage time to a non-vulnerable state $\{\boldsymbol{s} \in \boldsymbol{\mathcal{S}}: \boldsymbol{s^d} \notin \boldsymbol{\mathcal{S}'^d}\}$. For a state $\boldsymbol{s_i}^{\boldsymbol{d}}$ that does not correspond to a vulnerable state, we can either set $\boldsymbol{w_i}^{\boldsymbol{d}} = \boldsymbol{0}$, or envision estimating severity by how long, on average, one would stay vulnerable if one were to become vulnerable.

Besides the vulnerability profile, the model yields further insights into a person's situation. In particular, we can provide (i) guidance into what additional information could be useful (informative factors) and (ii) explanations (influential factors) by identifying which aspects of the person profile strengthen and weaken his/her profile. Both are obtained by performing one-way sensitivity analyses. For instance, let's consider domain d, and current vulnerability index $\boldsymbol{v_i^d}(\boldsymbol{\mathcal{E}})$, corresponding to knowledge $\boldsymbol{\mathcal{E}}$. For each factor $\boldsymbol{x_k^F}$ currently observed ($\boldsymbol{x_k^F} \in \boldsymbol{\mathcal{E}}$), we compute an artificial vulnerability index $\widetilde{\boldsymbol{v}}_{\boldsymbol{i}}^{\boldsymbol{d}}\left(\boldsymbol{\mathcal{E}} \backslash \{\boldsymbol{x_k^F}\}\right)$, assuming factor k is not observed. The difference between the vulnerability indexes, $\boldsymbol{v_i^d}(\boldsymbol{\mathcal{E}}) - \widetilde{\boldsymbol{v}}_{\boldsymbol{i}}^{\boldsymbol{d}}\left(\boldsymbol{\mathcal{E}} \backslash \{\boldsymbol{x_k^F}\}\right)$, provides an indication of the influence of that factor. A similar procedure is performed for factors that are unknown to determine how informative they could be.

Results

We applied this modeling framework to the domain of elder care in collaboration with the Beijing Academy of Science and Technology. Specifically, we developed a vulnerability model to help careworkers better support aging populations, focusing on fostering independent living while at the same time identifying declining mental and physical health as early as possible. Aging populations and support for independent living are a growing concern in both developed and developing countries. In fact, the WHO estimates that the number of older people who are no longer able to look after themselves in developing countries may quadruple by 2050 [8].

To build the Bayesian network model, we have used data from the US National Institute for Health (NIH), specifically their Longitudinal Study On Aging (LSOA, description and data available at http://www.cdc.gov/nchs/lsoa/lsoa2.htm). These data are based on an initial cohort of 9,447 persons who were age 70 and over in 1995. Those persons (or their proxies when deceased) have been interviewed at three different times (waves), approximately two years apart. We have chosen to use the last two waves, as the questionnaires were more similar between those two waves than between the initial and second waves. We thus obtained access to state variables at two-year intervals. The choice of vulnerability domains and higher level vulnerability categories was mostly driven by the availability of data and by local expert knowledge [9].

Table 1 provides a list of the vulnerability domains considered, grouped into six categories. The LSOA study contains several hundred different fields, and we have selected a subset of 61 features in addition to the 34 state variables described above. Some (limited) data cleaning effort was required. We have modified fields to reduce granularity; for instance, the field *Type of Residence* contained about 15

different possible answers, which we reduced to five different types, capturing the majority of the answers. Also, fields such as *Age* or *Number of Children* were discretized into smaller numbers of states.

Table 1– Vulnerability Domains

State Variables **Category(number of variables):**list of variables
Sensation (2): Sight – Hearing
Social Involvement (2): Socially Active with friends - Socially Active with relatives
Mental Health (2): Frequency of sadness or depression, self-rated memory
Fundamental Daily Activity (6): Ability to eat, bath, dress, walk , get out of bed or chairs and use the restrooms independently
Extended Daily Activities (2) : Social Living Abilities, Cognitive Living Abilities
Medical (3) : Self-rated Health, Injured from Fall, More than three chronic conditions

The Bayesian network model was learnt using the Jsmile reasoning engine for graphical probabilistic models (available at http://genie.sis.pitt.edu/). We used the greedy-thick-thinning algorithm with various combinations of the learning algorithm parameters (type of priors and maximum number of parents allowed). While we do not have data to validate the value of the vulnerability indexes, we chose the best set of parameters for the learning algorithm by taking the one that had the best next-period prediction accuracy, which we computed by applying the Bayesian network prediction to test data that we had held from the training data. The model was then integrated and deployed into a real tool currently being deployed in a Beijing neighborhood. Figure 4 provides a snapshot of the user interface associated with a previous iteration of our model (with fewer categories). In that interface, we do not directly present the full vulnerability profile (meaning values for each of the 14 vulnerability domains) but rather aggregate each category by reporting the worst vulnerability index associated with that category (second column). In addition, we provide historical values (third column) and contributing factors (fourth column) to the care worker using the dashboard.

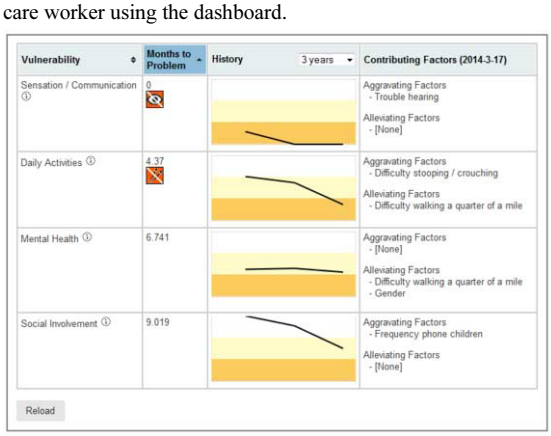

Figure 4 – Screenshot of the Eldercare Dashboard

To illustrate the effect of the known information on the vulnerability profile, we provide in Table 2 the profiles associated with four different information contents associated with a patient. Person 1 corresponds to a "Married 75 year-old man". Person 2 corresponds to the same profile, except that we also know that the person suffers from diabetes. Person 3 builds upon person 2 with the additional knowledge that the person has difficulty walking and that he feels depressed some of the time. Finally, person 4 is an even richer (and more dire) description of the person current situation. However, person 4's profile still represents incomplete knowledge of the person, capturing 10 out of the 61 factors contained in the model.

The first two columns in Table 2 are fairly similar, though there is a consistent minimal increase of vulnerability (decrease of the indexes) for person 2, who also suffers from diabetes. This is an example of cross-influences of a medical factor on social domains. The largest difference is associated with the *More Than Three Chronic Conditions* domain. As diabetes is a chronic condition, such change is logical. When comparing persons 2 and 3, we first notice that *Difficulty Walking* is now null for person 3, a direct consequence of the fact that we have observed this difficulty; it is no longer a vulnerability but rather a need. Notice again that many other vulnerability indexes have decreased as well, illustrating cross-influences. Only *Frequency Sadness and Depression* has increased, indicating lessened vulnerability. This is not surprising as feeling sad or depressed only *a little of the time* constitutes in fact positive evidence compared to the unknown state. Finally, person 4 represents a significant aggravation of person 3's state, with many additional physical and medical difficulties and a worsening of the mood. At this point, the profile enables the care coordinator to prioritize among the multiple dimensions considered, possibly leading to a focus on social living abilities and fundamental living activites as the most pressing problems for the patient, besides addressing his mental health need.

Table 2 – Illustrative Vulnerability Indexes (in Years)

	Person 1	Person 2	Person 3	Person 4
Difficulty Dressing	7.51	7.49	4.42	1.12
Difficulty Eating	15.55	15.52	11.10	5.34
Difficulty Walking	3.24	3.22	***0.00***	***0.00***
Difficulty Using Toilet	8.83	8.81	5.11	2.14
Difficulty Getting Out Chair Bed	5.77	5.74	2.97	1.10
Sight Level	6.54	6.54	5.82	4.70
Hearing Level	2.70	2.66	2.58	2.26
Socially Active Friends	12.28	12.27	11.33	9.29
Socially Active Relatives	23.12	23.11	20.58	15.98
Frequency Sadness Depression	6.65	6.61	***7.96***	**0.00**
Self-Rated Memory	32.10	32.06	31.69	31.01
Difficulty with Social Living Abilities	4.05	4.04	2.59	0.43
Difficulty with Cognitive Living Abilities	4.30	4.29	3.37	1.55
Injured From Fall	4.45	4.45	3.56	2.83
More Than Three Chronic	9.10	***7.11***	6.13	3.79
Self-Rated Health	13.92	13.78	9.69	4.50

Person 1: Married 75 year-old man
Person 2: Married 75 year old man with diabetes
Person 3: Married 75 year old man with diabetes and difficulty walking and feeling sad or depressed a little of the time
Person 4: Married 75 year old man with diabetes, hypertension, difficulty walking, stooping and finger grasping, feeling sad or depressed all of the time, who has not left his house more than 5 days in the past 2 weeks, who is a smoker and who is not able to do light house work in his home

Discussion

Person-specific standardized assessments have long been presented as one of the solutions to improve the effectiveness of social support. InterRAI [10] and the Northern Ireland Single Assessment Tool (NISAT) [11] are two suites of

coordinated assessment tools that provide such solutions in the domain of elder care. However, both NISAT and InterRAI constitute descriptive tools, seeking to capture and record an accurate profile of the patient at a given time. By contrast, the essence of our model is to predict the current and upcoming needs of a person without having to go through a complete assessment process. In that sense, it is complementary to these existing assessment suites. It can be used for triage/screening purposes to better prioritize actions to be taken, be they completing a given set of assessments, or direct action such as provision of services. Our model is also designed to bridge health and social care by providing an explicit representation of the interactions between domains.

The main impediment associated with our proposed modeling framework remains the challenge of building the underlying model from limited information. In the elder care case study that we presented, while we were satisfied with using the LSOA study, it is less than ideal as it represents an American cohort for a model to be applied in China. While some aspects of aging are universal, others are cultural and therefore local. To faciliate the construction of the model from limited data, we are currently exploring methods to build Bayesian network models from disparate, overlapping, and possibly conflicting sources of information. Indeed, in most practical cases, and especially when health and social issues are modeled together, it will not be sensible to assume that individual data will be available in one single datatable for all the variables required in the network. The novel methods that we are currently investigating will mean that the model does not require one clean dataset to be built but can be assembled from a collection of messy disparate sources of information such as

- Data sets at the individual level, covering a subset of the nodes in the network
- Aggregated information for a subset of the nodes of the network
- Expert information (influence statements and probability statements)

Specifically, we are extending methods from the artificial intelligence community. In particular, we have looked at adapting the PC algorithm [12] to build a Bayesian network from multiple overlaping datasets and from a set of expert statements extracted from the literature.

One useful feature of the model that we have not yet mentioned (and that is relevant to model building) is the fact that it can function with imprecise information. So far, we have assumed that the parameters of the model were point estimates (i.e., that we have enough data or definite domain expertise to determine a single value for each one). Again, this may not necessarily be the case in practice, either because data is limited, experts are unsure, or because multiple experts have proposed different values. In such situations, being able to handle imprecise information is essential if one does not have the time or budget to resolve conflicting information or gather more data. Both Markov chain and Bayesian network models admit imprecise extensions in the form of the Markov Set chain [13] and Credal Network [14] respectively, which enable researchers to rigoroulsy percolate the imprecision through the assessment in a logical fashion. Besides increased computational complexity, the only consequence of allowing for imprecision in the model is the fact that the vulnerability indexes would also become intervals and thus may be more difficult to interpret.

Conclusion

In this paper, we present a modeling framework for person-specific standardized vulnerability assessment in health and social care. This model combines a Markov chain model that describes the evolution of persons through states with a Bayesian network that enables researchers to customise the Markov chain parameters. The purpose of the model is to estimate the vulnerability profile of a person based on limited input information so as to provide health professionals and social care workers with a holistic view of the person's profile when they receive new situations or update existing ones. We present an application in the context of elder care though our model that can be applied in a variety of health- and social-care scenarios and is especially relevant for cases that bridge multiple domains.

Abstract

Mobile technology use is nearly ubiquitous which affords the opportunity for using these technologies for modifying health related behaviors. At the same time, use of mobile health (mHealth) technology raises privacy and security concerns of consumers. The goal of this analysis was to understand the perceived ease of use, usefulness, risk and trust that contribute to behavioral intention to use a mobile application for meeting the healthcare needs of persons living with HIV (PLWH). To understand these issues, we conducted focus group sessions with 50 persons living with HIV and 30 HIV healthcare providers. We used the e-commerce acceptance model to analyze our focus group data. Findings from the study demonstrated the need for mHealth to be perceived as useful, easy to use, with little perceived risk accompanied by a measure of trust in the creators of the technology. Findings from this work can inform future work on patients and providers' perceptions of risk, trust, ease of use and usefulness of mHealth technology.

Keywords:

mobile health; HIV; privacy; trust; security

Introduction

Mobile technology is nearly ubiquitous as increasing numbers of people carry a mobile device [1]. As such, mobile technology offers a unique opportunity for the diffusion of behavioral health interventions. Mobile health (mHealth) technology can guide decisions about health by providing round-the-clock real-time feedback [2] and opportunities for consumers to learn about and manage their disease.

These characteristics of timeliness and accessibility are particularly relevant to care for HIV which has shifted from a disease with a high mortality rate to one requiring lifetime chronic care and health monitoring. mHealth tools can help address many of the healthcare needs of persons living with HIV (PLWH) to promote retention in HIV care and adherence to medication regimens[3]. In the US, 1.2 million people are currently living with HIV [4], with worldwide estimates at 35 million [5]. A number of studies have shown promise for the use of mHealth for supporting HIV care [6-9].

Our study population included PLWH who were the targeted end users of a smartphone application (app) designed for monitoring and managing their health and for communicating with their care providers. PLWH is a relevant study population due to both their need for self-management support in chronic care as well as the persistent cultural stigma associated with HIV/AIDS [10].

Despite the promise of mHealth in monitoring health behaviors and improving the delivery of health care, little is known about users' concerns over privacy and information sharing using mHealth technology. Privacy has been a topic of interest to researchers in psychology, sociology and more recently information technology (IT) [11-13]. Existing research on privacy emphasizes data security and confidentiality, largely focusing on electronic medical records. Yet consumers concerns around privacy related to mHealth technology use remain poorly understood. There are a number of issues related to privacy and information security in HIT that need to be carefully monitored and addressed in order to offer a technology most likely to engage consumers. The purpose of this study was to understand the perceived ease of use, usefulness, risk and trust that contribute to behavioral intention to use a mobile app for meeting the healthcare needs of PLWH.

Theoretical Framework

We used the e-commerce acceptance model (EAM) to understand technology acceptance of mHealth for PLWH [14]. The EAM has not been previously studied in the context of health or mobile technologies. It builds on the most widely employed model of IT adoption, the technology acceptance model (TAM) which we have previously studied in the context of the delivery of HIV care through an electronic record [15].

The dependent variable in this model is the same as in the TAM: behavioral intention to use the technology. The key constructs in the TAM are perceived usefulness and perceived ease of use [16]. In the case of health information technology (HIT), perceived usefulness is defined as the extent to which a person believes that using the HIT system will enhance his/her outcomes. Perceived ease of use is defined as the degree to which system use will be free from additional effort [17].

In the EAM, trust and perceived risk are two key drivers added to the TAM variables using the overall structure of the Theory of Reasoned Action (TRA) [18]. Integration of the four independent variables were tested and their relationships were validated. The model proposes that these four drivers lead to the primary constructs of "intention to transact" and "on-line transaction behavior" in the e-commerce sector, which in many ways may mimic consumer behavior in eHealth.

Trust is a behavioral belief that has been studied in e-commerce and has been shown to have a favorable effect on consumers' intent to use a technology. Trust may be defined as the belief that the other party will behave responsibly and will not attempt to exploit the vulnerabilities of the user [14]. There are two kinds of trust: 1) party trust - trust in the

benevolence and credibility of a particular party; and 2) control trust - trust in the integrity of the transaction medium. The importance of trust is heightened when there is a high degree of uncertainty which can happen in the case of HIT when users don't understand where their information is being stored or how it is being transmitted.

For mHealth use, we would expect that consumer trust in the mHealth app is likely to influence behavioral intention to use the technology [19]. Trust is also related to perceived usefulness because users may not be certain that outcomes may be achieved unless there is confidence in the entities behind the HIT system. Trust is related to perceived ease of use because it reduces the efforts that would otherwise be necessary to monitor the proper functioning of the system. Trust is also related to perceived risk as a higher level of trust in an on-line entity reduces the perception of risk during the interaction.

Perceived risk is an important factor for eHealth use in light of the distance, in both time and space, between the consumer and the healthcare entity, as with most on-line transactions. It may be described as a degree of uncertainty related to use of the medium that is beyond the control of the information manager associated with the eHealth service. The consumer risks the possibility of suffering a loss while using the technology [20]. mHealth users perceive risk when the security of the infrastructure for securing their personal health information is not verified. Consumer perception of risk is negatively associated with intention to transact. Similarly, if an end-user perceives the risk of disclosure of their personal health information to be low then they are more likely to use a mHealth app.

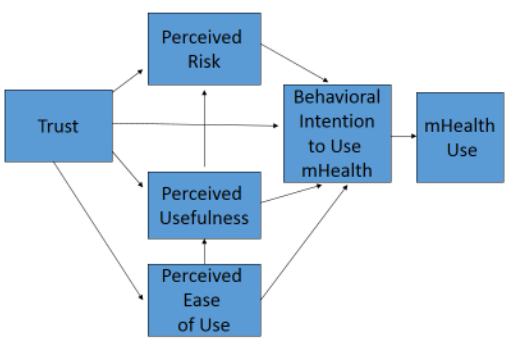

Figure 1– E-Commerce Acceptance Model applied to mHealth Technology Use

To better understand the applicability of this model for mHealth technnology, we used focus group data which was collected as part of a larger study to to inform the development of a mobile app for HIV treatment and care for PLWH. The purpose of the larger study was to elicit from potential app users and their care providers the desired content and features of a mobile app for meeting and improving the health care needs of PLWH. The goal of this analysis was to understand the EAM constructs that contribute to behavioral intention to use a mobile app for PLWH.

Methods

Design

This study applied user-centered participatory design methods to inform the content of a mobile app for HIV treatment and care. The qualitative study was implemented using focus group methodology.

Sample

The sample comprised PLWH and clinicians and case managers who provide care to PLWH.

Procedures

The Columbia University Medical Center Institutional Review Board reviewed and approved this study protocol. Focus group sessions were moderated by a trained facilitator using a focus group guide. Each focus group session was also attended by at least one additional study team member who recorded notes and tended to logistics such as consent forms, food, and compensation to ensure that the groups ran smoothly. Following completion of the individual informed consent process and prior to the start of each focus group session, participants completed a demographic survey.

Each PLWH focus group session took place in a conference room at the Columbia University School of Nursing campus, lasted between 48-72 minutes and was conducted in English or Spanish. The HIV clinicians and case managers' focus groups took place at a conference room at their workplace in the following locations: New York Presbyterian Hospital, the Brooklyn Hospital Path Center, and AIDS Service Center, a community-based organization. We gave $25 to our PLWH participants and $50 to the clinicians and case managers as a token of appreciation for their time. Food appropriate for the time of day was served during each focus group session. All focus group sessions were audio-recorded and transcribed for analysis.

We asked a series of questions during our focus group sessions to identify the functional specifications of a mobile app for PLWH. At the end of our focus group sessions, we specifically asked focus group participants: "What are some of the privacy and confidentiality concerns that you anticipate encountering when using a mobile health app on your phone?"

Data collection continued until saturation was reached, which occurred when we heard similar patterns and themes across groups and no new information was being shared [21].

Data Analysis

Descriptive statistics of the demographic information were calculated using SPSS version 21. To support the credibility of the data, we used "member checks," i.e., sharing of initial data interpretations with participants to ensure accurate interpretations. In addition, after each focus group, we conducted peer debriefing and triangulated findings across participants and facilitators. Research team members subsequently coded the transcripts using NVivo™ (QSR International, Victoria, Australia) software. We coded the data using the four constructs of the E-commerce acceptance model to deductively code focus groups to understand factors related to mHealth technology use. Coding of transcripts continued until consensus was reached.

Results

Sample

We conducted six focus group sessions with PLWH (n=50). Two of the focus groups were conducted in Spanish and one of the groups was comprised of only female participants. There were 37 male participants and 13 female. Participants' ages ranged from 18-59. Participants self – identified as Black (N =26), White (N =7), Pacific Islander (N = 1), and American Indian (N =1) and the remainder of the participants

did not report their race. Half of our participants (N =25) self-identified as being of Hispanic/Latino ethnicity.

In addition, we conducted three focus group sessions with HIV care providers which included clinicians and case managers. All focus groups were conducted in English. Participants' ages ranged from 23-62 years and included 5 males, 24 females and 1 transgender female. Participants identified as Black (N =9), White (N =17), Pacific Islander (N = 1), and Asian (N =3). Six participants self-identified as being of Hispanic/Latino ethnicity.

Findings

We used the four constructs of the EAM to understand factors related to mHealth use in PLWH. Our focus group findings were organized according to the four broad constructs: trust, perceived risk, perceived usefulness, and perceived ease of use (Table 1).

Table 1– EAM Constructs and Sample Quotes

Construct	Sample Quotes
Trust	• I am wondering why they're interested in all of this (creating and HIV app) all of a sudden." [PLWH]
Perceived Risk	• One of barriers is a concern that you'll be able to track the person. [PLWH]
Perceived Usefulness	• It's very non-confrontational that way, and I think that's a big benefit of texting [Healthcare Provider]. • It would be really good if the doctor or CDC put that in an app so that you have access to it and you can show it right then and there [PLWH]
Perceived Ease of Use	• Just to learn a new thing (app/ smartphone use) it's becoming difficult [PLWH]

Trust

PLWH recognized the need for security safeguards and controls so that they could trust using an mHealth app. For example, one participant said, "provided the company that furnishes the app, has the right security so the information does not leak. Having that security, then there is no problem." Another participant cited an example of a security system tied to the device which would make him feel comfortable using a mHealth app for PLWH. "The warranty from the company that makes it…the security the company has of itself, which in this case, well, benefits us, so that information does not leak." Participants had concerns over who would have access to their information and didn't trust certain entities to access their personal health information.

Perceived Risk

A number of participants expressed concerns over the risk of who would have access to their information, where it would be stored and if their HIV status had the potential to be disclosed. One participants said, "It's like she said about technology, you don't know where this information is going." Another participant had the perception that anyone can access any information that is on the Internet. She said "Because right now anybody could get into the Internet and go into your information."A younger participant in another focus group which was comprised of 21-24 year olds said, "As far as using an app I would probably never put information in, I wouldn't personally because technology is out of order now. People can find out anything. You can do the fingerprint thing. Where is this information going to, who is seeing it, because it's being documented? Where is it going?" Since smartphones have the functionality to detect your location, participants perceived a great risk to being tracked. For example one participant said "It's like I don't know…with the location settings with the iPhone and all that stuff." Participants did acknowledge that a certain amount of risk may be acceptable or unavoidable. One focus group participant said, "We just have to get, how can I say it, a little secure about it. Because I didn't like, where I worked at, I didn't like them scanning all my information and putting it on the computer. Because the computer can be hacked in, in any given time, you understand? But I got comfortable with it. So, it's a period you got to go through. You've got to adjust to certain things in life."

Perceived Usefulness

PLWH thought that mHealth had the potential to be very useful for their care. For example one patient thought that it would provide updates on medications. "Like new medications. Every couple of months they come out with new HIV medication." Another PLWH thought the mHealth would be a useful tool for creating reminders "I think some phones have a memo device where you could actually talk into it and say…" Participants also thought it would be useful for learning more about their disease or sharing information with others. For example, one PLWH said, "Since we already have our immune system compromised, we should know for example if we have something, know what it is, and the faster the better so we take care of our health."

Providers, like patients, thought that mHealth can be very useful in the delivery of care to PLWH in a private manner. For example, one provider said, "Think about it, when they're on the phone somebody else can hear their end of the conversation. If they're texting, no one knows what's going on." Providers also thought that mobile technology was important for their patients to be able to self-manage their care. "Some of them use their phones for alarms. They have alarms set on their phones and they have calendar applications where they can write appointments."

Perceived Ease of Use

Both PLWH and providers described a number of factors related to ease of use that would facilitate use if present and otherwise would present a barrier, such as reliable phones, simplicity, and operation autonomous from an Internet connection. One PLWH said that "I would be willing to use the app if I have the phone with no problems." Another participant echoed a similar sentiment and said that "because sometimes there are some apps that are a bit complicated and well people get frustrated immediately, and later they don't use them. It has to be something simple." Both PLWH and providers thought that an app should not rely on Internet connectivity. Specifically, one provider said "An app would be helpful if certain parts of the app didn't need internet."

There were also a number of patients and providers who described the need for a simple, easy to understand app. A provider commented on the need for information presentation to be understandable, even to patients with "cognitive disability." Specifically, she said, "So even a graph that can be simple to us may not be something they're easily able to read." Another healthcare provider, in a different group echoed a similar idea and said, "It has to be simple enough that the person can really get hooked to it."

Discussion

The increase in the use of mobile technology has the potential to improve the delivery of healthcare, but it has also raised new concerns over privacy and security of personal health

information [22]. At the same time little attention has been paid to understanding technology acceptance in mHealth with a particular focus on privacy and security. Mobile devices and apps have created a new set of privacy concerns since protected health information can be stored on mobile devices, processed within these apps or shared via networks that are not secure [23]. While mHealth holds great promise, if patients are not willing to use the technology because it is not perceived as useful, easy to use or they have concerns over data security then it will not be able to improve health outcomes.

Concerns over mHealth acceptance and use becomes particularly relevant as patients and consumers begin to transfer their personal health information from their mobile devices to a central electronic health record. For example, Apple has started a partnership with Epic [24]. In addition, open platforms such as Apple's Healthkit [25] and Google Fit allow patients to transfer their personal health information to a central electronic health record, yet these systems are still quite limited and are focused on fitness.

In this study, we sought to examine PLWH and their healthcare providers' perceptions of the technology acceptance factors necessary for PLWH to use an HIV app to manage their health. Many study participants thought that a mobile app for PLWH would be extremely useful.

Participants also stressed the need for the app to be easy to use, consistent with past research in HIV care. In particular, participants suggested the app not rely on Internet connectivity. Both PLWH and providers described the cognitive deficits that are often experienced by PLWH and therefore the need for the app to be very simple and straightforward.

At the same time, there was an underlying concern over security of their information. Participants throughout our sessions wanted to understand who would have access to their personal health information. They emphasized the need to trust the "owner" of the app and if a particular company or institution was associated with the app then they would not be willing to use the app for accessing, entering or sharing their personal health information.

Perceived risk was an underlying theme throughout our nine focus group sessions. Participants were concerned over where their data was being stored and who would have access to their data. Their concerns included trust in the institutions that collect, store, or transmit their data as well as general apprehension about data transfer using the Internet network and technological devices which are continually under development. In the US, there have been a number of policy initiatives at the federal level to protect patient health data being transferred electronically. Of note, the Markle Common Framework has a set of published principles that provide the foundation for managing personal health information within consumer accessible data streams[26]. The Markle Connecting for Health Framework has guided the US government implementation of IT including the Health Information Technology for Economic and Clinical Health (HITECH) Act [27].

Even with this guiding set of principles which is quite extensive and comprehensive, consumers remain concerned that their personal health information is not secure and they have particular concerns regarding the risks associated with mobile technology in sharing and accessing their personal health information.

We did not specifically ask study participants about their intention to use this technology. Instead, we examined study participants' perceived ease of use, usefulness, trust and privacy. The lessons learned from our examination of each of these constructs are important for the development of this technology especially in a highly stigmatized population [28]. As a result, the intersection between the findings from each of our study constructs is likely to predict a PLWH's behavioral intention to use a mobile app for managing his/ her health.

Limitations

We conducted this study in New York City, which limits the generalizability of the findings to one geographic area. Even so, New York City has the greatest number of PLWH in the Unites States making this an appropriate setting for conducting this work [29]. In addition there may have been a response bias from our study participants since our methods relied on self-report.

Conclusion

Findings from this work can inform future work on patients and providers' perceptions of risk, trust, ease of use and usefulness of mHealth technology. Findings from this work have broader applicability to others living with chronic diseases as well as any individuals who seek to use mobile technologies for accessing, storing and sharing their personal health information. Future development of mHealth technology needs to integrate ease of use, usefulness, trust and perceived risk to facilitate the use of mHealth technology for consumers.

Electronic Health Record System Contingency Plan Coordination: A Strategy for Continuity of Care Considering Users' Needs

Marcela T. Fernández, Adrián R. Gómez, Américo M. Santojanni, Alfredo H. Cancio, Daniel R. Luna, Sonia E. Benítez

Health Informatics Department, Hospital Italiano de Buenos Aires, Argentina

Abstract

Electronic Health Record system downtimes may have a great impact on patient care continuity. This paper describes the analysis and actions taken to redesign the Contingency Plan Procedure for the Electronic Health Record System of Hospital Italiano de Buenos Aires.

After conducting a thorough analysis of the data gathered at post-contingency meetings, weaknesses were identified in the procedure; thus, strategic actions were recommended to redesign the Contingency Plan to secure an effective communications channel, as well as a formal structure for functions that may support the decision-making process. The main actions were: 1) to incorporate the IT Contingencies Committee (Plan management); 2) to incorporate the Coordinator (general supervision of the procedure); and 3) to redefine the role of the Clinical Informatics Resident, who will be responsible for managing communication between the technical team and Electronic Health Record users. As users need the information for continuity of care, key users evaluated the impact of the new strategy with an adapted survey.

Keywords:

Downtime; IT Management; Survey; SWOT Analysis.

Introduction

Continuity of patient care as a health care process acquires great potential through information technology (IT). However, when applications or systems fail, the technologies become a dangerous vehicle for the perpetuation of erroneous information that may lead to mistakes in diagnosis and higher monetary costs [1]. The critical nature of hospital care impacts patient information management, therefore institutions are forced to plan and formalize courses of action to maintain their IT infrastructure at times of crisis[1].

During the review of the events experienced at Hospital Italiano de Buenos Aires (HIBA) and relevant literature [2,3], it has been noted that when all instances of "redundancy" and "control" designed to support and guarantee service continuity are exhausted, the institution's own alternative procedures are implemented in order to protect all crucial information. The impact of technology and informatization on hospitals' operating processes must be addressed as a complex process developed over time where an institution-wide transformation process is evident [3]. This process involves knowing and rating systems' "life cycles", as well as the importance of weighting the lessons learned from disasters and crises that may jeopardize patients' data management. In order to offer continuity of patient care, technology is useful if the regulation, standardization, and protection of critical operating processes and relevant information are solved beforehand [4]. Therefore, it is essential to make periodic adjustments to the action plans designed by the institution for contingencies. The objectives of this study are to describe the redesign of the contingency plan of the Electronic Health Record (EHR), as well as to know the users' perceptions of it.

[1] Crisis or disaster recovery, such as power failures, general hardware failures, logical or physical breaks in data connections, or downtimes planned for application updates.

Materials and Methods

Background

The HIBA is a high complexity teaching hospital founded in 1853. It is member of a nonprofit health care network that runs a second hospital, 25 outpatient clinics, and 150 doctor's offices distributed throughout the city of Buenos Aires and the surrounding metropolitan area. This infrastructure also includes 750 hospital beds, 200 of which are prepared for intensive care, 1200 home care beds, and 41 operating rooms. The network is composed of 2800 physicians, 2800 health care agents, and 1900 management and administration staff.

A Health Information System has been gradually implemented since 1998, based on an in-house development process where medical and administrative information is managed from data gathering to data analysis. A modular, patient-centered, web-based EHR focused on problems, and known as ITALICA, has been implemented by the hospital. This EHR may be used to register outpatient care, hospitalization, emergencies and home care related data.

There is a formal procedure that defines the actions and forms of communication for maintenance of the processes while the EHR system recovers from a significant disruption.

This procedure was implemented in planned and unplanned downtimes. The procedure was tested during the following year, and after every downtime there were meetings with key users of the EHR system in order to learn of the impact to the workflow. Since the preliminary results showed inefficient communication, the procedure was redesigned.

The key users involved the most critical processes of the hospital, such as the Emergency Department, Laboratory, Nursing Department, Patient Admission area, Imaging Department; and specialized areas of the Health Informatics Department (HID) such as the Help Desk, Software Engineering, Clinical Informatics, and Policies & Procedures involved in the development process and operations for the activation and deactivation of the Plan. The IT Contingencies team is composed of key users of the EHR and members of the HID staff.

Definitions

For the purpose of this research, the following definitions were used (see Figure 1):

- Patient Care Continuity [5]: Different aspects referred to the treatment to be applied to a specific health condition, from both chronological and geographical standpoints.
- IT Contingency Plan: A program detailing the methods and means necessary to control risk in information systems and to minimize negative consequences.

In this paper, we have analyzed the "high availability" and "IT Contingency Plan" concepts as two different yet supplementary notions. The "high availability" and "IT Contingency Plan" principles are IT management tools that represent the purpose of "continuity". The first concept refers to technology and information systems-based mechanisms, while the second one secures continuity based on alternative procedures that encompass all of the hospital's resources, including paper records of patients' medical evolution.

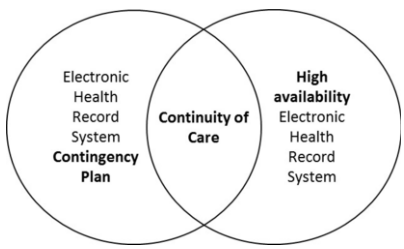

Figure 1 - Institutional Framework for Continuity Care

The redesign process is diagrammed in the following figure (see Figure 2). The first step was the SWOT analysis of the original procedure. A survey administered to key users was the next step. Finally, a new version of the survey was designed and validated by a committee of experts.

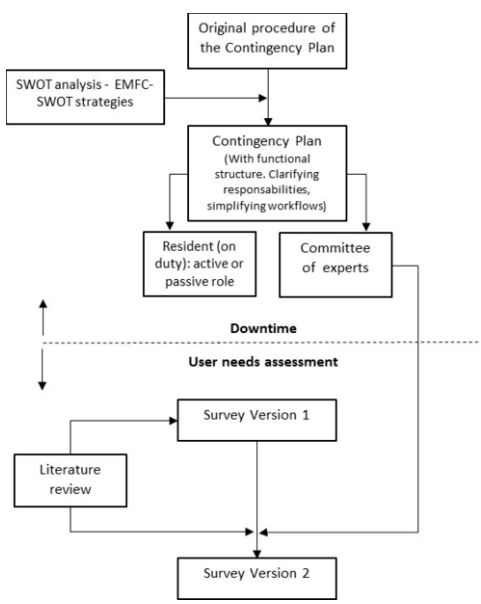

Figure 2 - Global Chart of the Redesign Process

Redesign

A SWOT analysis (see Table 1: strengths, weaknesses, opportunities and threats) was performed to redesign the procedure, and four possible implementation strategies were prepared[2]. Additionally, the work structure applied was based on rules and standards.

On the one hand, the NIST special publication 800-34 [6] and the guidelines for Contingency Plans preparation and drafting were considered to structure the Contingency Plan management and coordination; and on the other hand, the ISO 22301:2012 standard about "business continuity" management was considered to approach the "Plan-Do-Check-Act" [7] process applied to plans and procedures maintenance. Even though COBIT Management Guidelines [8] were considered, this paper is focused on users' needs.

Table 1 – SWOT Analysis of the Procedure of the Contingency Plan of EHR N°98/12 01 00

Strengths	Opportunities	Weaknesses	Threats
Technical capabilities of key areas of the HID	The Institution has specialized technicians and analysts to define processes and procedures	Lack of a clear position that handles the coordination and supervision to ensure the effective conduction of the proceedings	Facing crisis and contingencies, regarding critical services, is a process that relies on "key actors"
Includes a flow of communication for the activation and deactivation of the plan			
Use of software especially designed for contingencies	There is an institutional interest in reviewing plans based on the Policy "Continuity of Patient Care"	The procedure should clarify the active or passive mode of the workflow by the Resident on duty	The level of participation of critical sectors in post-contingency meetings does not meet the expectations
Clearly defined times of response			

EMFC-SWOT [9] Matrix results (Explore, Maintain, to Face, Correct) were obtained as a result of the SWOT analysis performed (see Table 2).

Impact assessment

With an adapted survey [10], key users assessed the impact of the new strategy. The redesigned procedure was evaluated after the unplanned downtime that took place on June 24, 2014.

With the findings of the first adapted survey and the literature review [11], a new version of the survey was designed. Once the preliminary list of questions was elaborated, the steps to follow were: (a) assessment by a committee of experts, (b) pretesting, (c) the validation itself, and (d) implementation. Pretesting was conducted with key users, who invited new users to participate in successive iterations.

[2] The analysis universe was the EHR Contingency Plan Procedure N° 98/12 01 00. Strengths and weaknesses refer to the features of the procedure (internal environment), while opportunities and threats refer to the microenvironment context, in this case the HIBA.

The EHR system was affected by the unplanned downtime that took place on June 24, 2014. The post-contingency review was conducted on June 25 and July 17, 2014.

Results

Tests of the original procedure were conducted from December 2012 (formal publication) to June 2014. The post-contingency documentation and data analysis were conducted between April and June 2014.

As a major input, the SWOT analysis suggested a new allocation of responsibilities regarding procedural coordination and supervision. Strategies derived from the analysis were implemented and continue to be in place to-date (EHR Contingency Plan Procedure N° 98/12 01 01), taking into account the following strategic EMFC-SWOT Matrix that considers the four most relevant strategies to be followed:

Table 2 – EMFC-SWOT Matrix. Strategies to correct weaknesses detected in the procedure

Evaluation		Strategy		Action
weaknesses	Lack of definition in the coordination and monitoring of the process	**correct**	Develop a well-defined functions' framework	**I**
threats	Strong dependency on "key actors" on critical services	**to face**	Develop a procedure for activation and deactivation of the Plan, and update the instruction manuals in critical areas	**I**
strengths	Use of software especially designed for contingencies	**maintain**	Expand the use of contingency focused applications to all critical services	**V**
opportunities	There is a Policy for the Patient Care Continuity Plan	**explore**	Develop a Standard / Policy on the IT Contingency Plan	**P**

***I**: Immediate application; **P**: Programmed; **V**: Viability should be studied*

New procedure

The following recommendations are made based on the findings of the procedure's post-contingency analysis:

- Incorporating two new players: the *IT Contingencies Committee*[3] (Plan management), and the Coordinator (general supervision of the procedure).
- Redefining the role of the *Clinical Informatics Resident,* who will be responsible for managing communication between the technical team and EHR users.

[3] This is a department Committee formalized by Policy N° 73/14 IT Contingency Plan. The IT Contingencies Committee is made up of the Head of HID, the Deputy Head of HID, the Head of Clinical Informatics, the Head of IT, and the Head of Software Engineering.

Findings of the first version of the survey

The redesigned process was subjected to evaluation through a survey conducted post-contingency of the unplanned downtime of June 24, 2014. The survey showed:

Table 3 – Survey Results. Unplanned downtime, included EHR: June 24, 2014. Post-Contingency survey: June 25 & July 17, 2014

Questions	A	B	C	D	E
1. How downtime affected the workflow?	Great Impact	Moderate	No impact	No impact	No impact
2. Were there problems to communicate with HID?	YES	NO	NO	NO	NO
3. How long did you wait to launch the Contingency Plan?	10'	Up to 5'	Up to 5'	1 hour	1 hour

***A**: Imaging services Department; **B**: Laboratory; **C**: Emergency Department; **D**: Nursing Area; **E**: Admissions*

Validation of the second version of the survey

The operationalization of variables and the questionnaire design were validated by the IT Contingencies Committee for the purpose of measuring users' opinion on the redesigned procedure and how it affected their workflow from downtime to uptime.

The new survey variables are: knowledge of the procedure; Plan implementation; user's response capacity; accessibility during downtime; post-contingency data restoration; communication (between the HID and the areas); workflow impact; registration possibilities; and the time needed to activate the Plan.

The pre-testing, started on January 19, 2015, assessed the post-contingency of the downtime planned for January 7, 2015. This assessment was conducted by 12 representatives of the hospital's critical areas or services. The pretesting resulted in the reorganization of questions and the modification of some words for a better understanding.

The most important pretesting findings were related to communication, an alternative work plan, and training. Users perceived that communication with the HID has improved. As for planned downtime, they have recognized to have an alternative work plan when downtime occurs. As for unplanned downtime, they stated that training is necessary.

Discussion

This paper describes the analysis and actions taken to redesign the HIBA's EHR Contingency Plan. It also provides answers to questions regarding the importance of regularly reviewing plans, as well as of formally describing a functions structure.

The procedure's redesign was changed while structuring functions, and it triggered the creation of an IT Contingencies Committee that comes into play in case of contingencies so as to facilitate the Plan's management coordination, supervision, and communication. The original procedure showed the flow of activities were conducted so that the HID may activate and

deactivate the Plan, but it did not clearly describe the decision making process. Restructuring functions and responsibilities while redesigning the Plan turned out to be essential to providing the team with adequate leadership, and to make decisions despite the uncertainties proper of any contingency.

According to the findings of the first version of the survey that was performed after the unplanned contingency, the workflow of the imaging services department was the most affected, as, unlike all other services, communications with the HID reported to be delayed. During the downtime period, most services used paper-based forms while only two services used the software and hardware specially designed to face the contingency.

Although it may be assumed that recommendations made regarding the IT Contingencies Committee, the procedure's supervision, and the coordination role to improve communication with all other sectors, will positively affect the Plan's execution, these results may not be generalized, as the survey was only conducted on key users. In addition, the survey (see Table 3) was translated from English to Spanish and it did not take into account cultural differences, nor was it validated. The second version of the survey, although already validated by the Committee, is still being tested. The main findings of this study are from first survey and the pretesting step of the second survey. The final version is expected to be conducted on general users by June 2015, after correction and validation.

As for the implications of the results, the need to regularly review procedures that are part of contingency plans becomes apparent in the systems' "lifecycles". These are not static procedures; they keep pace with the dynamics of IT systems that may change either gradually or abruptly as cutting edge technology moves forward. Therefore, the maintenance stage is an important part of the EHR Contingency Plan.

An important aspect of this paper is how users' needs have been approached. Despite the fact that authors do not pay much attention to this [12,13], it is important to consider users because they are in contact with the information system and are responsible for recording the patient's clinical evolution.

Based on our findings, we suggest three future lines of work:

1. Performing a new IT risk analysis to supplement the Standard on IT Contingency Plan and the institutional Standard/Policy on Continuity Plan;
2. Conducting the EHR downtime survey validated by the IT Contingencies Committee;
3. Developing contingency applications for internal support purposes (redundancy of elements).

Because of the importance of EHR systems for hospitals [14], regularly reviewing the Contingency Plan designed for such system is paramount to achieve care continuity [15]. This review must include an efficient communication channel as well as a formal function structure that may support the decision making process.

Conclusion

First, it is important to recognize the dynamic aspect of organizations, which involves regularly reviewing their contingency plans; second, in order to make efficient decisions in a contingency scenario, it is important to have a structure in place that may guarantee the Plan's direction and supervision. As for the approach, taking into account users is key to any Contingency Plan; as in any ideal situation, it is they who should guarantee that all the information needed to achieve care continuity will be recorded.

Acknowledgments

The authors gratefully acknowledge the contribution of the "IT Contingencies" team members.

Flexibility First, Then Standardize: A Strategy for Growing Inter-Departmental Systems

Arnvør á Torkilsheyggi[a]

[a] *Computer Science and Informatics, Roskilde University, Roskilde, Denmark*

Abstract

Any attempt to use IT to standardize work practices faces the challenge of finding a balance between standardization and flexibility. In implementing electronic whiteboards with the goal of standardizing inter-departmental practices, a hospital in Denmark chose to follow the strategy of "flexibility first, then standardization." To improve the local grounding of the system, they first focused on flexibility by configuring the whiteboards to support intra-departmental practices. Subsequently, they focused on standardization by using the whiteboards to negotiate standardization of inter-departmental practices. This paper investigates the chosen strategy and finds: that super users on many wards managed to configure the whiteboard to support intra-departmental practices; that initiatives to standardize inter-departmental practices improved coordination of certain processes; and that the chosen strategy posed a challenge for finding the right time and manner to shift the balance from flexibility to standardization.

Keywords:

Standardization; Electronic Whiteboards; Organizational Implementation.

Introduction

The design and implementation of IT systems in hospitals has received increased attention as a way to improve healthcare through standardization [1, 10]. The standardization of health data facilitates comparison between departments and hospitals which subsequently allows decision-makers to make informed decisions about best practices [11], while standardization of clinical practice has shown to improve quality and reduce patient harm [9]. The reach of standards can vary; some have global reach and have already been crafted (e.g. International Classification of Diseases), while others are national, regional or even more local (e.g. a department developing a list of diagnoses for their own use). Clinicians will often perceive standardization as an unwelcome constraint on their practice, and any attempt to standardize practices through the design and implementation of IT systems is faced with the challenge of balancing the need for standardization against the clinicians' need for a technology that can support flexibility of use [2, 5]. Some have proposed to find this balance by first focusing on standardization and then configuring the standards to the local context, or in other words: first standardize, then localize [2].

This paper reports a case where the reverse approach was chosen. The case consists of the development of an electronic whiteboard system for hospitals in Region Zealand, Denmark. The system was designed in collaboration between a Norwegian vendor, Region Zealand, and Roskilde University. In 2009, the system was implemented at the four Emergency Departments in the region with the purpose of supporting their maintaining an overview of the patients at the department. The system is web-based and the basic layout of the whiteboards can be likened to a spread-sheet, with a row for each patient and columns displaying selected information about the patient such as triage level, room, chief complaint, responsible nurse, responsible physician, and current treatment activity (see Figure 1).

In the beginning of 2013 the whiteboard system was introduced at all departments in one of the hospitals in the region. The purpose of this implementation was to support and improve inter-departmental practices through standardization.

Figure 1 – The electronic whiteboard system.

Because the whiteboard system is highly customizable, the whiteboards could be configured to fit and support the practices in the wards. In order to circumvent resistance of a top-down standardization attempt, it was decided to postpone standardization attempts and to focus on securing the local grounding of the system in the wards. Selected super users were appointed to be responsible for the implementation on their respective wards, which included configuring the system to support their intra-departmental practices. These super users were shown pre-configured templates (e.g. Figure 1) and were then trained to re-configure the templates; by adding or removing columns, deciding how data should be inserted and displayed and so forth. In addition, they were trained in how to configure views or filters that the other users could activate by clicking on a button; for example if the users wished to only see patients with a certain problem, or only patients in a certain part of the ward.

The approach in the beginning of the implementation primarily focused on flexibility and configuring the whiteboards to local contexts. When the system had been configured to support intra-departmental practices and had been in use for a while, the management facilitated activities where clinicians from different departments were called together to use the whiteboards as a starting point to negotiate standardization of inter-departmental practices. This paper investigates to what extent the chosen approach of "flexibility first, then standardize," which in the managers' perspective has been a viable approach for finding a balance between standardization and flexibility in the implementation process.

Related Work

This section summarizes previous work in the following three areas: 1) the benefits and potential of standardization within healthcare; 2) the importance of developing technologies that support flexibility of use; and 3) the challenge of finding a balance between standardization and flexibility.

Several studies have pointed to the potential benefits of standardization. Some have stressed the importance of standardizing health data in order to enable comparisons and thus to allow decision-makers to make informed decisions about best practices [11]. Others have found that the standardization of practice through protocols and checklists has shown to improve quality and reduce patient harm [9]. It has also been argued that the development and implementation of IT holds the potential to improve quality and increase patient-safety through the standardization of otherwise error-prone work processes [1].

When designing and implementing technology, researchers have increasingly acknowledged that it is impossible to design a perfect system prior to actual use [2]. This acknowledgement has motivated the development of approaches that allow for local customization and reconfiguration to be performed after the implementation of the technology, when the users have had the opportunity to use the technologies in their real work [3, 6, 7]. It follows that in order to support customization and reconfiguration, the implemented technology must be configurable and flexible; in other words, it must allow for continued design-in-use [7]. Flexibility in this sense refers to developing technology that allows for further changes and reconfigurations as well as flexibility in the patterns of use [5]. However, most design-in-use approaches do not explicitly address the challenges that arise when the agenda of allowing flexibility clashes with the agenda of standardizing practices across departments, specializations and staff-groups.

Although IT can potentially support standardization, clinicians may perceive the IT as a constraint on the way they usually go about their work on various wards. This is a well-known issue within the research area of information infrastructures [2]. In order for an inter-departmental IT system – like the one described here – to be adopted by the clinicians, it has to be useful in the local context [4]. The agenda of standardization inevitably is faced with the challenge of finding a balance between standardization and flexibility [2]. Finding this balance is, however, no easy task. In their study of the customization process of an electronic triage and tracking system that was configured to be used in eight Canadian emergency departments Bjørn et al. [2] realized that it was impossible to reach a shared (standardized) solution without constraining crucial work in the departments. They therefore proposed to find the balance between standardization and flexibility by first having actors from different departments focusing on how much can be standardized without constraining local flexibility and then focus on configuring the standardized template to the local context. In other words, they proposed the approach: first standardize, then localize [2]. The approach reported in this paper suggests the opposite: focusing on flexibility first and then standardization. In the following discussion, the chosen approach will be discussed and evaluated in relation to the approach proposed by Bjørn et al.

Method

The study was conducted at a medium sized hospital in Region Zealand, Denmark, where the author has followed the implementation and use of the whiteboard system for two years. The study was approved by the hospital management. The findings are primarily based on semi-structured interviews with managers that on different levels have been responsible for managing the implementation process. Table 1 provides an overview of the interviewed managers and their responsibilities. Local Coordinator 1 (LC1) was a nurse with special qualifications who in September 2012 was asked to be a system administrator and to support the implementation process. She held this position until December 2013. At the time of our study, LC2 was the local coordinator.

Table 1 – List of Interviews

Position	Responsibilities
Deputy Director of the Hospital	Head of the local steering committee
Regional Project Manager	Managing the regional project
Local Coordinator 1	Managing the local implementation process
Local Coordinator 2	Managing the local implementation process
Chief Physician	Managerial responsibilities within the surgical department

The interviews were semi-structured. An interview guide was sent to the interviewees prior to the interviews. The guide mainly revolved around the topics: what have the challenges been in regards to managing the implementation process and how have they been dealt with; what initiatives have been taken in order to achieve standardization; how have you dealt with the challenge of balancing standardization and flexibility.

All five managers agreed to have the interviews audio-recorded. The interviews were subsequently transcribed and

analyzed according to a grounded theory approach. Each interview was coded using an open-coding process. The codes were registered in a spreadsheet along with a short description as well as an indication of which interview they originated from. The initial codes were then arranged and re-arranged through an iterative process until the three overall categories emerged: 1) Flexibility and the local: The facilitation of a user-driven process focusing on local grounding to support intra-departmental coordination; 2) Standardization and the global: The need for managerial support when standardizing inter-departmental coordination; and 3) The challenges of balancing these two concerns.

Results

Flexibility to Achieve Local Grounding

Even though the purpose of the implementation was to support and standardize inter-departmental practices, it was decided to focus first on achieving the local grounding of the system through a user-driven process. The message that the management wanted to send to the users was: *"We have been saying: we know that you are doing a great job. We know that you have the knowledge, competences and the abilities to make this even better."* (project manager). The initial focus therefore concentrated on supporting the wards in configuring the system to support intra-departmental practices.

A nurse with special qualifications from the surgical department was appointed as local coordinator. She was trained to be a system administrator and was asked to support the implementation process and to train selected users in configuring and using the system. During the fall of 2012, hospital management asked the hospital department managers to appoint 2-3 clinicians from each ward. These clinicians were given the responsibility of being super users. The super users' responsibility was to support the implementation process in their respective wards by configuring the whiteboard and teaching their colleagues how to use it. The process of training the super users to take on this responsibility started with workshops, where they were trained in configuring the whiteboard. After these introductory workshops, super users were further encouraged to attend additional workshops, where they could come and receive support in configuring their whiteboards. These workshops were, however, optional and only the super users from some of the wards chose to accept the offer. When asked why these workshops were optional, the local coordinator replied: "*We wanted to say that we really do not have an agenda. Because you should bring your agenda to us! We are just here to help you, if you need help with changing the columns, making filters etc."* (LC1). Because the management chose to focus on flexibility first, the super users were given free reins as to how they chose to configure the whiteboards. According to the local coordinator, this strategy was chosen because it was expected to increase the chances of a successful implementation if the super users (and the other clinicians in the ward) felt like they could influence the appearance of the whiteboards. However, because the system was intended to support inter-departmental communication, it was important to secure a basic level of standardization. There were, therefore, some columns that the super users were required to include in their configuration of the whiteboard. These columns were referred to as "global columns" and displayed information like social security number, name, problem and plan. For some of these global columns, it was up to the super users to decide what and how data should be registered in them. When deciding how the problem-column should be used, some super users created a list of problems that were typical for their ward and the end-users were then required to choose one of these predefined problems when entering data into the column. On other wards, end-users were allowed to write free-text in the problem-column.

The super users were encouraged to configure the whiteboard system to support their intra-departmental practices by focusing on their daily routines. The interviewed chief physician explained how he and the other super users from his ward had solved this task: *"Nurses, secretaries and I […] defined what we wanted to see in the morning. Those 20-25 patients that we were going to treat. We wanted to get an overview. You had to look at your workday and say: how do we configure this to our work while simultaneously realizing that you may need to change your organization."* (Chief physician). This quote shows that the super users were not oblivious to the fact that even though they focused on configuring the whiteboards to their existing practices, they also realized that the whiteboards would potentially change the way they went about their work. The chief physician explained that he saw this configuration process as a fantastic opportunity, because it was the first time that he had participated in an implementation process where he had an opportunity to say what he wanted the system to look like. According to the local coordinator, many wards succeeded in configuring the whiteboards to support their intra-departmental practices.

Increased Standardization

It did, however, become increasingly clear to the clinicians that there was a need for increased standardization, if the system was to be used to support inter-departmental practices. Even though the super users had been required to include the global columns in order to enable inter-departmental communication, they could – if they felt that one of these columns was less important on their ward – choose to configure their whiteboards in such a way that these columns were not easily seen (and therefore typically ignored) by the clinicians on their ward. Additionally, most wards made frequent use of the predefined views that the super users had configured and these views only displayed selected columns. Because the whiteboards differed from ward to ward, clinicians in one ward did not know what clinicians in others wards actually saw: "*Everybody was like: I want it to be like this and I want the columns to be there and the views to search for that and that. And yes, the message was: you can get what you want. But when we wanted to communicate then we discovered that we couldn't. The information that I put into the system did not reach the intended receiver."* (chief physician). The chief physician pointed out that because of the lack of standardization with regards to columns and views, the super users realized that if they wanted to ensure that the information on the whiteboard reached the intended receiver, they had to cooperate with super users in other wards: "*If anyone wanted to inform another ward or group about something, then you had to say [to the super user in the other ward]: you have to modify your filter to include information from this field."* (chief physician). Thus, even though information was entered into the system with the intent of sharing it with another ward, the lack of standardization in terms of the appearance of the whiteboard meant that the system in practice could not be used to support inter-departmental communication.

As it became increasingly clear to the clinicians that there was a need to increase standardization, the management also became increasingly aware that it was time to constrain the flex-

ibility that had been given to the wards. Therefore, super users and management across departments gathered to negotiate and agree on rules about how to configure and use the whiteboards to support inter-departmental communication.

It was decided to take a more top-down approach in order to initiate the standardization of selected inter-departmental work processes: "*We said: well, let us try to focus on certain work processes and then get some common ground regarding how we want it to be.*" (LC1). The first example of the standardization of such an inter-departmental work process concerned the boarding of patients for surgery. The local coordinator convened managers and super users from the relevant departments to discuss how the boarding should be supported by the whiteboard: "*And they really got up to a discussion (...) and I thought, how can I close this discussion! (...) But in the end of the first meeting, they were about 80% in agreement.*" (LC1). After a few more meetings, the involved clinicians agreed on a standard checklist that entailed 7 steps that were required in order to secure a safe transfer for patients that needed surgery. When all 7 items on the checklist had been checked, the patient could be transferred from the ward to the OR. The local coordinator configured the whiteboard to include this checklist to support the agreed inter-departmental work process. The standardization of the boarding of patients for surgery thus required super users and the management from several relevant departments to agree on a standard. When this standard had been agreed upon however, the work of implementing the standard still remained: the clinicians in the departments had to be trained in adhering to the standard and using the whiteboard in a structured way. For a few weeks, the clinicians could use both the old way of boarding patients (fax and phone) and the new way through the whiteboard. After a trial period, it was decided by the hospital management that all patients had to be boarded through the whiteboard. The process of using the whiteboard as a starting point to standardize inter-departmental work processes has subsequently also been used in other areas (for example for ordering physiotherapists). Presently, the hospital is pilot testing a new checklist in the whiteboards to be used in the referral of patients from the ED to other departments. The new checklist has also been designed based on a standardized practice that clinicians from relevant departments have agreed upon. The region now plans to implement these standards in other hospitals in the region, where the whiteboards are presently being implemented.

Another important issue in regard to standardization has to do with the standardization of data and how the whiteboards can be used to generate statistics about the workflow in departments and hospitals. Presently, the region is working to generate regional standards with regards to the content that is registered within the columns. This includes the generation of lists of classifications that the clinicians can choose from rather than typing free-text. According to the present local coordinator, there has been a wish to work on these classifications for a long time, but the whiteboards have been a catalyst for focusing on and negotiating much needed standardization across departments and hospitals in the region.

Balancing Flexibility and Standardization

When the whiteboards were implemented, the hospital management chose to pursue a bottom-up approach to improve the chances of local grounding. In this first phase, the focus was on flexibility, where the super users seemingly were given free rein to configure the system to support intra-departmental practices. When local grounding had been achieved, the management decided to proceed with the actual goal of standardizing inter-departmental practices. Several of the interviewed managers reported how it had been a challenge to make the transition from flexibility to standardization: *"When do you go from saying: use it, if it makes sense for you – to saying: Use it! When do you make that switch?"* (project manager). The deputy director felt that the transition was dependent upon whether the system was in use in the wards: *"When the basic use of the system is widely grounded in our organization (...) then we need to cut back on the free reins and work to control how we use the whiteboards."* (deputy director). Thus, the management should not focus on standardization until the system was being used to a sufficient degree in the wards.

The interviewed managers stressed that the standardization of inter-departmental practices had been highly dependent upon the engagement of the top management in the hospital. The deputy director stated that he too was aware of the importance of the top management's engagement and therefore recently made an official announcement that all departments are required to use the whiteboards to a certain degree and for selected practices. According to the initial local coordinator, the work to standardize inter-departmental practices prompted a shift in the managerial approach: "*It resulted in the use of some coercion. When we put these work processes into the system, we removed the old way of doing it. It was like saying: It is no longer a question of whether you want to or not. This is now the way to do it!*" (LC1). In order to agree on inter-departmental standards and to get the clinicians to adhere to them, the hospital management and the local coordinator chose to use some coercion and hence to constrain the flexibility that had been central in the first phase of the process.

The shift from flexibility to standardization also brought forth a shift in challenges. The deputy director explained that when the implementation was driven by super users, the main challenge was to reach decisions about inter-departmental practices. He did however also see the approach as a promising investment: "*It has some clear advantages in that you get to develop things that are clinically relevant.*" (deputy director). With a more management-driven process, it is easier to make decisions about inter-departmental issues but it can be a challenge to foster good (clinically relevant) ideas: *"How do we make sure that we foster good ideas? How do we make sure that we realize what the best practice actually is?"* (deputy director). He therefore saw the importance of continued close cooperation with super users on every ward and setting up the proper forums to secure a bottom-up flow of knowledge and good ideas from the clinicians (in terms of how the whiteboards could be used to develop and standardize intra- and inter-departmental practices).

Discussion

As shown in the preceding section, the chosen strategy for the implementation of the whiteboards, in terms of finding a balance between standardization and flexibility, was one of "flexibility first, then standardize." The following discussion will focus on whether this approach was a viable alternative to Bjørn et al. [2] approach of first standardize, then localize.

In the first phase, the management chose to focus on flexibility by facilitating a user-driven approach and refraining from setting too many criteria for the super users. On many wards, this meant that enthusiastic super users welcomed the configurability of the system as an opportunity to influence both the appearance and the use of the system in their daily work. The decision to achieve local grounding before standardization

meant that the whiteboards were perceived as useful by the clinicians on wards, where super users had successfully configured the whiteboards. When the implementation entered the second phase, standardization, clinicians had already adopted the whiteboards in their local context and were becoming increasingly aware of the need for negotiating standards across wards. Even though this standardization process meant that some super users felt that they had to roll-back some of their changes, they acknowledged the standardization as a necessity if the whiteboards were to support inter-departmental coordination.

Due to the management in the first phase (flexibility) choosing not to set (or reveal) their agenda or boundary conditions for the change process, the super users in some wards never managed to incorporate the whiteboards into local practices; they simply did not know what was expected of them. Several of the managers acknowledged that the users had been given too much flexibility and too little direction. Their explanation was that the hospital management wanted the process to be user-driven. This however points to a somewhat misunderstood notion of what is required to manage a user-driven process. Within the tradition of Participatory Design, which is one of the central user-driven disciplines, it has been highlighted as to how important it is that the participants in the design have "close links to project management" [8]. According to Simon [12], an open-ended design process requires more of the users than a process with clear directives and she therefore argues for helping users in user-driven processes by "scaffolding" their participation. The management of user-driven processes thus requires the provision of supportive resources, tasks, and guidance upon which the super users can build their confidence and abilities.

When the management took more control in order to address standardization, they stated that there was a shift, where the process could no longer be driven by users; rather, the users had to be told what to do and how to use the whiteboards. In the light of the aforementioned scaffolding perspective, one might argue that both flexibility and standardization rely on the management scaffolding (super) users' participation in terms of how to use the whiteboards to improve and develop intra- as well as inter-departmental practices. When the deputy director stressed the importance of setting up forums to secure a continued bottom-up flow of knowledge and good ideas from clinicians, he was basically talking about how to scaffold a user-driven change process.

Conclusion

When implementing IT in an attempt to standardize inter-departmental practices, this study suggests that it can be a viable strategy to focus on flexibility first, then standardization. The first phase, flexibility, was succesful in terms of configuring the whiteboards to secure local grounding in most wards. In hindsight, however, several managers stated that the users had been given too much flexibility and too little direction. In the second phase, standardization, it was an advantage that the whiteboards had been widely adopted and that users experienced the need for standardization. The strategy also poses challenges in terms of managing the user-driven process, scaffolding the clinicians' participation, and in finding the right time and manner to transition from flexibility to standardizaiton.

Acknowledgments

This study was co-funded by Region Zealand as part of the Clinical Communication project. Special thanks are due to the interviewed managers.

Human Factors Predicting Failure and Success in Hospital Information System Implementations in Sub-Saharan Africa

Abstract

From 2007 through 2014, the authors participated in the implementation of open source hospital information systems (HIS) in 19 hospitals in Rwanda, Burundi, DR Congo, Congo-Brazzaville, Gabon, and Mali. Most of these implementations were successful, but some failed. At the end of a seven-year implementation effort, a number of risk factors, facilitators, and pragmatic approaches related to the deployment of HIS in Sub-Saharan health facilities have been identified. Many of the problems encountered during the HIS implementation process were not related to technical issues but human, cultural, and environmental factors. This study retrospectively evaluates the predictive value of 14 project failure factors and 15 success factors in HIS implementation in the Sub-Saharan region. Nine of the failure factors were strongly correlated with project failure, three were moderately correlated, and one weakly correlated. Regression analysis also confirms that eight factors were strongly correlated with project success, four moderately correlated, and two weakly correlated. The study results may help estimate the expedience of future HIS projects.

Introduction

HIS implementation has gained momentum in Sub-Saharan Africa in the past decade. In the period from 2007 to 2014, the authors participated in the implementation of the open source OpenClinic GA HIS [1] in 19 hospitals in Rwanda, Burundi, DR Congo, Congo-Brazzaville, Gabon, and Mali. Many of these implementations have been successful, but some of them turned into failures. Introducing HIS proved to be a complex process. There was no single standard pathway to successful implementation. Sometimes what failed in one health facility seemed to work very well in another one. In the beginning, many solutions had to be discovered by trial and error. Nevertheless, at the end of a seven-year implementation effort a number of risk factors, facilitators, and pragmatic approaches related to the deployment of HIS in Sub-Saharan health facilities have been identified. These elements have been categorized in the following classes:

- Infrastructure
- Patient administration
- Financial information management
- Reason for encounter and diagnostic coding
- Medical record management
- Lab information management
- Medical imaging
- Reporting and statistics
- Systems integration
- Project management issues and human factors

Many of our findings were in line with earlier publications that shed light on isolated aspects of health information system issues [2,3,4,5] and environmental country-specific problems [2,6,7]. Many of the issues that were encountered during the OpenClinic GA implementation process were not technical, but could be brought down to human, cultural, and environmental factors. Although such issues were frequently irrational and hard to solve, they seemed to be fairly predictive in determining the success or the failure of a project. In order to formally evaluate the predictive value of these human factors in our HIS implementations in the Sub-Saharan region, a retrospective, descriptive, and semi-quantitative study has been set up.

Materials and Methods

In the course of the 19 HIS implementation projects, implementation logbooks have systematically been kept that document a wide range of problems that arose, solutions, and workarounds, as well as the results that were obtained from implementing the solutions. Analysis of the logbooks—which included feedback from the local project managers in the 19 health facilities—resulted in the identification of the aforementioned 10 different classes of issues. The *Project Management Issues And Human Factors* class consisted of a list of 14 factors that could potentially be related to project failure and 15 factors that were potential candidates for predicting sustainable implementation success.

A global project implementation success score ranging from 0 (complete failure) to 5 (complete success) has been awarded to each of the 19 health facilities in our research. This score was derived from the level of agreement expressed by the hospital management staff and an external evaluator with a series of six statements ranging from 0 (completely disagree) to 5 (completely agree):

1. All goals which have been set out in the project scope have been achieved.
2. All project results have been delivered in time.
3. All intended users have been trained and are using the system.

4. The health information system implementation contributed to the improvement of health facility productivity.
5. The health information system has contributed to quality improvement of health care services.
6. The health facility is able to self-support post-project operational costs related to the health information system.

For every health facility, a score was then allocated representing the relevance of each of the 14 failure and 15 success factors. Scores ranged from 0 (irrelevant) to 5 (of highest importance) and the scoring of each factor was the result of a consensus between local health facility management and an external implementation evaluator. An average *risk level* score was then calculated for each health facility based on the average failure factor scores that were previously allocated. Similarly, the average score for the success factors was called the *opportunity level*. Finally, correlations were calculated between individual factors and project success scores.

Results

Implementation Failure Factors

Several authors have published extensive lists of potential pitfalls and failing factors for HIS deployment in developing countries. In 2002, Heeks [8] drew a rather pessimistic view of the health informatics landscape in the developing world mainly based on a perceived mismatch between information systems design and local user actuality. In our HIS implementations, we specifically tried to address issues related to such implementation gaps. Failure factors identified in our research substantially differed from Heeks' and other authors' [4,5] observations. What follows is a tabular summary of a number of factors that could be predictive for eventual project failure (Table 1). Predictive values show the correlation *r* with global project success and the *p*-value for the F-test on the regression with a confidence level of 95%. Significant correlations below 0.60 are labeled as having *low* predictive value, between 0.60 and 0.75 *moderate* predictive value, and above 0.75 *high* predictive value.

Table 1 – Project failure factors evaluation.

Failure factor	Description	Predictive value
1. Unclear goals	When no clear definitions of an intended outcome exist, measurement of success becomes extremely difficult. False and unrealistic user expectations are very likely to generate a perception of project failure.	r = 0.70 p<0.001 moderate
2. Absence of a project champion	Project champions are extremely important for aligning user behavior to set out project scope. Absence of a project champion often leads to disinterest and lack of user motivation.	r = 0.70 p<0.001 moderate
3. Resignation to poor health service quality	Hospital management resigning to the poor health status of patients and accepting inadequate health care practice are bound to fail in implementing information systems. Implementations can only be justified by health services improvement.	r = 0.81 p<0.0001 high
4. Psychological factors	Initial, often irrational user resistance and physician skepticism are predictive for slower implementation progress.	r = 0.78 p<0.0001 high
5. Organizational culture and silo mentality	Health facilities composed of individual relatively autonomous departments with minimal perception of system-wide collective goals carry a risk of fractional implementation. Lack of trust can also play a pernicious role.	r = 0.76 p<0.001 high
6. Resistance to change and power shifts	Documented resistance to change based on fear of losing a job or an advantageous position are often present in insecure working environments. If no measures are being taken to address such issues, partial or total project failure is more likely to occur.	r = 0.74 p<0.001 moderate
7. Time	Unrealistic implementation timeframes are bound to fail. Another time factor relates to the fact that information and communication technology (ICT) tools should never lengthen the time needed for performing routine operations. Systems that reduce users' productivity will rarely survive.	r = 0.90 p<0.0001 high
8. Poor technical assistance	In several sites, perceived technical assistance quality was directly correlated with overall users' system appreciation. Effective technical support is key to information systems being seen by users as dependable working instruments.	r = 0.80 p<0.0001 high
9. Insufficiently skilled staff	Health facility staff with extremely low ICT skills are somehow predictive for failure as they add an	r = 0.59 p<0.01 low

	additional burden to training and user assistance, and increase funding requirements.	
10. Insufficient training	Inadequately trained users provide inadequate results. Although such logic does not apply to ICT-based systems exclusively, often ICT-training inadequacy is being translated into excessive system complexity. Additionally, continued training should address staff turnover.	r = 0.77 p<0.0001 high
11. Discontinued follow-up	Users being left alone after initial start-up training creates a sense of disinterest. Result-oriented implementations must address the need for individual follow-up.	r = 0.90 p<0.0001 high
12. Poor mapping on prevailing practices	ICT tools which are poorly mapped onto existing routines and practices will be abandoned in the end. If users fail to find personal interest in developed instruments, they will not use them.	r = 0.27 p = 0.26 NA
13. Perceived complexity	Modules that contain a high level of perceived complexity will frighten many users and induce unnecessary resistance to change. ICT skills being scarce in Sub-Saharan Africa, complicated systems must be avoided.	r = 0.77 p<0.001 high
14. Low user satisfaction	Low user satisfaction in the course of project implementation must always be considered an alarming element. In the case of clear user dissatisfaction, ongoing implementation should be reconsidered.	r = 0.97 p<0.0001 high
Global risk level	Average score for all of the above failure factors.	r = 0.95 p<0.0001 high

Based on our study set, 9 of the 14 factors were strongly correlated with project failure, 3 factors were moderately correlated, and 1 factor had low predictive value. The evaluation of factor 12 (poor mapping on prevailing practices) produced no valuable output because too few health facilities faced this kind of issue. The calculated global risk level score demonstrated a strong, statistically-significant correlation with project success (Figure 1).

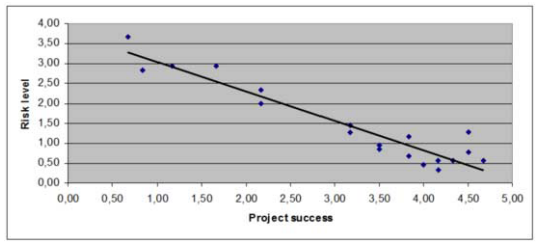

Figure 1 – Risk level and project success regression.

Implementation Success Factors

Similar to the identification of failure risks, a list of elements that increase the likelihood of successful project implementation have also been isolated. A number of such factors has already been described by Hendricks [4] based on a review of 31 reports on electronic health records implementations in developing and developed countries. In our study results we found that many of the factors in Hendricks' report did not fit the Sub-Saharan healthcare reality. What follows is a tabular summary of a shorter list of success factors that applied to our own research experience (Table 2).

Table 2 – Project success factors evaluation.

Success factor	Description	Predictive value
1. Broad staff enrollment	When the majority of users at all levels of the health facility have the feeling of participating in the implementation effort, HIS can develop beyond the stage of being a management whim.	r = 0.68 p<0.01 moderate
2. Clear communication	Clear, broad communication of the goals and the potential impact of the new technology on work organization helps to cope with resistance to change and distrustful mindsets.	r = 0.85 p<0.0001 high
3. Realistic timing	Timing should be realistic enough to address reasonable stakeholders' expectations. A well-planned implementation with a feasible schedule assures better synchronization between different projects' tasks.	r = 0.80 p<0.0001 high
4. Progressive change management	Big bang implementations where massive business process change is pushed through complex organizations, such as health facilities, is a dangerous practice. Gradual and progressive introduction of new modules often appears more successful.	r = 0.70 p<0.001 moderate

5. Incentives	Motivation of HIS users in the form of an official recognition, a small reward, or even a simple pat on the back have been found mainly in successful projects.	r = 0.43 p<0.07 Not significant
6. Business process reengineering ability	The ability of a health organization to cope with necessary transformations of business processes that get in the way of information systems implementation is important for achieving the best productivity improvement.	r = 0.81 p<0.0001 high
7. Stakeholder consensus	Optimally, HIS implementation must be in line with the goals of all stakeholders. Reorientation of project scope must therefore always be based on stakeholder consensus.	r = 0.75 p<0.001 high
8. Holistic approach	Systems that efficiently integrate information from different departments better contribute to global business targets, such as generic patient health status improvement and hospital productivity.	r = 0.82 p<0.0001 high
9. *Quick wins* implementation	*Quick wins* can constitute an essential step in bridging the start-up gap between systems' potential and users' mistrust. They can greatly motivate users for continuing to invest in a project.	r = 0.91 p<0.0001 high
10. Sufficient and continued training	Users' needs for training must always be considered seriously. Users who feel comfortable with the system's operating procedures show a more positive attitude towards the project, resulting in better outputs.	r = 0.68 p<0.01 moderate
11. Clinician and ICT staff intermediaries	The presence of health IT experts can resolve many communication errors between IT technicians and clinical staff pro-actively. This can reduce frustration and inadequate allocation of development time.	r = 0.54 p = 0.02 low
12. Consideration of prevailing practice	HIS should never dictate users' business processes, but rather adapt to the actuality of the activity they support. Doing so can transform these systems into highly valued instruments that facilitate work.	r = 0.56 p = 0.01 low
13. Adequate technical assistance	Many users don't mind facing technical problems once in a while, as long as these can be quickly and effectively addressed by technical support staff. Unresponsive support staff can compromise project survival.	r = 0.85 p<0.0001 high
14. High measured user satisfaction	Obviously, a high level of user satisfaction being measured in the course of project implementation is a strong indicator of important user concerns being appropriately addressed.	r = 0.94 p<0.0001 high
15. Perceived user-friendliness	Simplicity and suitability of user interfaces for performing frequent tasks are generally perceived as user-friendly, which improves user acceptance and reduces initial resistance to change.	r = 0.69 p<0.01 moderate
Global opportunity level	Average score for all of the above success factors.	r = 0.91 p<0.0001 high

Regression analysis confirms 8 factors are strongly correlated with project success, 4 factors have a moderate correlation, and 2 factors have a weak correlation. The average opportunity level also strongly and significantly correlates with project success (Figure 2). For factor 5 (incentives), no statistically significant relationship to eventual project success can be demonstrated.

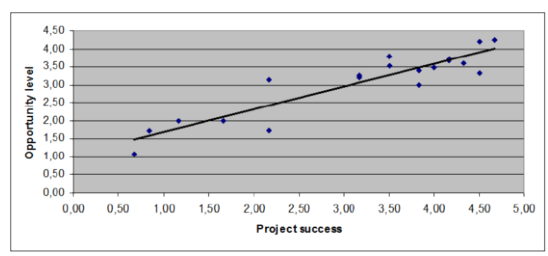

Figure 2 – Opportunity level and project success regression.

Conclusion

The developed failure risk assessment scheme confirmed, to a large extent, the relevance of the failure risk factors we extracted from many interviews with several hundred health facility users. As expected, the user-oriented nature of the OpenClinic GA HIS led to results that were substantially different from data that had been previously published by other authors [4,8]. This mainly resulted in a low predictive value of risk and success factor 12 (mapping on prevailing practices) in our study sample.

Although every health facility constitutes a specific case and no absolute information can be derived from the listed risk and success factors, they may offer some grip for estimating the potential expedience of future HIS projects that are being considered.

Abstract

Digital technologies are being used as part of international efforts to revolutionize healthcare in order to meet increasing demands such as the rising burden of chronic disease and ageing populations. In Scotland there is a government push towards a national service (Living It Up) as a single point of reference where citizens can access information, products and services to support their health and wellbeing. The aim of the study is to examine implementation issues including the challenges or facilitators which can help to sustain this intervention. We gathered data in three ways: a) participant observation to gain an understanding of LiU (N=16); b) in-depth interviews (N=21) with stakeholders involved in the process; and c) analysis of documentary evidence about the progress of the implementation (N=45). Barriers included the need to "work at risk" due to delays in financing, inadequate infrastructure and skill-set deficiencies, whilst facilitators included trusted relationships, champions and a push towards normalisation. The findings suggest that a Scottish ehealth service is achievable but identifies key considerations for future large scale initiatives.

eHealth; Chronic Disease;Wellness Programs; Implementation

Introduction

Population ageing in the 21st century is a major issue with the World Health Organisation (WHO) forecasting that the number of people aged 60+ around the world is set to reach 2 billion by 2050 [1]. This represents the fastest growing age group anywhere in the world. While, this can be seen as a cause for celebration, ageing is changing the shape of society and therefore introduces enormous challenges, particularly in relation to the provision of health and social care services to a population with increasingly complex needs. A consequence of this demographic shift is the increased prevalence of non-communicable diseases (NCD) associated with ageing; also known as chronic diseases. Each year NCDs are the cause of 36 million deaths; in Scotland 60% of all deaths are attributable to a chronic condition and they account for 80% of all general practice consultations [2,3,4]. This has major implications for primary care provision within the United Kingdom (UK) as 90% of all patients' interaction within the National Health Service (NHS) 'starts and ends in primary care'[5]. Current models of care are unsustainable, costly and inadequate. There is a need for innovative approaches and solutions which can meet the demands of a fragmented system. The Scottish government aim to be at the forefront of innovation in becoming a "world class digital nation by 2020" with policy intending to help people to live longer and healthier lives at home or in a homely setting using digital technologies as an enabler [6]. The focus within primary care is on prevention, supported self-management and patient-centred holistic care. Healthcare is a lucrative and expanding market and the call to revolutionize it using digital technology has been seen as a key driver in creating innovation. However one of the most critical issues impeding previous efforts has been the gap between what we know can optimise health and wellbeing to what actually gets implemented in everyday practice. This has been referred to as a 'translational gap' where the normalisation of an intervention commonly fails [7]. The *purpose* of this study is to report on the *mid-point* views of stakeholders' on the factors which can promote or inhibit successful implementation of a large-scale digital health and wellbeing programme (Living It Up) across Scotland.

Materials and Methods

Participant Recruitment & Data Collection

In order to gain a wide range of perspectives and obtain a holistic picture of the implementation journey we contacted via email a purposive sample of stakeholders (N=16), representing local, national and international organisations. This sample spanned six sectors (industry, health and social care, housing, education, voluntary and statutory), all working together as a collaborative consortium within the Living It Up (LiU) project. Qualitative studies of stakeholders views are important to understand factors which affect implementations on the ground, for example a study on EHRs in Sweden identified discrepancies between the views of professionals and consumers which affected EHR utility and uptake of a national system designed to improve health provision [8].

Data Collection

Ethical approval for this study was obtained from the University of Glasgow, College of Medicine, Veterinary and Life Sciences Ethics Committee (2000130029). We collected and triangulated multiple sources of data through: a) prolonged participant observation; b) semi-structured interviews; and c) collection of a wide range of documentary evidence. Participant observation in this study involved two components: 1) observing monthly stakeholder meetings and 2) collecting data from quarterly meetings held between stakeholders (key informants) and researchers which served a primary purpose of capturing the changing face and shape of a digital health and wellbeing service which started as a 'blank

canvas'. These translated to a total of N=16 participant observation sessions over a period of 14 months (October 2012 to December 2013) and approximately 62 hours of interaction. Secondly, we conducted a total of N=21 semi–structured interviews (January to July 2014) which helped us identify and understand the barriers and facilitators to implementation. In order to capture both breadth and depth within the study we collected both a longitudinal and cross-sectional dataset. The longitudinal data included follow-up interviews conducted with N=6 participants (project managers) at baseline and mid-point (after 6 months). N=1 project manager resigned after 6 months and therefore we were not able to carry out their interview and this was not part of our final dataset. The cross-sectional dataset included mid-point interviews with N=10 participants that were service and technical partners involved in high-level strategic decision making. The interview questions were informed by Normalisation Process Theory (NPT) [9] and each interview lasted approximately 60 mins. All interviews were transcribed verbatim and coded in addition the research team undertook 'data coding clinics' where coding was discussed and agreed to ensure consistency and validity of the coding framework. Lastly, we collected N=45 multiple sources of documentary evidence such as Quarterly Progress Reports, Service Specifications, Alignment Interviews, Recruitment Reports and Evaluation Updates that were synthesised in order to capture and map out the implementation journey and to create a 'thick description' of the project over time. These methods maximized our ability to grasp the subjective behaviours of a multi-stakeholder environment.

Data Analysis

Each transcript was subject to theory-led qualitative analysis with reference being made to the Ritchie & Spencer (1994) thematic framework for data interpretation (familiarization; identifying a thematic framework; indexing; charting, mapping and interpretation)[10]. NPT was used as the theoretical framework underpinning our study as it is widely advocated and cited as a robust explanatory framework which captures the 'work' of implementing, embedding and integrating new technologies or services into routine practice [11]. The framework makes reference to four key domains namely: Coherence, Cognitive Participation, Collective Action and Reflexive Monitoring. The first domain looks at the '*sense-making'* work that people do individually or collectively in order to develop a shared understanding of a new intervention. The second domain reflects on the '*relational*' work that people do to encourage people to engage, buy-in and sustain a new intervention. The third domain simply refers to the '*operational work*' that people do and what needs to be done to ensure that the new intervention works in a real-life setting. The final domain looks at the '*appraisal*' work that people do to assess and understand the impact of a new intervention. We mapped our thematic findings to NPT in order to help us understand our data. The analytical process as a whole was facilitated using QRS Nvivo ® Version 10.0.

Results

The Makeup a Scottish Digital Health & Wellbeing Service

Living It Up (LiU) is part of a £37 million UK-wide project titled Delivering Assisted Living Lifestyles at Scale (dallas). The aim of dallas is to demonstrate how innovative technologies and services can be used for 'preventative care to promote independent living and improve peoples lifestyles' between June 2012 and May 2015 [12]. LiU is a digital platform (www.livingitup.org.uk) accessible via various modes of familiar technology, which aims to impact 55,000 people aged 50+ approximately 10% of the total Scottish population to improve their quality of life and independent living. The project targets 5 specific geographical locations namely; West Lothian, Moray, Highlands & Islands, Forth Valley and the Western Isles capturing a mix of urban, rural and remote rural areas. LiU has been hailed as a 'national ground breaking service' by government representatives. It aims to help the citizens of Scotland find local, trusted and personalised information on services which can support health and wellbeing [13]. The platform was developed using a co-design approach with intended users (members of the general public), creatives, technology designers and over 30 organisations (Figure 1). The LiU deployment is being led by the Scottish Centre for Telehealth and Telecare (SCTT) and NHS 24 which are government bodies' established with a purpose of facilitating the shift towards how health and social care services are provided, perceived and consumed.

Figure 1 –International Stakeholders for Living It Up

LiU is a platform that provides consumers with access to four key services: Connect, Discover, Flourish and Shine. The first being a service which supports *digital participation* among communities in providing a means for people to remain 'connected' with their friends and family as well as an opportunity to up-skill and learn how to go about using technology. This service enables users to remain 'connected' to their care-giver via Cisco Jabber Client video conferencing (VC) suite. The second service 'Discover' is based on *asset mapping* national and local information about organisations, services, activities and groups which consumers may find useful in meeting their needs. This service is powered by a national database called ALISS (A Local Information System for Scotland). This provides a personalised search and collaboration tool for users and enables organisations themselves to use it for sign-posting [13]. Users also have the ability to 'rate' services in an open format and share recommendations.

Flourish provides a suite of interactive tools to support people in *self-managing* their chronic condition. This includes approved health information and advice, text messaging alerts and remote-monitoring services to help support people with conditions such as Heart Failure (HF). The final service 'Shine' centres on community *capacity building*. It is advertised as the 'front door' to LiU. This service taps into the value of the contribution that citizens can make to society.

The service provides a 'profiling tool' which enables people to identify, nurture and refine their individual skills and experience in a way to 'give back' to their local community. This approach is being used to help contribute to improved wellbeing and stronger, more connected communities. Users of LiU can access the entire platform free of charge and there is an opportunity to become a member which will present them with a personalised dashboard. The final aspect of this platform is the 'Innovation Zone' which provides a space for enterprise where companies can advertise new solutions, apps or products which require testing or exposure ultimately fostering wealth creation [13].

Implementation Barriers

Working at Risk

This section provides an overview of the key mid-point themes that emerged as barriers during the national deployment of the LiU platform. A challenge amongst stakeholders in the beginning was to identify an agreed approach and direction. Due to the ambitious nature of the programme it was deemed important to engage with a wide range of different types of stakeholders. However, as this collaborative consortium combined a large number of organisations (local, national and international) from various backgrounds and with varying expertise, this introduced a degree of tension when voicing opinions, settling agreements and making decisions. This, coupled with the use of a co-design approach prolonged the design phases a great deal. For example, it was anticipated that a 'soft launch' of LiU would be live by March 2013 but in reality this occurred in November 2013 this attests to the scale of delay. Further to this, there were contractual difficulties which distorted the traditional tendering process and in order for stakeholders to proceed with their involvement in the project they usually had to 'work at risk' and obtain a letter of intent in relation to delayed financial payments. "*There was a huge bureaucratic delay in getting the thing set up and a contract out… The project was officially meant to start in June…you know, as a delivery partner, we did not get a contract until the following January. So, you know, we worked at risk. You know… to try and be a good partner but, you know, for a business that's not satisfactory and that means that you can't commit all the resources you would like to when you don't know if you're going to get a contract*". "*So, there's a slow start but what made it worse… was it took far too long to decide what LiU would be, you know…Our job was delivery of the requirement. Now, it took probably a year to decide on what the requirement was*"[LiU11]. "*LiU works in quarters. The financial approval process is so far off the pace of the work process that it's not only late it's almost at the end of the process…There's two things you can do as a supplier, one is you can say I'm not moving until I get approval…or else you can proceed at what's called…working at risk. I'd say it's uncommon*"[LiU20]

No Complete End-to-End Testing Environment

LiU aims to provide consumers with an integrated seamless journey of care. There was a consensus amongst stakeholders that delivering this vision was a complex process. Some partners worked in 'silos' within their organisations and concentrated on a particular piece of work which meant that difficulties were only recognised when that piece of work became integrated within the wider programme. This impacted the implementation process because there was no complete end to end testing environment across the entire programme. "*So basically what happens is a supplier, a technical partner is used to the principle of building something and then they put it into their test environment and test it. Right…now the problem is until you have interlinked them you don't know they are going to work. So supplier A could build product 1 and test it but when it goes live it might not work because of something that supplier B has running on their website…now it would cost a lot of money to build a complete end to end test environment"*[LiU20].

Inadequate Infrastructure – Challenging Boundaries

In some cases, the ability to deliver the innovation meant that transformational re-modelling of the current care model was required. This meant that LiU was being impeded in some aspects as current infrastructure was not suitable to adopt some elements of the platform."*I think we're certainly ahead of the game. Looking at international markets and speaking to our counterparts in the UK I think this is very much a pioneering project. ..We've actually moved to a kind of model that's maybe five years ahead of its time*". [LiU06]

Educating Stakeholders

In a multi-stakeholder environment, the need for all LiU consortium members to have a shared sense of understanding required a level of learning. It was clear that some stakeholders required more 'training' than others which slowed down the implementation process as well as the concept of innovation as a whole. "*There was a lack of understanding of digital technology and what it can do now. A lot of the people were not familiar with the use of digital technology and, you know, on the service side, the people that were designing the services did not themselves use this type of technology, so they were not pushing the boundaries*" [LiU11]

Designed for Local vs. International

This national platform aims to become Scotland's premier source for health and wellbeing; and stakeholders wanted to become a beacon for other countries but faced a challenge in identifying how to go about that. Several issues emerged in identifying the customer and market which led to concerns that the consortium might be taking too myopic a standpoint. "*The requirements were gathered from people in Scotland. Now, the market is not people in Scotland. The market is outside Scotland...for LiU to be commercialised…to become a product or service that people will buy…it needs to meet the needs of people outside Scotland. The current users are in Scotland but the future users are not in Scotland…""A big assumption was made that what suits Scottish people in the Scottish context will suit a world market and I think that's wrong". "There's a fundamental mismatch.* [LiU11].

Implementation Facilitators

Trusted Customer – Supplier Relationship

This section provides an overview of the key mid-point themes that emerged as positive enablers, or facilitators during the deployment of the LiU platform. The first being that over the course of the implementation, stakeholders developed a professional but friendly bond which changed the usual dynamics of the customer-supplier relationship. This introduced new ways of working in which representatives from sectors such as housing, healthcare and voluntary indicated that it helped drive the implementation forward. "*Normally that relationship is one of customer–supplier, and the public service has a very thorough obligation to treat all private organisations equally. You know, no favours, no special conditions and that's fine when you're trying to buy…you know…it's a plaster. It's just a question of who*

makes the cheapest plaster that passes the requirements". "But it's not a good way of handling things when you want to do innovation, because with innovation you need trust, you need a relationship, you need the ability to be able to say, in a trusted way from one side, this is what we want, and the other side says, well this is what, at the moment what I can deliver, but maybe I can move towards that over the next six months. And that's the only way that you can do joint innovation. And that's basically what Dallas has delivered…""We've moved from a customer–supplier relationship to a more of a partner relationship. And I think that's absolutely essential to solving some of these problems that we have in using technology to provide health care". "So I don't want to just be the telehealth guy. I'd hope we can be broader than that…""I'd hope we don't go back to customer- supplier". [LiU08]

Iterative User Feedback Shapes Development

Consumers have a crucial role as a stakeholder within the consortium as they are continuously consulted throughout the life cycle of the project in various ways both online and offline; and this provided an opportunity for grass-root level engagement and innovation to occur such as personalisation of health and wellbeing services. "*Sometimes they'll be giving the feedback on a one-to-one basis at workshop events and that goes through…we consolidate that…to shape the development of LiU. If they go through the digital portal then…that goes directly to support office who then again push that out …and see if things can be improved* "[LiU05]

Local Champions Driving Implementation

A key facilitator has been the establishment of local champions who are people that live in the target communities that either a) have a vested interest in co-designing LiU or b) have identified the value of LiU as part of their daily lives. They have been identified as a key driving force in creating awareness and encouraging regular people to buy-in to LiU. *What I've done is I've been very lucky and I've got a great group, a core group of local community champions, who are basically... in a way, I'm leaving it to them, because I think it sells it better if it's coming from actual users. So we've got one guy who's writing a regular blog about living with long-term conditions, you know, he gives practical advice based on his own experiences, and that's been very popular with people, given it a human edge, if you like*. [LiU07]

Product Ownership & Business Opportunities

It was largely agreed by small and medium-sized businesses (SMBs) that working on a large national collaborative project such as LiU created new business opportunities and ventures. This helped to provide a platform in which the vision of wealth creation and innovation could be achieved. More importantly stakeholders were identified as product owners in different elements of LiU and therefore this enabled them to showcase this work as well as a 'collection' of individual works within their respective organisations; an opportunity that they may not have had without being part of LiU. "*As a company we've had great benefit from being a part of this project because it has allowed us to establish a position in the individual health market and you know, we're working for Living It Up, we're working for all the Dallas projects. So, we're not restricted to Living It Up, although that's given us opportunity*" [LiU11]

Push Towards Sustainability and Normalisation

The push towards scaling LiU and making it sustainable far beyond the official end date of 2015 has positively influenced the implementation process. Stakeholders themselves are thinking long term but more importantly in 'real-terms' as to how LiU can be integrated into daily practices. This is a key overall positive factor in ensuring that the project as a whole is a success. "*We're going to run some workshops, actually, just to see how health and care professionals can implement if there's some of the tools. I mean, not all of them, but we're going to have just some of the tools that are relevant to them and their clients or their service users. So we will be kind of running workshops in all of the areas just on how we can do that, and actually just get them to implement it in as part of their daily working*" [LiU_15]

Discussion & Conclusion

This study explored the views, knowledge and understanding of stakeholder personnel and organisations involved in the deployment of an on-going national digital health and wellbeing project at scale in Scotland. The results of the study show that obtaining stakeholders views on factors affecting the implementation process provides valuable insights which can help to inform its future development in becoming a sustainable service for Scottish citizens. A limitation of our work is the lack of data from end-users of the LiU services and the fact that we are describing a deployment still "in process", however a strength of this study has been the use of the NPT framework in capturing the 'work of implementation' as well as providing a basis for learning and critical reflection in understanding the valuable lessons that have been learned throughout this journey of implementation. The use of the NPT framework has helped us to highlight barriers and facilitators and we apply it here in order to interpret and synthesise our findings.

Coherence

This domain refers to the '*sense-making'* work that people do individually or collectively in order to develop a shared understanding of a new intervention. It is clear that there was some difficulty experienced by stakeholders in developing a shared direction of travel due to several factors such as the number of stakeholders involved in the process, identifying requirements to match future need and having to 'work at risk'. Although facilitators such as the creation of 'trusted' relationships and the move towards embedding this intervention into everyday practice has helped to overcome this barrier. It seems that these risks were necessary when implementing a project which is at the forefront of innovation. Recent research has confirmed that having good existing relationships or links between senior management or strategic level players helps to improve communication among implementers as well as securing long lasting change [14]. Our findings within this domain clearly demonstrate the need to understand organisational cultures as a key ingredient and basis for any innovative digital health and wellbeing project.

Cognitive Participation

This domain refers to the '*relational*' work that people do to encourage people to engage, buy-in and sustain a new intervention. A key barrier that needed to be addressed was lack of knowledge/skill-set deficiencies and the need to educate, upskill and train stakeholders in digital technologies as it was clear that not all stakeholders had the same level of understanding. This finding unearthed a link between the 'Collective Action' domain and the 'Cognitive Participation' domain due to the fact that this process was required to take place before stakeholders actually engaged with LiU in order for them to go on to endorse or promote it themselves. Local champions however helped to overcome the barriers that

stakeholders faced by not concentrating on the technology but on personalising the benefits to demonstrate to potential users how this product can help them in their daily lives. Previous research in Australia has shown that use of clinical champions can play a critical role in helping to promote uptake and sustainability of telehealth; with the authors pointing out that it is more important to get the service model right rather than the technology itself [15]. This is key as there is a lack of evidence in relation to participation and engagement within the field of ehealth and wellness [16].

Collective Action

The third domain refers to the '*operational work*' that people do and what specifically needs to be done to ensure that a new intervention works in a real-life setting. Barriers which affected the practical application of LiU included inadequate infrastructure, constraints on resources (including finances) and limited testing environments which are key findings that align with available evidence from the United States of America [17]. In Scotland there remains a challenge in delivering services to people living in remote locations which compounds the existing burden on the system. The need for adequate infrastructure and resources to support digitally enabled self-care has been recognised and the Scottish Government have recently launched a national programme to enhance the current broadband and fibre optic capabilities.

Reflexive Monitoring

The final domain looks at the '*appraisal*' work that people do to assess and understand the impact of a new intervention. A challenge was designing to meet all needs but positive themes such as the creation of business opportunities and iterative user feedback emerged as key facilitators in assessing the impact of LiU. Particular focus on the latter finding is significant as it illustrates the value of input from Scottish citizens in dictating their own care and becoming 'active' recipients with increased choice about how and where they receive services as opposed to the traditional passive role that is played. There is a considerable amount of value from capturing the process and journey of implementation at scale. Lessons that have emerged as key learning points include the need for flexible and trusted working environments to support multi-sector working partnerships and the need for policy to support innovative business models. This report highlights difficulties faced in delivering new digital health and wellbeing services at scale and the need for further research to help understand implementation issues in order to a) bridge the 'translational gap' and b) inform future ehealth policy and practice.

Acknowledgments

We would like to thank the Scottish Government and Innovate UK (Technology Strategy Board) who are sponsoring the Living It Up project and the Medical Research Council UK who are funding our research.

Abstract

Although national eHealth strategies have existed now for more than a decade in many countries, they have been implemented with varying success. In Germany, the eHealth strategy so far has resulted in a roll out of electronic health cards for all citizens in the statutory health insurance, but in no clinically meaningful IT-applications. The aim of this study was to test the technical and organisation feasibility, usability, and utility of an eDischarge application embedded into a laboratory Health Telematics Infrastructure (TI). The tests embraced the exchange of eDischarge summaries based on the multiprofessional HL7 eNursing Summary standard between a municipal hospital and a nursing home. All in all, 36 transmissions of electronic discharge documents took place. They demonstrated the technical-organisation feasibility and resulted in moderate usability ratings. A comparison between eDischarge and paper-based summaries hinted at higher ratings of utility and information completeness for eDischarges. Despite problems with handling the electronic health card, the proof-of-concept for the first clinically meaningful IT-application in the German Health TI could be regarded as successful.

Keywords:

eHealth Strategy; Health Telematics; Electronic Health Card; Nursing; Patient Discharge.

Introduction

National eHealth and Health Telematics strategies came into existence more than a decade ago [1] and have been implemented with varying success [2, 3]. In Germany, the Health Telematics Infrastructure (TI) based on an electronic health card for the patient and an electronic health professional card, was announced in 2004 but was delayed several times due to politically motivated criticism of the physician associations and other stakeholders [4]. Consequently, systems based on other technologies, and pursuing other approaches, were developed [5, 6]. In the meantime, the development of the Health Telematics Infrastructure (TI) had been carried on, the use of the electronic health card all over Germany is mandatory from January 2015 on [7], and basic IT-applications such as the online management of patient demographics are ready for piloting in several federal states. So far the electronic health card contains administrative data only. The clinical eHealth-applications that had a true chance to run on the Health TI were rather unclear at the onset of the project, so was a realistic timetable of the availability of the TI.

Against this background, it seemed desirable to develop and test applications with a high potential impact on patient care that make use of TI elements such as the electronic health card as a gatekeeper to the patient data. Among these applications, the electronic health record possesses paramount importance for supporting all health care processes as well as for supporting the discharge process. Discharge management is particularly crucial in patients with chronic conditions and is reported to be problematic in many countries [8]. However, when organised properly, discharge management can help significantly. This, for example, could be demonstrated in geriatric patients [9], just to mention one group of patients that benefit from these measures. Elderly patients often require medical and nursing information to be transmitted at discharge to the institution providing follow-up care in order to maintain the continuity of care [10].

We, therefore, aimed at developing a prototype for an eDischarge application based on an EHR that was embedded into a laboratory Health TI and served as a proof-of-concept for the TI. The eDischarge application should transport administrative, nursing, social and medical data between health care organisations. In this study, we particularly wanted to evaluate its technical-organisational feasibility, usability, information completeness and utility.

Materials and Methods

Discharge application embedded into Health TI

The eDischarge application was built on the ground of the German national HL7 CDA based standard of the eNursing Summary [11]. It included data about the patient and the health care professionals involved in the structured CDA header, and nursing, social and medical data in the body. In detail, the body contained the nursing process, social information, references to legal documents, home care status and medical information, mainly medical diagnoses and medication (extracted with authorisation from the medical summary). The eDischarge solution was a Web application that was connected to a central electronic health record (EHR), in which the eNursing Summary documents were stored. The eDischarge solution also included a certified card reader for the electronic health card (eHC). Patient's demographics were

read via the eHC and nursing, social and medical information of the patient were entered manually via the eDischarge client. Authentication via the health professional card was simulated by a software-key. Patient data could only be accessed when this key was invoked and the eHC was inserted (authorisation and authentication principle of the Health TI). As the current version of the eHC card that had been rolled out to the citizens did not have a pin-code on it, a second card carrying this information was used in the tests.

Certified card readers for the eHCs, software-key, electronic health record kernel and server and secure client-server communication constituted the laboratory Health Telematics Infrastructure, which had been developed by Fraunhofer Fokus in a previous project and was extended in this project to demonstrate the feasibility of implementing the Health TI specifications. The eDischarge application and the laboratory Health TI formed the proof-of-concept to be evaluated. The EHR server was located at the University Hospital Göttingen to comply with the privacy and data security regulations.

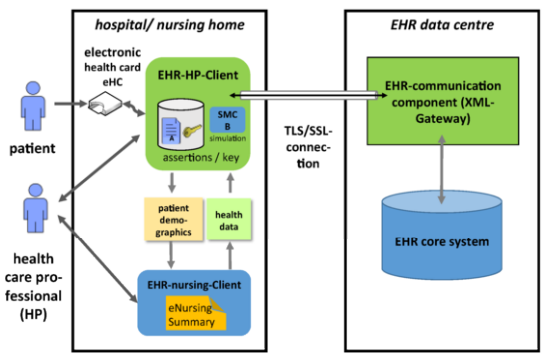

Figure 1 – Laboratory Health Telematics Infrastructure (TI)

Evaluation phases

The eDischarge application and its communication with the EHR server were evaluated during four phases, in which we aimed at measuring different targets (Table 1). The applications tested comprehended the creation and update of the eNursing summary and its storage into and retrieval from the central EHR server. Thus "sending" and "receiving" a discharge document were technically identical to storing and retrieving it centrally.

Table 1 – Evaluation Phases and their duration

No.	Primary aim	Duration
Ia	technical feasibility	(14/01 – 03/08/2014)
Ib	technical-organisational feasibility	(04/08 – 31/08/2014)
II	usability	(01/09 – 28/09/2014)
III	usability and utility	(29/09 – 31/03/2015)

In phase Ia, we wanted to know what types of problems occurred once the application was transferred from the technical laboratory of the developers to the *field laboratory* of the evaluators. The system was operated by two nurses of the evaluation team. In phase Ib, the evaluation took place at two clinical sites with two chief users (nurses) testing the system in a *realistic environment (office at clinical site)* with 20 realistic but fictitious discharge documents. Phases Ia and Ib covered the issues of a formative evaluation where the system still was technically adapted in accordance with the evaluation results. During all the phases, the users recorded the type, location and severity of the problems in standardised and structured log books. In addition, usability was assessed in phases II and III by the IsoMetrics questionnaire [12]. During these two phases, nurses, who were on duty, operated the system in the *same realistic environment* as in phase Ib. In phase II, data of six past discharges (real documents with modified identification data) were sent. Finally in phase III, 13 ongoing discharges were included in the study. Phase III was particularly designed to measure information completeness and utility of the eDischarge application in comparison to a paper-based discharge. To this end, discharge patients were randomly allocated to the eDischarge group or the paper discharge group. In phase III, we were also interested whether there were specific problems using the electronic health card and obtaining the declaration of consent.

Evaluation setting

We chose two evaluation sites in Osnabrück that were used to cooperating and communicating with each other; a municipal hospital with 717 beds (Klinikum Osnabrück) and a health system with nine nursing homes and three ambulant nursing services (Diakoniewerk Osnabrück). The testing was based on bi-directional communication, thus we looked at the discharge from the hospital to the nursing home and also from the nursing home to the hospital. To this end, we involved the Department of Neurology at Klinikum Osnabrück and Küpper-Menke-Stift (137 residents) as one of the nursing homes within the Diakonie. Two chief users from Klinikum Osnabrück and Diakonie accompanied the study in phases Ib to III.

During two information meetings, representatives from the two evaluation sites were informed about the study, its aims, the procedure and the technology involved. There were four user trainings that took place on the 21st and 25th of July 2014 in Küpper-Menke-Stift and the 22nd and 24th of July 2014 in Klinikum Osnabrück. In case of problems, the two chief users supported the users when operating the system. All users belonged to the group of nurses. The patients involved in phase III testing had to give their informed consent to take part in the study and also to allow the organisations to transfer their discharge data to the other organisation. The study design obtained approval from the ethics committee of Klinikum Osnabrück.

Pretest eNursing Summary as the eDischarge data set

In order to make sure that the HL7 eNursing Summary standard was suitable for the eDischarge application, we tested it against commonly used discharge forms. We were particularly interested in whether there were any data in the forms that were not covered by the HL7 standard and vice versa. We drew a regionally clustered random sample of 375 institutions throughout Germany (hospitals, ambulatory nursing services and nursing homes), which covered all three types equally. They were asked to send us their discharge forms. We received a set of 69 forms, which was enriched by forms retrieved from the Internet. Finally, a set of 114 different forms was obtained and independently analysed by two nurses regarding the match of potential data entries.

Results

Pretest results

The analysis of the 114 forms showed that all nursing, social and medical information found in the forms could be matched with fields in the HL7 standard. Only very specific information that was found in individual forms that concerned organisational issues and specific information on hygiene and physiotherapy could not be represented in the standard. In contrast, none of the forms contained all information items of the HL7 standard. Most of the forms were problem-oriented (77%). However, even if the problem could be entered, only in 23% the reason could be inserted. Only in 45% the interventions, and in 44% the means that were associated with a problem could be given. We concluded that the HL7 eNursing Summary was a valid and suitable standard for the eDischarge application, which contained more information to be carried than the paper forms.

Technical-organisational feasibility

The evaluation results are presented in the following in accordance with the respective research questions and topics.

In phase Ia, a series of many problems occurred. Examples are: installation of the clients in the hospital and the nursing home, the compatibility of the card reader, moving the server to the University Medical Centre Göttingen, terminology used in the application, workflow and pdf presentation. These problems could be solved during a continuous formative evaluation with several feedback loops that took eight months all in all (Table 1). The actual evaluation started in Phase Ib. In the following the results, which were obtained from analysing the logbooks in terms of the number and severity of problems, are presented. The logbooks allowed entries describing the following steps of operating the application: starting the program, reading patient demographics, creating a new summary (inserting, buffering, resuming, changing and deleting), transforming into pdf, printing, storing in EHR (sending), opening/browsing EHR and retrieving/viewing eDischarge summary (receiving). Problems and their severity could be documented for each of these steps.

The percentage of problems per discharge session (Figure 2) decreased from phases Ib to II and rose again when operating the system during real discharges (phase III).

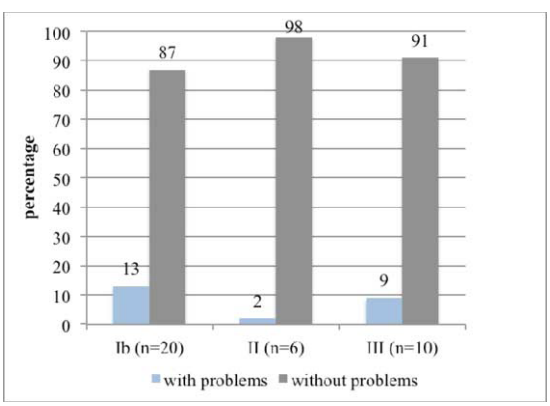

Figure 2 – Mean percentage of problems in phases Ib – III

Out of the 26 individual problems in phase Ib, 46% were rated as "1" and 46% as "3". On a severity scale from 1-3, "1" was denoted as "a problem that could be solved during the session" and "3" as "several problems that could not be solved during the session". Four percent of the problems in Ib were rated as "2" and 4% as "4". In phase II there was only one problem that was judged "1" and in phase III 25% of the 12 problems received the lowest severity level "1" and 75% level "3".

Usability

Usability data from phases II and III were pooled due to the small number of different nurses who actually used the system. Selected results for suitability of the task (median 4), error tolerance (median 3.25) and suitability for learning (median 3) of the IsoMetrics questionnaire [12] are shown in Figure 3. The scale ranged from 1 (strongly disagree) to 5 (strongly agree).

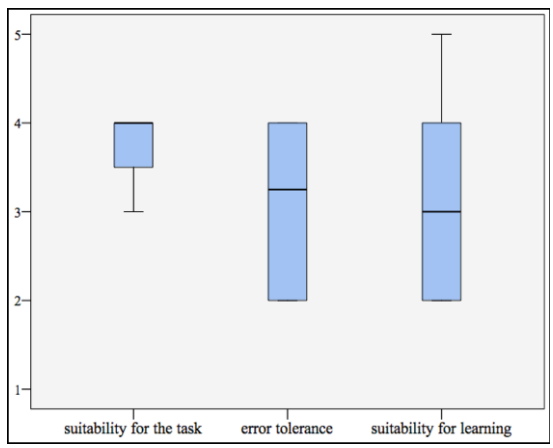

Figure 3 – Usability profile in phases II and III (n = 6 nurses)

eDischarge vs. paper discharge: utility and completeness

Fourteen patients met the criteria for inclusion in phase III. In one case, no consent for the participation could be obtained. In the other case, the electronic discharge summary could not be opened by the recipient due to a severe error (type 3). Thus, nine electronic and three paper discharges were rated with on the utility and completeness by the recipient on a six-point Likert scale (1 being very good and 6 very poor) in phase III.

Electronic discharges were rated better than paper discharges both with regard to utility and completeness (Figure 4). This judgement corresponded with the sum of entries of 18.4 (±2.5) for eDischarge summaries and 10.7 (±6.7) for paper summaries. Table 2 shows the average number of entries per category.

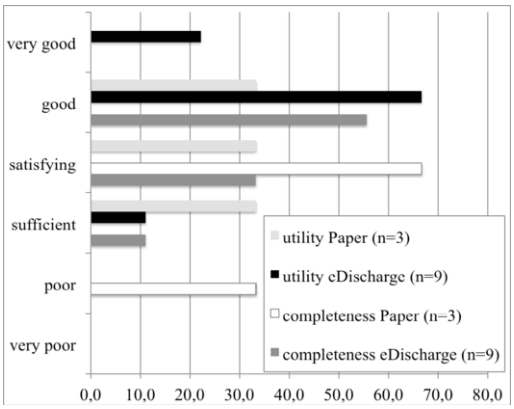

Figure 4 – Ratings of utility and completeness by recipients

Table 2 – Average number of entries

Category	eDischarge n=9	Paper discharge n=3
sender	1	0.3
recipient	1	1
patient demographics	4.4	2.7
nursing problem/intervention	4.3	2.7
assessments	1.0	0
social/administrative information	4.3	2.0
living environment	1.6	0.7
comments	0.8	1.3

The number of entries in eDischarge summaries exceeded the number in paper discharges in all categories with the only exception of "comments" and information about the "recipient". There were no assessments mentioned in the paper-based discharge form because the nurses decided not to include it in the summary.

There were a couple of problems associated with the handling of the electronic health card; in one case, the card was not available, and in the other case, the patient belonged to the group of privately insured persons who are not obliged by law to obtain an electronic health card. There was a general problem of getting the informed consent for sending the data electronically to the other institution. All the patients involved could not decide for themselves and thus the consent from a relative or the guardian had to be given. This procedure turned out to be complicated.

Discussion

This study is the first to investigate the feasibility and usefulness of the German Health Telematics Infrastructure in a clinically meaningful scenario. In addition, it is the first to evaluate the TI using a German national HL7 based standard, the eNursing Summary CDA. It is noteworthy, that the scenario tested mainly embraced nursing discharge management, which is a scenario that has been severely neglected by German TI executives before [13] and that still is not covered properly by the law [14].

There was a rather long period that was dedicated to formative evaluation in phase Ia with many feedback loops and meetings between the developers and the evaluation team. This long time proved to be absolutely necessary for having a system that worked in an acceptably stable manner and was adjusted to the workflows both at the hospital and the nursing home. The evaluation would not have been possible if the system had been taken out of the technical laboratory into the field without modifications. This particularly held true because the application still was in a proof-of-concept state. A dedicated phase of intertwined less formal evaluation and technical adaptations therefore seems advisable for applications in early stages to be evaluated successfully later.

The results of the formal evaluations in the following phases show that the software application stabilised with regard to the number and the severity of problems from phase Ib to II reaching almost no problems at all. However, the number and severity rose again in phase III, which was probably caused by the new users operating the system. They had received a training session but still may have felt unsure about how to use the system correctly.

The most important finding with regard to the usability was the good and quite unanimous rating for the suitability for the task. Analysing the usability also showed a median of 3.25 for error tolerance, which is slightly above the value in the middle of the codomain and corresponds with the number of errors particularly in phase III. Also, the suitability for learning was rated only moderately with a high variability showing that there is still enough room for improvements.

What counts at the bottom line is what the receivers say. Their judgement about the utility and the completeness gives an account of what the system can achieve. In both cases, the eDischarge approach yielded better ratings than the paper discharge. This was not surprising. It was very likely caused by the different types of forms used for eDischarge and for discharge as usual, i.e., a two-page paper form designed by Klinikum Osnabrück and a one-page summary used by Küpper-Menke-Stift. Whereas the eNursing Summary allowed the user to insert many different types of information and as often as necessary, the paper form was restricted to the maximum of two pages and so was the amount of information.

All of these results have to be treated with caution due to the small number of discharges in phase III. More data will have to be collected.

There are several limitations due to the laboratory Health TI into which the eDischarge application was embedded. They include first and foremost the complicated workaround because of the missing pin codes on the current version of the electronic health card and the non-usage of health professional cards for nurses. Their implementation is planned but has not yet materialised.

Adoption of IT standards such as the HL7 CDA based eNursing Summary and the eMedical Summary are rather slow in Germany due to unclear regulations. This was the reason why we could not test the standard in a fully fledged manner, i.e., connecting systems from different vendors.

Problems with handling the eHC that had been anticipated generally in the context of the Health TI actually occurred in

our small sample and therefore seem to be quite likely. Card based access control is a safe and elegant way but can cause a considerable delay in the process once they are not available. In this test environment, we could overcome the missing eHC via the manual input of patient data and via the second card with the pin code that was produced for each patient in this test. In the real world scenario, a missing card would have prevented the health care professional from reading the data not only on the card but also in the EHR. Thus, patients controlling their own health data is a highly desirable goal but it can turn out to be a big barrier when the card and the patient have to be at the same place at the same time. It is therefore advisable to rethink the use of eHCs in a discharge scenario.

Obtaining informed consent for elderly people who need assistance due to physical or mental disorders was not easy, but is feasible. Regulations for allowing health data to be transmitted electronically between health organisations in Germany, therefore, must be changed. A more generic solution seems appropriate, i.e., a citizen giving an informed consent that applies to many cases of when the data need to be transferred.

Meanwhile, the German government announced an eHealth act to give a fresh impetus to the Health TI and its applications [15]. The act addresses various clinically meaningful scenarios, in particular the electronic discharge summary, the medication plan and the emergency data set. This underpins the importance of this study, which provides useful insight into the mechanism of one of the high priority scenarios. However, it needs to be said that the eHealth act in its current version refers to nurses only as potential future users, despite its focus on the demographic change.

In summary, this study could demonstrate the technical-organisational feasibility of Health TI supported discharges. The usability of the web-based eDischarge application definitely needs to be improved for daily routine usage and to be integrated into the real Health TI. The study also highlights the importance of electronic data and electronic data transmission in terms of completeness of the information and demonstrates the utility of eDischarges. It thus makes the case for eDischarges in general and in nursing particularly. eNursing summaries and their standardisation and implementation must become a high priority goal in eHealth, and this not only in Germany [16].

Acknowledgements

This study has been funded by a grant of the German Federal Ministry of Health. We would like to warmly thank all participants (staff and patients) from the two organisations for their consent, time and effort.

Abstract

According to the literature, Denmark has a leading position in the dissemination and use of health informatics. However, there is a lack of systematically collected and documented experience of telemedicine solutions in Denmark. This evidence is being established with a new project, which maps out all telemedicine initiatives in Denmark. Data on all the initiatives is collected in a single database and some of the data is analyzed in this paper. It is shown that there are a very large number of telemedicine initiatives in Denmark and that the elements from the national strategy for telemedicine are clearly visible in the telemedicine map. The very large number of projects could, however, also indicate a lack of national coordination of initiatives and a need for evaluation activities to systematically collect and communicate the learning outcomes from all the new projects.

Keywords:

Telemedicine; dissemination; monitoring; evaluation.

Introduction

Denmark is among the world leaders in digitization of the health care sector [1, 2]. The small size of the country (5.5 mill. inhabitants), the relatively well-organized health sector, which is almost entirely publicly financed by tax money and the fact that every citizen has had a unique personal identifier since 1968 has enabled an efficient and penetrating implementation of computer systems. The systems were in the beginning mainly used for administrative purposes, but during the last decades also for clinical applications. All hospitals have EHR systems, including clinical notes, medication, all kinds of laboratory data, and imaging RIS/PACS. All general practice physicians are fully digitized, and citizens can all view their medical record online including lab tests and medication, renew prescriptions and in many cases book consultation with their GP. Because of the unique personal identifier and a pioneering work with the development of a national health data network, communication of health data has also been possible for a long time, which means that clinicians use it routinely. Of course the development of the many different health information systems and their integration has not been a walk in the park, many problems have had to be overcome and many conflicts have been resolved – it rather means that there exists a huge amount of experience.

Due to the pioneering efforts in health informatics, huge efforts have also been exercised in telemedicine, where Denmark also has been mentioned as the world leader by several sources [3, 4]. The Danish Government, Local Government Denmark, and the Danish Regions launched a national action plan for dissemination of telemedicine in August 2012 [5]. The plan outlines a number of new possibilities with telemedicine:

- Improved and more coherent patient care
- More individually planned treatment and self-reliant patients
- Increased professional competences across sectors
- Financial gains in municipalities and regions

To realize these potentials, a stronger framework must be established which includes reference architectures and standards, common assessment models, and overview of telemedicine solutions.

The national action plan for telemedicine notes that there is a lack of systematically collected and documented experience of telemedicine large-scale solutions that have been in operation over a longer period of time. To gain such experience, five specific telemedicine initiatives have been launched: clinically integrated home monitoring; home monitoring for COPD patients; tele-psychiatry; internet psychiatry; and national telemedical assessment of ulcers.

To produce an overview of telemedicine solutions and as a first step to systematize the wealth of telemedicine experience, all existing telemedicine projects in Denmark have been mapped in a single database [6]. The objective of the database is to annually collect and publish an overview of the diffusion of telemedicine in health care. The mapping is updated continuously through a proactive outreach work from MedCom. For each telemedicine project, the database contains data in the following categories:

- Master data (title, aim, etc.)
- Involved actors (managers, users, etc)
- Disease area
- Activities (Consultation, diagnostics, screening, monitoring, shared care, etc.)
- Relation to specific trajectory programs
- Applied technologies (hardware, software, specific integration to other systems)

The inclusion criteria of the database has been the WHO definition of telemedicine: "*The delivery of health care services, where distance is a critical factor, by all health care professionals using information and communication technologies for the exchange of valid information for diagnosis, treatment and prevention of disease and injuries, research and evaluation, and for the continuing education of health care providers, all in the interests of advancing the health of individuals and their communities*" [7]. The database contains data of 372 projects, which have been collected among national initiatives, initiatives in the five regions and the 99 municipalities in Denmark. As the private healthcare sector in Denmark with regards to health informatics and telemedicine is negligible, the coverage of the existing projects is regarded complete.

The database provides an opportunity to monitor the actual state of telemedicine in Denmark. The aim of this study is to

explore the numerous telemedicine projects in operation in Denmark with a particular focus on the aim of the telemedicine projects, the actors involved, the specific activities and the applied technology.

Methods

The study is designed as a cross section study. The data has been collected to the database from October 2013 to October 2014. Each Region has been responsible for the reporting in process and ongoing telemedicine projects. The regions and the municipalities have had the opportunity to enter the data directly into the database or sending the data to MedCom who then has completed the data entry process. MedCom has verified the data entered by the regions or the municipalities and the regions have verified the data entered by MedCom. For data viewing, the database has a query form interface as well as a graphic interface based on Google Maps. The complete content of the database can be downloaded in an excel format file.

Data Analysis

Parts of the data exist in the database as free text; however, a significant amount of the data is categorized and entered as numerical or dichotomous data. The analyses in this paper are limited to frequency counts of the central structured parameters and a few cross tabulations.

Results

372 telemedicine initiatives are included in the database. The majority of 204 initiatives are still in a project state, which means that development is still going on and they are financed by temporary funding. 157 are run in a daily operation modus, and 11 initiatives are in a stage of dissemination to regional or national coverage.

Disease Area

The initiatives cover a wide area of diseases. Figure 1 shows the distribution of the disease areas covered by the 372 initiatives. As some projects cover more than one area, this explains why the sum is exceeding the total number of initiatives.

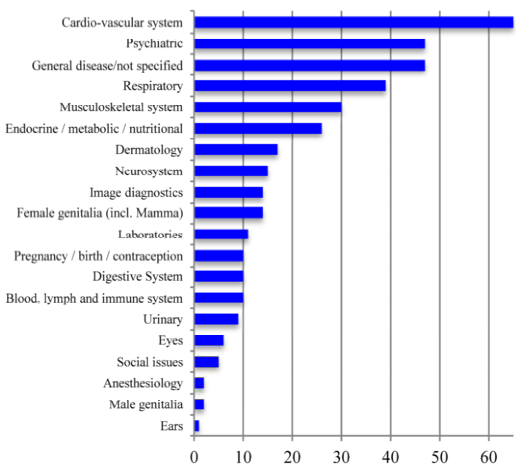

Figure 1 - Disease areas covered by the telemedicine initiatives in Denmark (n=372)

Cardiovascular diseases are the dominant area, closely followed by psychiatric diseases. The general disease area covers mainly general health surveillance in specific population groups, but can also include e.g., pain in geriatric areas, oncology in pediatric areas or ulcer assessment. Respiratory diseases are quite common for telemedicine initiatives, particularly COPD. Telemedicine systems for musculoskeletal diseases are predominantly directed at rehabilitation activities. Endocrine, metabolic and nutritional initiatives are various systems for diabetes patients. Denmark has a large program in telemedicine for ulcer surveilance where homenurses transmit images taken by a mobile phone or smartphone to the hospital based dermatologist or other health professionals.

Locality of Service

The telemedicine activities take place at many different localities, but the absolute predominant locality is in the hospital. 55% of all the initiatives include activities at hospital units. 31% have activities at municipal institutions (nursing homes, rehabilitation centres, social institutions etc.). 30% include activities at patients' or citizens' home. 6% take place at outpatient clinics, and 4% take place at GP' offices or local psychiatric units.

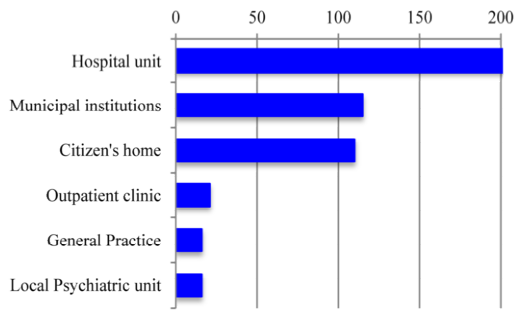

Figure 2 - Locality of service for telemedicine initiatives.

Hardware

Figure 3 shows what hardware is used in the telemedice initiatives.

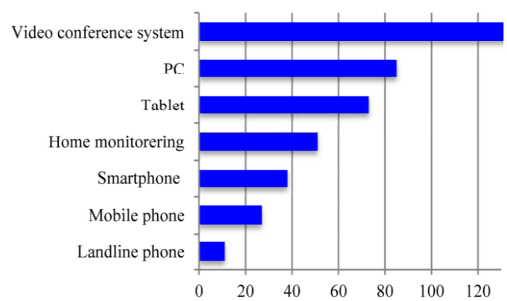

Figure 3 - Hardware used in the telemedicine initiatives

Video conference systems are used widely as they are included in many different tele services. Most of the cases as traditional video conferencing between various professional groups located in different hospitals, but also when teleinterpretation is necessary in the treatment of patients who do not speak Danish or English. Video cenferencing technologies are also applied in rehabilitation projects for instructing patients in their home, and to communicate with COPD patients.

Personal computers, tablets, and smartphones are used mainly in hospitals and municipal institutions by health professionals, whereas homemonitoring equipment is used in patients' home. Mobile phones and landline phones are used very little compared to the other more advanced technologies.

Integration to Other Health Care Data Systems

Few of the 372 telemedicine projects integrate to other health care data systems, as shown in Figure 4. 15 projects integrate to Electronic Health Record data in hospitals, and eight projects integrate to a GP system of which five also integrate to a hospital EHR. Seven projects integrate to homecare records in the municipalities, and six to the national health portal "Sundhed.dk".

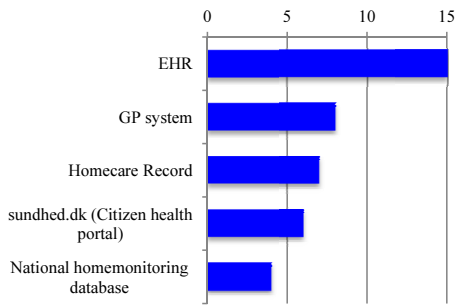

Figure 4 - Integration to other health care data systems

Discussion

It has been surprising how many projects have been reported to the database. Obviously the relatively broad definition of telemedicine from WHO can be interpreted to include a wide range of projects. For instance the high number of projects that use video conferencing will in a few years probably not be regarded as telemedicine projects, but just a normal part of professional communication as it is in many other sectors. The broad interpretations of telemedicine recur in other official documents in Denmark as well as in documents from private interest groups, not to mention the debate in general. From this perspective, the study cannot contribute with a precise presentation of the most important key aspects of a telemedicine solution – the spectrum remains very broad in the general discourse, as pointed out by Greenalgh et al [8].

The national strategy from 2012 [5] specifically mentions the following 5 initiatives as focus areas:

Clinically integrated home monitoring

Home monitoring for COPD patients

Demonstration and dissemination of telepsychiatry (Teleconferencing between health professionals)

Demonstration of Internet psychiatry (Depressions)

Dissemination of telemedical assessment of ulcers

The initiative on clinically integrated home monitoring was meant to include 2,000 patients in Denmark's largest cross-sector home monitoring project meant to run 2012-14. Patients with COPD, diabetes or inflammatory bowel disease as well as pregnant women with and without complications should be included in the project. The main objective was to provide experience of utilising a common technical solution for home monitoring of different groups of patients and to ensure coherent treatment procedures across the sectors in the health service. It was also the aim of the project to develop integration with the existing IT infrastructure, such as the EHR systems. Apart from a high number of projects concerned with cardiovascular diseases, which often is the monitoring of patients in their own home, it is difficult to see a significant concordance with the registrations in the database and the ambitious aims in the clinically integrated home monitoring initiative. As this is a cross section study, it is only possible to report on factual data from simple frequency counts and cross tabulations of the data available, hence it is not feasible to point to causal explanations of the observations.

Concerning the other initiatives there is a significant convergence between the strategy and the areas of diseases reported to the national telemedicine database.

The most predominant area of diseases is cardio-vascular disease. The projects in this category are often the monitoring of patients in their own home, but we also find many of the projects using information and communication technology to communicate between health professionals either individually or as a tele-video conference. The other main disease areas include the traditional chronic somatic diseases (Diabetes, COPD, Arthritis etc.) and the psychiatric area. The psychiatric area has two different categories of systems. One is termed telepsychiatry, which is video conferencing between psychiatric health care professionals to provide better courses of treatment for adult psychiatric patients. The other category, Internet psychiatry, is psychiatric treatment through an online IT program that is supposed to help patients suffering from depression. It is estimated that approximately 250,000 Danes suffer from depression, 30 percent of whom do not receive any treatment. It is estimated that four times more patients can be treated as in conventional treatment. The majority of the projects that indicate they cover general disease is mainly because they do not specify the area more precisely or because they cover more than one disease area, and therefore feel they are not covered by the list of disease areas.

The predominant localization for telemedicine projects registered in the database is professional institutions e.g. hospital units, municipal institutions, outpatient clinics, general practices, or psychiatric clinics. Activities in the patients' home are only stated by 106 of the 372 projects. This could underline the significance of the use of telemedicine to health professional communication.

The Methodological Approach

The data has been open for registration of projects to those responsible for the telemedicine projects in the five regions and 99 municipalities in Denmark. It has also been possible to send the data to MedCom to have them assist with data entry. However, as the decision on which projects to register has been up to the regions and municipalities, it is possible that some of the most active authorities have registered projects that are marginal to telemedicine, and more closely related to wellfare technologies. One example is a project focusing on the use of robot vacuum cleaners in the home of chronic deseased elderly citizens. Other projects might have been overlooked because of limited manpower in the municipalities and regions.

There are also large variations in the categorizations of the single parameters. Some projects have been very active in reporting - all the different technologies involved and, all the disease areas that they might face in the project, whereas other projects have underreported, omitting important fields. The validity of the database will be improved by a systematic validation of all the projects. However, the current state of the database is assessed to be valid for a broad characterization of the situation for telemedicine dissimination in Denmark.

Conclusion

In relation to the national strategy for telemedicine in Denmark, the database gives an overview of the initiatives in the regions and municipalities. It shows that the elements of the strategy are well prioritized following the guidelines in the strategy. The very large number of projects could also indicate a lack of national coordination.

A national coordinated evaluation of all the initiatives could improve the outcome of the projects in relation to both health outcome and cost related to development, implementation, and deployment.

Abstract

Clinical informatics workforce development is a high priority for medicine. Professional board certification for physicians is an important tool to demonstrating excellence. The recent recognition of clinical informatics as a subspecialty board in the U.S. has generated interest and excitement among the U.S. informatics community. To determine the extent of similar programs in countries around the world, we performed literature searches with relevant keywords and internet searches of websites of informatics societies around the world for mentions or descriptions of certifications and reviewed publicly available sources. The U.S. certification was prominent in the recent published literature. Germany and Belgium have long-standing certifications with South Korea and Sri Lanka considering similar programs. This is the first global view of clinical informatics board certification for physicians. Training and certification for non-physician informatics professionals in allied areas are widespread. Official recognition and certification for physicians and all informatics professionals represents a key component of capacity building and a means of addressing the shortage of a skilled informatics workforce. Wider adoption of certification programs may further attracting talent and accelerate growth of the field.

Keywords:

Clinical informatics, board certification, physicians, informatics workforce.

Introduction

There is a global need for sustaining and growing the informatics workforce. A key aspect of fostering interest and attracting talented candidates is to provide opportunities for training and career advancement in the field. Voluntary 'certification' of professionals is a highly-visible quality indicator and a tool to improve physician recognition. Professionals from diverse backgrounds such as nursing, pharmacy, clinical medicine, and computer science work in the field of clinical or health informatics. While there are many opportunities for certifications in allied fields such as information technology and information systems, there are fewer opportunities in the field of informatics. In the U.S., nursing informaticians have had a certification program [1, 2] and there are efforts underway to establish an interprofessional certification [3]. While physicians are eligible to apply for certification pursued by informatics professionals, there are limited opportunities exclusively designed for physicians.

Specialty training and "certification" by a professional board after graduating from medical school represents a path for physicians to demonstrate expertise and dedication in a specific area of clinical medicine. This common route for physicians practicing in the US exists in comparable pathways in Africa, Asia, Americas, Australia, and Europe. Well-recognized board certification pathways exist in most countries for clinical specialties such as internal medicine, family practice, surgery, pathology, or radiology. Many countries offer subspecialties in medical and surgical fields. These pathways are considered important and in the US have become essential for practicing clinical medicine, hospital staff privileges, faculty appointments in schools of medicine and to establish appropriate credentials and qualifications with healthcare purchasers [4].

Clinical informatics was recognized in 2011 as a medical subspecialty in the U.S. for physicians. The modern seeds were sown in 2005 during a town hall meeting conducted by the American Medical Informatics Association (AMIA) [5]. Subsequent development of the core content and fellowship requirements by leading informatics professionals [6, 7] formed the foundation of the recognition of clinical informatics as a distinct subspecialty [8, 9]. The subspecialty certification is co-sponsored by the American Board of Preventive Medicine and the American Board of Pathology. Until 2017, it is available to any physician who possesses a license to practice and an unexpired board certification in any other specialty from the American Board of Medical Specialties and can demonstrate more than 25% clinical informatics efforts for three of the last five years.

One of the motivations for the U.S. subspecialty certification was the recognition that informatics is now considered an essential component to the practice, education, and research aspects of all medical specialties and subspecialties [10, 11]. It is anticipated that in the short-term, the ability to show competency and expertise in this new field will act as a catalyst for the training and recruitment of experts to advance clinical informatics in hospitals and practices. In the long term, certification should allow for uniformity and standardization in training for physicians and prepare expert clinical informaticians. It is reasonable to assume that the desire and need to have qualified physician informatics specialists to fill positions such as chief medical/health informatics officers, directors of clinical informatics, and physician leads of EHR implementations will increase in the future.

With the excitement generated by the U.S. board certification [8], we sought to review existing data on the status of clinical informatics as a specialty or subspecialty for physicians outside the US. The hypothesis was that countries with well-established informatics infrastructure will have similar certification programs for physicians.

Methods

Literature Search

We used combinations of the following keywords for literature searches: "clinical informatics", "health informatics", "biomedical informatics", "specialty" or "subspecialty", "board certification", "physicians", "doctors" to search PubMed, Medline, Scopus, Web of Science, World Cat, CINAHL and Google Scholar. These databases were accessed through the University of Utah intranet.

Internet Search of Informatics Society Web Sites

A listing of member societies of the International Medical Informatics Association (IMIA) was reviewed as of November 30, 2014 from the IMIA website [12]. Brief descriptions of the member societies as listed on the IMIA page were first reviewed. Subsequently, individual society websites were accessed and contents reviewed for evidence of clinical informatics certifications or qualifications with an emphasis on physicians. Websites in languages other than English were reviewed using the automatic translation feature of either Google Chrome or Bing through Internet Explorer. Complying with rules for good scientific practice, all webpage screenshots or pdf versions used for this publication were archived.

Informal Discussions with Informaticians at International Meetings

The authors discussed the topic of board certification in clinical informatics for physicians with informatics professionals at the 2014 Asia Pacific Association of Medical Informatics (APAMI) held in New Delhi, India in early November 2014 and at the Annual Symposium of the American Medical Informatics Association (AMIA) in Washington, DC in mid-November 2014.

Results

Results of Literature Search

In reviewing the literature, the concept of an informatics subspecialty is not entirely new and was raised as early as 1985 and 1993 [13, 14]. The forward looking vision of Kunstaetter in 1985 is impressive [14]: *"The medical profession has to become directly involved by establishing and supporting medical informatics as a new specialty. To do otherwise would be equivalent to leaving the practice of radiology to physicists or medical therapeutics to the pharmaceutical industry."*

The search of databases yielded few relevant results related to clinical informatics board certification for physicians; as shown in Table 1, most of the recent papers were related to the US experience [5-11, 15]. The papers trace the history of the US board certification from concept to setting requirements to administration of the examination. The US certification generated considerable excitement in the US physician informatics community. The next step in this process is the establishment and sustenance of accredited fellowship programs for clinical informatics that will train the next generation of clinical physician informaticians.

During the literature search for clinical informatics certification, we noted separate pathology informatics training for pathologists in the US [16-18]. It is important to note that pathologists are eligible to apply for the US subspecialty board certification in clinical informatics.

Roger France *et al* review the certification process in existence in Belgium for physicians since an official ministerial decree was passed in 2001 by the Belgian parliament [19]. The criteria for being designated a "*Physician Specialist in Health Data Management"* in Belgium include being a licensed physician and requirements for formal coursework and practical training (each one year) and presentation of an original dissertation. There are no published articles regarding the success and challenges of this program nor an estimate of the number of physicians who hold this certification.

Two articles describe a "supplement medical informatics" qualification for German physicians first approved in 1991 [20, 21]. This qualification requires 1.5 years of formal coursework and practical experience that has to be certified by the physicians' institutional leadership. For this certification, we were unable to find published data on the number of physicians who hold this certification.

South Korea has established a formal training program in biomedical informatics for physicians [22]. The 18-month program leads to Certified Physicians in BioMedical Informatics (CPBMI), certified by the Korean Society of Medical Informatics (KOSMI). Kim anticipates that the next step would be to establish a board certification in biomedical informatics similar to the US program. There are numerous academic training programs (degree and non-degree granting) that are open to physicians with recommendations for standards and accreditation [23-25]. Several countries offer certification and recognition processes for informatics professionals including physicians [26, 27].

Table 1. Results of database searches for literature pertaining to clinical informatics board certification specifically for physicians (see text for combinations of keywords used)

Databases	Relevant articles from manual review of main search and 'related searches' (and top 100 results from Google Scholar)
PubMed, Medline, Scopus, Web of Science, World Cat, CINAHL and Google Scholar	Applicable specifically to physician certification: US related [5-11, 15]; World: [19-22]

Results of Internet Search of Informatics Society Web Sites

A review of the brief descriptions of the member societies charters on the IMIA website revealed training and career development of informatics professionals as an often cited goal with no specific mentions of certification specifically for physicians.

We reviewed the websites of 58 member societies of informatics listed on the IMIA website and 5 regional member associations. Countries listed as "Corresponding members" did not have websites listed. As shown in Table 2, most were amenable to review by virtue of being in English or translated using either Google Chrome or Bing. Information on certification specifically for physicians was noted on the US site (American Medical Informatics Association, AMIA). Information on the German site matched the literature search [20, 21], as did the link to the certification for physicians on the South Korean site [22]. There was no mention of the certification available in Belgium on their website. All other accessible websites had no mention of certification specifically for physicians.

Many countries offer certification for all informatics professionals and physicians would likely be eligible for those training and certification processes. Examples include the UK, Australia, and Canada.

The IMIA website and those of the Asia Pacific Association of Medical Informatics, European Federation for Medical Informatics, and Pan African Health Informatics Association yielded no information on certification specifically for physicians. The Regional Federation of Health Informatics for Latin America and the Caribbean website did not load and the Middle East Association for Health Informatics had no website listed.

Results of Informal Discussions with Informaticians

A meeting with the President of the Health Informatics Society of Sri Lanka resulted in our being alerted to the existence of the Specialty Board in Biomedical Informatics in that country at the Postgraduate Institute of Medicine at the University of Colombo and the possibility of a board certification for physicians in informatics in the near future (personal communication, Prof. Vajira H. W. Dissanayake). In performing internet searches on this topic, the Sri Lankan society on the IMIA webpage briefly mentions a master's course in biomedical informatics offered by the Specialty Board in Biomedical Informatics that is specifically offered for medical doctors and dentists in Sri Lanka [28].

Informal discussions with members of the editorial boards of the Applied Clinical Informatics journal and the International Journal of Medical Informatics at the 2014 AMIA Annual Symposium indicated no board certification pathways in clinical informatics for physicians in Brazil or Australia.

Discussion

Over the years, clinical informatics has had a significant impact on the practice of medicine. Demand for increasing quality and efficiency, while decreasing costs and errors, requires an informed and well-trained workforce in clinical informatics. As in any field, we face challenges in recruiting and retaining talented professionals to clinical informatics.

Table 2. Review of International Association of Medical Informatics member society websites for information on clinical informatics-related board certification opportunities and pathways specifically for physicians

Continent	Results/Comments
Africa	Cameroon, Kenya, Mali, Nigeria, South Africa: No information on clinical informatics board certification for physicians Burundi, Côte d'Ivoire, Ghana, Malawi, Togo: No website listed
Americas	Canada, Chile, Cuba, Uruguay: No information on clinical informatics board certification for physicians Argentina, Mexico, Peru: Website failed to load Brazil: Page could not be translated Colombia: No website listed ***USA: Information on US board certification for physicians***
Asia	China, Hong Kong, India, Japan, Pakistan, Philippines, Singapore, Taiwan, Thailand: No information on clinical informatics board certification for physicians Israel: No website listed Sri Lanka: Website failed to load Iran, Saudi Arabia: Website under construction ***South Korea: Link to certification for physicians in Biomedical Informatics***
Australia	Australia, New Zealand: No information on clinical informatics board certification for physicians
Europe	Belgium, Croatia, Czech Republic, Great Britain, Greece, Hungary, Finland, France, Ireland, Norway, Romania, Slovenia, Spain, Switzerland, Sweden, The Netherlands, Turkey, Ukraine: No information on clinical informatics board certification for physicians Austria: Page could not be translated Bosnia and Herzegovina, Italy: Page failed to load ***Germany: Medical informatics certification specifically for physicians***

A formal certification process with subsequent tangible benefits such as official acknowledgement and recognition of excellence, qualification for a named position of authority and possibly monetary benefits would go a long way in attracting and retaining professionals to this field.

Physicians are an integral part of the clinical informatics team that consists of dedicated professionals from various disciplines. While physicians are likely satisfied to be recognized for their knowledge, skills, and experience in informatics, it would also be important to recognize those that have achieved

official board certification in their chosen field. In this context, the US clinical informatics subspecialty board certification fulfills a long awaited aspirational need and has generated much excitement and discussion [29, 30].

With the news of the recent U.S. certification, we set out to find other similar programs in countries worldwide. As with the U.S., short- and long-term training and degree granting programs exist for informatics in many countries and these are open to physicians. It was more challenging to determine if there are programs that are reserved and specifically designed for physicians.

Our hypothesis that countries with well-established informatics infrastructure will have similar certification programs for physicians was not validated. It was interesting to note that the US is the latest to join a very short list of countries such as Germany and Belgium that have had programs equivalent or similar to US board certifications for physicians in the field of clinical informatics for many years. With South Korea and Sri Lanka actively considering similar programs, there appears to be an opportunity for other countries to consider and organize their training to offer similar recognition. The motivations and tangible returns will likely vary for different countries as will the infrastructure, logistics, social and political will to establish such programs.

We acknowledge several limitations of our study. Key word searches of online literature databases may be incomplete based on filtering for English language articles and choice of keywords. Our search would have missed the non-English literature. The automatic translation of non-English language websites was not independently verified by those familiar with the language and thus we may have missed references to board certification pathways. There were some sites that were not amenable to translation from their native language.

As this topic generates more interest among the international informatics community, there may also be opportunities to formally engage the IMIA member societies in dialog regarding certification opportunities and pathways for physicians. This could be conducted via email, online, or in-person surveys at international informatics meetings. IMIA might even serve as an authority on certification for member societies.

We encourage and request individuals with knowledge and experience with training and certification programs exclusively tailored for physicians in different countries to email us with details. We also encourage stewards of national informatics societies to email us with details of clinical informatics related certifications and qualifications for physicians in their countries. It would be important to have an exhaustive and as-complete-as-possible inventory of such programs so that best practices, motivations and lessons learned could be shared among informatics professionals.

Acknowledgements

We wish to acknowledge our international informatics colleagues who freely discussed this topic with the authors at various informatics meetings. We wish to appreciate the efforts of prominent informatics leaders from AMIA who worked tirelessly to pursue the US board certification and the American Board of Preventive Medicine for taking the lead to make the certification a reality. We thank Marjorie Carter (VA Salt Lake City Health Care System) for editorial and formatting assistance. There was no specific grant funding for this project.

The views expressed in this article are those of the authors and do not necessarily reflect the position or policy of the US Department of Veterans Affairs, the United States government, the American Board of Preventive Medicine, the International Medical Informatics Association, or our respective universities.

Abstract

We previously developed a prototype computer-based simulation to teach residents how to integrate better EMR use in the patient-physician interaction. To evaluate the prototype, we conducted usability tests with three non-clinician students, followed by a pilot study with 16 family medicine residents. The pilot study included pre- and post-test surveys of competencies and attitudes related to using the EMR in the consultation and the acceptability of the simulation, as well as 'think aloud' observations. After using the simulation prototypes, the mean scores for competencies and attitudes improved from 14.88/20 to 15.63/20 and from 22.25/30 to 23.13/30, respectively; however, only the difference for competencies was significant (paired t-test; t=-2.535, p=0.023). Mean scores for perceived usefulness and ease of use of the simulation were good (3.81 and 4.10 on a 5-point scale, respectively). Issues identified in usability testing include confusing interaction with some features, preferences for a more interactive representation of the EMR, and more options for shared decision making. In conclusion, computer-based simulation may be an effective and acceptable tool for teaching residents how to better use EMRs in clinical encounters.

Keywords:

Education; Electronic Medical Record; Physician-Patient Relationship; Simulation-Based Training.

Introduction

The potential and actual benefits of health information technology in general, and electronic medical records (EMRs) in particular, have been widely discussed. However, some concerns have been raised over unintended consequences and especially the impact of EMRs on patient-clinician communication [1]. Communication skills are central to patient-centered care and have been associated with patient satisfaction, conflict resolution, adherence to treatment, and a myriad of health outcomes [2]. Research has shown that the use of EMRs affects the patient consultation in both positive and negative ways. On the positive side, the use of EMR improves the exchange of medical information between physicians and patients. However, it often interferes with maintaining eye contact, establishing rapport, and psychological and emotional communication. Furthermore, physicians rarely utilized resources within the EMR, and the computer in general, for patient education [3].

Currently, the training provided to clinicians focuses mostly on technical aspects (e.g. how to document, how to prescribe a medication electronically) of using the EMR and not on how to best integrate it into the patient consultation; however, the need to "go beyond the nuts and bolts (operator skills) of using new technologies" [4] has been recognized. In previous studies, we identified some of the cognitive issues underlying the impact of EMRs on patient-physician communication, as well as strategies and best practices employed by physicians in order to overcome the negative and maximize the positive influences of the EMR on the consultation. Based on these findings, we developed and tested a simulation-based training intervention with standardized patients (actors) aimed at enhancing family medicine residents' competence in computerized settings [5]. However, widespread implementation of this simulation is compromised by its cost and scalability. Therefore, we developed a prototype computer-based simulation, named EMR-sim, which can be widely distributed and implemented [6]. The purpose of this study was to pilot test the prototype computer-based simulation in an attempt to: 1) identify usability and design issues, 2) examine its impact on family medicine residents' self-reported competencies and attitudes related to using the EMR in the consultation, and 3) assess the acceptability of the simulation to its intended audience (family medicine residents).

Methods

The Computer Based Simulation: EMR-sim

We described the development of the computer-based simulation—EMR-sim—elsewhere [see 6]. The current version of our EMR-sim is a Flash -based application that runs in a browser. To keep the cost minimal, it was developed using Adobe Captivate 7, which does not require extensive knowledge in programming and employs basic graphics. The application presents the user with screen captures from the EMR that can be enlarged by hovering a mouse over a magnifying glass image, dialogue texts, and decision buttons (Figure 1). The scenarios captured such issues as dealing with privacy and safety concerns related to documenting information in the wrong patient's chart [7], communicating with a triadic patient who may be distracted by the computer

[8], and using the EMR for patient education (e.g. by visualizing trends in lab results and use of risk calculators). After completing each scenario, the trainee is presented with feedback, specifically tailored to his or her choices, and references to support the feedback.

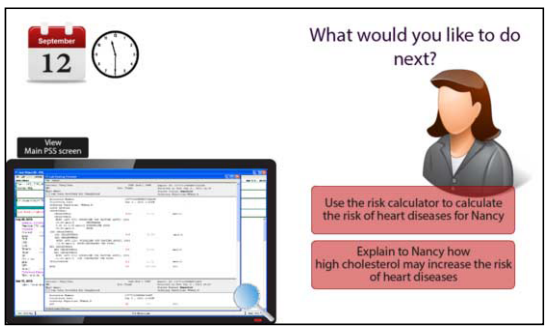

Figure 1- Screen Capture from EMR-sim

Phase 1: Pre-Pilot Usability Testing

A pre-pilot usability study was conducted as part of a course on usability evaluation at the Faculty of Information (iSchool) of the University of Toronto. Two of the authors (NF, ASk) and a third student conducted the pre-pilot under the guidance of the course instructor. A convenience sample of three Master of Information students with no clinical experience served as participants. They were assessed individually in separate 40-45 minutes sessions. Each session began with an introduction to the study and EMR-sim, followed by 'think aloud' observation [9] in which participants interacted with the simulation prototypes while verbalizing their actions, thoughts, and feelings. One of the researchers facilitated the observation using prompts such as "What are you trying to do now?," "What did you expect to happen (when you…)?," or "How did you feel about that?." A second researcher took notes.

Phase 2: Pilot Study

Participants' Recruitment and Data Collection

We sent email invitations to participate in the study to 49 Family Medicine residents from two teaching hospitals in Toronto (Sunnybrook Health Sciences Centre and Women's College Hospital), with a reminder email two weeks later. 16 residents consented (response rate: 32.7%) and were enrolled in 2 similar one-hour evaluation sessions (one with 11 and the other with 5 participants) during the lunch break (with lunch provided). At the end of the evaluation session participants received a $50 gift card honorarium.

At the beginning of each session, the purpose of the study was explained and the informed consent form was reviewed with the participants. After signing this form, participants filled in a pre-test questionnaire comprised of 5 items for self-reported competencies (measured on a 4-point scale ranging from low to excellent), and 6 attitudes items (measured on a 5-point Likert scale of agreement) related to using the EMR in the consultation. Demographic characteristics of participants (gender, age group, and year of residency) were also collected on the pre-test questionnaire.

After completing the first survey, participants interacted with the simulation prototype for two scenarios and then filled in a post-test questionnaire. The post-test questionnaire included the same measures for competencies and attitudes, plus additional items to assess the acceptability of the simulation and overall rating of the session. It also included a space for free text comments on the session.

Items measuring competencies, attitudes, and overall evaluation of the session (SEVAL) were taken from our previous study with standardized patients [5], with some modifications. Acceptability of the simulation was measured using the Technology Acceptance Model (TAM) [10]. TAM is a widely used model, which consists of 3 constructs: Perceived Usefulness (PU), Perceived Ease of Use (PEOU) and intention to use the system (INT). Although other instruments such as the Unified Theory of Acceptance and Use of Technology (UTAUT) typically explain greater portion of the variance in usage intention [11], TAM is a useful tool for practical purposes such as assessing the acceptability of an information system because of its parsimony. Our survey instrument included 6 items for perceived usefulness, 3 for perceived ease of use, and 4 items for usage intention. During the sessions, we observed 6 of the participants (3 in each session, 5 females and 1 male) as they interacted with the simulation and asked them to 'think aloud' as described before. The observers took notes and participants were audio recorded.

Prior to beginning the research, the study was approved by the research ethics boards of Sunnybrook Health Sciences Centre and the University of Toronto, and all participants gave written informed consent.

Quantitative Data Analysis

Reliability (Cronbach's alpha) of the measures for self-reported competencies and attitudes related to using the EMR in the consultation were tested using the pre-test data. Perceived usefulness, perceived ease of use, intention to use the simulation and participant's evaluation of the session were only measured on the post-test, and their reliability was tested using the post-test data. Except for attitudes towards using the EMR in the consultation that was low, scale reliability of all other measures was acceptable or good (Table 1).

Table 1 – Scale reliabilities of the measure instrument

Measure	Reliability (Cronbach's alpha)
Patient-physician-EMR competencies	0.75
Attitudes towards using the EMR in the consultation	0.28
Perceived usefulness of the simulation	0.92
Perceived ease of use of the simulation	0.76
Intention to use the simulation	0.80
Overall evaluation of the session	0.75

Data were analyzed using IBM SPSS Statistics 22. Combined scores for competencies and attitudes were calculated by summarizing the scores of all individual items and average scores were calculated for perceived usefulness, perceived ease of use, intention, and evaluation of the session. After testing for normality of the data distribution, we used paired-samples t-tests to compare competencies and attitudes scores before and after using the simulation prototypes. Effect sizes were calculated using G*Power 3.0.10 software. Inter-rater agreements on perceived usefulness, perceived ease of use, intention, and evaluation of the session were calculated by entering the data into MS-Excel and using the rWG(j) formula [12].

Qualitative Data Analysis

Qualitative data were analyzed as follows. First, researchers read through the free-text comments and notes from the 'think aloud' observations to familiarize themselves with the data. The three researchers who conducted 'think aloud' observations (AS, NF, and AS) met to review their notes for

clarification, compare the notes, and discuss preliminary themes that emerged. Then, free-text comments, notes, and audio recordings of the 'think aloud' sessions were entered into NVivo 8 qualitative data analysis software. The first author applied open coding to the data, adding new codes as they emerged. Codes were then grouped into categories and reorganized to develop the final coding scheme. The first author then used the scheme to recode all the data. To establish trustworthiness, a second researcher (EB) also coded a subset of the data (the free-text comments) using the same coding scheme. There was high agreement on coding (91% as calculated by NVivo) and moderate agreement on categorization (κ=0.56). The two researchers then discussed their interpretations, following which consensus on coding and themes had been reached.

Results

Pre-Pilot Usability Testing (Phase 1)

As participants were not clinicians, they gave little feedback on the content of the simulations and focused mainly on the navigation, clarity, and overall usability of the scenarios. Positive findings included reaction to emotions shown by the patient's avatar, particularly when tears were shed. All participants found this to be very effective.

The pace of the doctor-patient dialogue was one of the main issues identified by our participants. The unnaturally slow pace caused users to attempt to rush through the dialogue and subsequent navigational prompts and miss certain cues. Another key issue was a lack of clarity of system navigation. The original prototypes included a video play bar, which is added by Adobe Captivate by default. The majority of participants attempted to interact with this bar, instead of using the decision buttons, to progress through the scenario. A third issue was the 'mouse over' interaction with the magnifying glass that was confusing.

Based on these findings, we modified the pace of the dialogue and removed the video bar from the prototypes. The interaction with the magnifying glass is more difficult to change. We decided not to change it at this time but explain this mode of interaction at the beginning of the pilot sessions.

Characteristics of Study Participants

Descriptive statistics of the phase 2 pilot study participants are presented in Table 2. Of the 16 Family Medicine residents who participated in the study, the majority (n=14) were women. Except for one participant who was 40 or older, all participants were between ages 20 and 39—most of them (n=9) in their twenties. The majority of participants (n=10) were in their first year of residency (PGY1).

Table 2 – Characteristics of phase 2 study participants (N=16)

Participant characteristic	N
Gender	
Female	14 (81.2%)
Male	2 (12.5%)
Age group	
20-29	9 (56.3%)
30-39	6 (37.5%)
40-49	1 (6.3%)
Year of residency	
1st year	10 (62.5%)
2nd year	6 (37.5%)

Effect of Using the Simulation Prototypes on Skills and Attitudes

The combined score for self-reported competencies of integrating the EMR into the patient consultation improved from 14.88±2.63 before to 15.63±2.80 (M±SD; out of maximum 20 points possible) after using the simulation prototypes. This difference was statistically significant with a large effect size (Table 3). When the scores for individual items were compared, the scores for 4 of 5 items increased from pre- to post-simulation, but this improvement was only significant for 2 items: technical aspects of operating the EMR during the patient visit (paired t-test; t=-2.611, p=0.020) and using the computer for patient education (paired t-test; t=-2.611, p=0.020), which improved from 2.63±0.81 to 2.94±0.77 and from 2.75±0.86 to 3.06±0.77 (M±SD; on a 4-point scale), respectively. The score for one item (prevention of EMR-related errors) dropped from 3.31±0.60 to 3.06±0.68 (M±SD; on a 4-point scale), but this was not statistically significant (paired t-test; t=1.73, p=0.104).

The combined score for attitudes related to using the EMR during the patient visit also increased from 22.25±2.44 before to 23.13±2.16 (M±SD; out of maximum 30 points possible) after using the simulation prototypes. However, this difference was not significant (Table 3). The scores for 5 of 6 attitude items improved from pre- to post-simulation and decreased for one item ("use of the EMR enhances my performance"); however, none of these changes were statistically significant.

Table 3 – Self-reported competencies and attitudes related to the use of the EMR in the consultation.

	Pre-test		Post-test		t(df=15)	Sig.	Effect size (dz)
	M	SD	M	SD			
Competencies[a]	14.88	2.63	15.63	2.80	-2.535	0.023	0.63
Attitudes[b]	22.25	2.44	23.13	2.16	-1.754	0.100	0.44

[a] Combined score out of maximum 20 points possible.
[b] Combined score out of maximum 30 points possible.

Analysis of the free-text comments from the post-simulation questionnaire supports the positive impact of the computer-based simulation. In particular, respondents commented that the simulation increased their awareness of issues surrounding the use of EMR in the consultation *("Awareness of EMR pros and cons"* [p. 4]), and that it provided them with reassurance for their current practices *("Served to reinforce that my current practice is consistent with recommended/ acceptable practices"* [p. 7]).

Acceptability of the Simulation

The mean scores for acceptability of the simulation and overall evaluation of the simulation session, as measured on the post-simulation questionnaire, are presented in Table 4. Scores for perceived ease of use and perceived usefulness were good (4.10±0.73 and 3.81±0.74 on a 5-point scale, respectively). Intention to use the simulation and overall evaluation of the session were rated just above average. Inter-rater agreement on all scores was high (rWG(j)≥0.8)

Table 4 – Acceptability of the simulation and overall evaluation of the session.

	PU		PEOU		INT		SEVAL	
	M	SD	M	SD	M	SD	M	SD
	3.81	0.74	4.10	0.73	3.50	0.63	3.16	0.79
rWG(j)	0.90		0.82		0.89		0.80	

The qualitative data analysis provided additional support for the acceptability of the computer-based simulation. Participants commented that the scenarios were realistic, that the prototypes were easy to use and enjoyable *("Great, fun, simulation that is very realistic"* [p.7]), and that it would be effective for teaching Family Medicine residents how to better use the EMR in clinical encounters. However, they thought it would be most effective in earlier stages of the Family Medicine residency program: *"Use this to teach all residents! Would have been an excellent tool to have in the first month of residency. I would have definitely used this tool often when first learning how to use an EMR ..."* [p. 5]. Two participants, however, thought it would be difficult to teach these issues using a software application that cannot fully capture the nuances and range of patient behaviors: *"I find it is difficult to teach you how to balance using the computer during the actual encounter with patient interaction through an app, as the balancing act requires 'learning through doing' and is better done at clinic"* [p.12].

Usability and Scenario Design Issues

Several usability and scenario design issues emerged from the 'think aloud' observations. First, it was noted that, as opposed to the Master of Information students who focused mostly on the software itself, residents concentrated on the clinical aspects of the simulation; i.e., they spent substantial amount of time reviewing the information presented on the EMR and commented on the clinical decision options. Participants commented that they would like the EMR representation in the simulation to be more interactive—much more like the real system they were using (*"Creating an interface where we can actually use EMR during the simulation session"* [p. 8, in response to the question "what would improve the simulation?"]). They also wanted to have additional choices available—especially for shared decision making (e.g. "*I would ask her if she would like… it's hard for me to choose what I recommend"* [p.1,'think aloud' session]).

The pace of the simulation, which has been modified following the pre-pilot, did not seem to be an issue for most residents, except for two who commented on it on the post-simulation survey—one of whom was also observed in the 'think aloud' and seemed to be a very fast reader. Interaction with the magnifying glass was still confusing for some of the participants. Finally, through the 'think aloud' observation, we discovered a number of additional usability and scenario design issues that were not captured in the pre-pilot. For example, we noted that in a scenario discussing recent discovery of hypercholesterolemia, the EMR's screen capture indicated that the patient was already taking medications for this problem, which was confusing to participants. Other minor issues included a blank references screen when no references for the feedback were available, and one slide transition that was too fast.

Discussion

The effect of using EMRs on patient-clinician relationships has gained considerable research attention. However, educational interventions aimed at improving clinicians' competence in computerized settings are still rare. As part of our effort to bridge this gap, we have developed several interventions, of which EMR-sim is one [5, 6].

The results of this pilot study suggest that a computer-based simulation would be a useful tool for teaching Family Medicine residents how to better integrate the use of EMRs—and the computer in general—into the patient consultation. The combined scores for both self-reported competencies and attitudes related to using the EMR in the consultation improved from pre- to post-simulation (although this change was only significant for competencies), and so did most individual item scores. Our data suggest that the simulation is acceptable to users with good scores for perceived ease of use and usefulness. Free-text comments provided by participants support this analysis and suggest that the simulation may be especially useful in the early stages of the Family Medicine residency program. As a computer-based simulation is more scalable, compared to previous interventions such as simulation with standardized patients [5], we believe that it is worth further development and testing.

A pre-pilot usability testing with Master of Information students and a pilot test with Family Medicine residents proved to be a useful combination, as the students focused more on the interaction with the tool itself, whereas the residents examined mostly the medical information and decisions, and the display of the EMR component on the simulation prototype. This allowed us to identify some human-computer interaction issues, such as the pace of the conversation and interaction with the magnifying glass, as well as issues related to decision choices and interaction with the EMR component of the simulation prototype. In particular, residents pointed out that they would like to have more options for shared decision making. It has been suggested that the EMR can be effectively utilized for sharing understanding between patients and clinicians [13]. Additional scenarios that address this issue should be developed and tested. Second, residents preferred the simulated EMR to be more interactive—much like the real system they use. A potential way to achieve this is by integrating the simulation with an educational EHR system, such as the one developed by Borycki et al. [14].

Limitations and Directions for Future Research

The main limitations of this pilot study are that we used a small convenience sample and relied on self-reported measures. Although the results are promising, they should be taken with caution as the possibility of type 1 errors cannot be excluded. The intervention was short and only two simulation prototypes were tested, which may explain the lower score for the overall evaluation of the session. For future research, more extensive interventions should be developed and evaluated. A randomized controlled trial with a larger sample and using more objective measures could be implemented, such as video observation of real-life consultations and rating of patient-physician-EMR skills by external observers.

Scale reliability for attitudes related to using the EMR in the consultation was low. This may be due to the small sample

size and the fact that items are substantially different from each other that they may not be unidimensional [15]. To overcome this limitation, we summarized the scores for all items to create a combined attitudes score. However, future research may seek to develop a more reliable instrument for measuring participants' attitudes related to using the EMR in the consultation.

Our goal was to develop a simple, low cost, simulation using tools that do not require expertise in programming or graphic design [6]. However, some participants suggested a more realistic representation of the patients may be useful. Alternative designs that include animation or video segments may better portray patient behaviors—including non-verbal communication—and should be explored.

Finally, the simulation focused exclusively on the use of an EMR system. Increased use of more comprehensive EHRs and patients' access to their information through portals and personal health records (PHRs) introduce new challenges to the patient-clinician interaction during the patient visit. These challenges should be further explored and addressed in future designs of the simulation.

Conclusion

The study suggests that computer-based simulation may be an effective and acceptable tool for teaching Family Medicine residents how to better use the EMR in the consultation, and potentially other clinicians who face similar challenges of using EMRs in the clinical encounter. This potential should be further explored in future research. Usability testing with both clinicians and non-clinicians is a useful approach for identifying a variety of human-computer interaction and scenario design issues.

Acknowledgments

The study was funded by SIM-one (Ontario Simulation Network) Research and Innovation grant. We would like to thank the students and residents who participated in the study. The help of Samer Elamrousy in developing the computer-based simulation is greatly appreciated. Paul Fisher also assisted with the pre-pilot. Professor Joan Cherry was the instructor for the course in which the pre-pilot was held.

Mind the Gap: The Discrepancies between Patient Self-Reported Quality of Life and Medical Staff-Estimated Quality of Life

Yumiko Shimamoto[a], Mai Miyabe[a], Shuko Shikata[a], Eiji Aramaki[a]

[a] *Center for the Promotion of Interdisciplinary Education and Research, Kyoto University*

Abstract

Information on patient quality of life (QOL) is essential to many clinical decisions. Therefore, studies that aim to extract QOL information from patient narratives are increasingly drawing attention. Also, several studies have noted that web services for patients, such as patient social networking services, may represent promising resources for QOL research. However, it is still unclear whether patient narrative text contains corresponding amounts of QOL information as self-reported QOL. This study investigates if medical staff can accurately estimate patient QOL from only patient narrative texts. We analyzed (1) QOL of cancer patients estimated by medical staff from patient autobiographical texts and (2) self-reported QOL scores of cancer patients. We compared patients from the following 3 disease groups: (1) gastrointestinal cancer, (2) breast cancer, and (3) lymphoma. The SF-36v2™ Health Survey was used to measure patient QOL in both materials, and the QOLs were compared. We found significant differences between self-reported QOL and estimated QOL in breast cancer patients and lymphoma patients, but not in gastrointestinal cancer patients. In particular, the medical staff tended to underestimate physical QOL scores. Medical staff may underestimate several aspects of QOL scores. On the basis of these results, we may be able to achieve more precise QOL estimation from patient narratives.

Quality of Life; Cancer; Self Report; Narrative Medicine; Social Network Service; Support Systems.

Introduction

Advancements in information and communication technology (ICT) have facilitated the collection of patient narrative data in the form of self-descriptions and self-reports, and the enormous amount of such information (so-called Big Data) is now actively used in medical analyses [1].

"***PatientsLikeMe***"[1] is one of the more successful examples of the use of ICT services in healthcare. In this network, people are able to connect with others with the same disease or condition and share their experiences. In addition to ***PatientsLikeMe***, various other communication services for patients have been increasingly launched over the years [2-5]. "***LifePalette***" is one of the earliest patient communication services established in Japan, and focuses mainly on cancer patients. Another service, "***DIPEx-Japan***", provides patient narratives via videos of patient interviews. Similarly, the "***Healthcare Information Bookshelf Project***" also shares the same goal through the provision of illness narrative books [6]. ICT services are available not only for common diseases, as several rare disease communities have also launched their own social network services (SNS) to communicate with one another. These include the ***GISTERS*** network for gastrointestinal stromal tumor (GIST) patients, the ***Remudy*** registry for dystrophy patients, and the ***Re:me*** network for general rare disease patients. One of the main purposes of such services is to allow patients to share their experiences and support one another. However, the possible secondary applications of such data are also drawing attention.

One promising application of patient narrative data is to understand personal experiences of illness, and to enable training medical staff to improve the quality of care [7-11]. Several studies have reported that patient narratives can provide insight into the feelings of patients. Another secondary use of patient narratives is in quality of life (QOL) research [12, 13]. If accurate QOL data can be obtained from these narratives, the rich amount of text in SNS could provide more patient QOL information than was previously available.

This study is a pilot study to compare narrative data and self-reported data from the viewpoints of QOL. We investigate if medical staffs are able to accurately estimate patient QOL from narrative texts. To investigate this preliminary question, we collected (1) QOL of cancer patients estimated by medical staff based on patient autobiography texts and (2) self-reported QOL scores of cancer patients.

Materials

We utilized 2 types of materials as data sources: Material A (estimated QOL) and Material B (self-reported QOL). In both materials, we used the SF-36v2™ Health Survey (Japanese version) to estimate QOL[2].

Material A (Estimated QOL)

We identified illness narrative books written in Japanese by patients and had been published prior to June 2013. The initial sample comprised 53 books that were available at July 2013 (Authors: 23 men, 30 women; mean age: 36.7±19.7 years). From each of these books, 2 sets of 10 consecutive pages were randomly selected (10*2*53=1,060 pages in total).

These books were classified according to the ICD-10 disease codes for each author (Table 1). QOL estimations were conducted by 5 professional medical staff, comprising of 3 men and 2 women (mean age: 25.6±1.82 years). Each medical staff member read the selected passages, and then estimated the QOL of each patient author based on these passages. The estimations were conducted using the SF-36v2™ Health Survey, which consists of 36 questions. Using information from the books, the medical staff answered the questionnaire by speculating on the author's perspective.

	(C15-C26)	11 (20.0%)
	(C30-C39)	6 (10.9%)
	(C40-C41)	1 (1.8%)
	(C43-C44)	0
	(C45-C49)	2 (3.6%)
	(C50-C58)	12 (21.8%)
	(C60-C63)	1 (1.8%)
	(C64-C68)	1 (1.8%)
	(C69-C72)	1 (1.8%)
	(C73-C75)	0
	(C76-C80)	2 (3.6%)
	(C81-C96)	15 (27.3%)

Material B (Self-Reported QOL)

In order to obtain self-reported patient QOL scores, which is the gold standard, we asked 56 patients from ***LifePalette***[3] (an SNS for Japanese cancer patients) to participate in the SF-36v2™ Health Survey. The results were classified according to the ICD-10 codes of each respondent's disease (Table 2). This survey was conducted online through a dedicated website; the evaluation period was from June 16 to June 27, 2014. The effective response rate was 98.2% (13 men, 28 women, and 14 respondents of unknown sex; mean age: 52±9.9 years).

The SF-36v2™ Health Survey (Japanese Ver.)

For the investigation of both materials, we used the SF-36v2™ Health Survey (Japanese ver.)[4] to evaluate the health-related QOL of the cancer patients. The Japanese version of the SF-36v2™ questionnaire produces results in 8 sub-scales and 3 component summary scores (Table 3) [14-16].

Table 2– Material B: Patient Characteristics of the "LifePalette" Users

		n = 55
Age (years)		52±9.9
Sex	Male	13 (24%)
	Women	28 (51%)
	Unknown	14 (25%)

Methods

The narrative books were obtained in June 2013. The investigation period for Material A was from August 2013 to September 2013. We compared the estimated QOL (Material A) scores and the self-reported QOL (Material B) scores for each disease. From Material A, each of the 5 medical staff members who read the autobiographies produced a QOL value for each patient, resulting in a total of 5 QOL values for that patient. We calculated the average of these 5 QOLs as the estimated QOL of each patient author.

We then classified the patients according to their ICD-10 code disease categories in both Materials A and B (shown in Tables 1 and 2). We calculated the average QOLs in each category, which were regarded as the category QOL.

Comparisons were conducted for categories that had 4 or more patients (n>=4).

Patients were classified into the following 3 categories according to their ICD-10 codes: (1) C15-26 (Malignant neoplasms, digestive organs; or "gastrointestinal cancer"), (2) C50-58 (Malignant neoplasms, breast and female genital organs; or "breast cancer"), and (3) C81-96 (Malignant neoplasms, stated or presumed to be primary, of lymphoid, hematopoietic and related tissue; or "lymphoma"). Figure 1 illustrates the workflow design of this study using the example of breast cancer patients.

Results

The results are shown in Figure 2 for ICD-10 codes C15-26 (gastrointestinal cancer), Figure 3 for C50-58 (breast cancer), and Figure 4 for C81-96 (lymphoma).

In gastrointestinal cancer patients (Figure 2), the results showed no significant differences between Material A (n = 11) and Material B (n = 4) in all sub-scales.

In breast cancer patients (Figure 3), there were significant differences observed between Material A (n = 12) and Material B (n = 10) in 3 of the sub-scales (PF, RP, and GH) and one of the 3 summary scales (PCS).

Lymphoma patients (Figure 4) showed smilar results to the breast cancer patients (Figure 2): there were significant differences observed between Material A (n = 15) and Material B (n =4) in 4 of the sub-scales (PF, RP, VP, and SF) and one of the 3 summary scales (PCS).

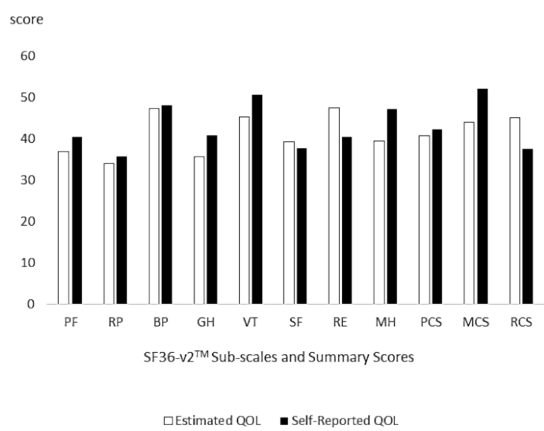

Figure 2– C15-26 (Differences between estimated QOL and self-reported QOL in gastrointestinal cancer patients)

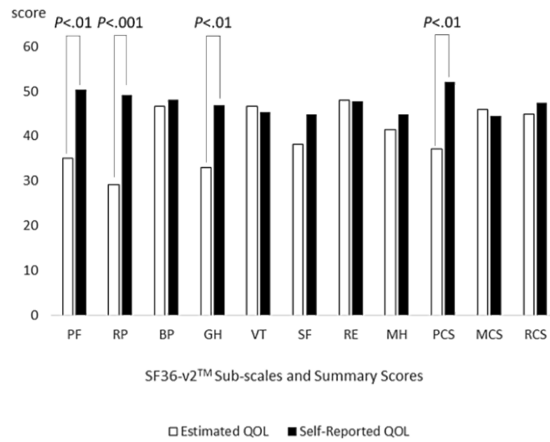

Figure 3– C50-58 (Differences between estimated QOL and self-reported QOL in breast cancer patients)

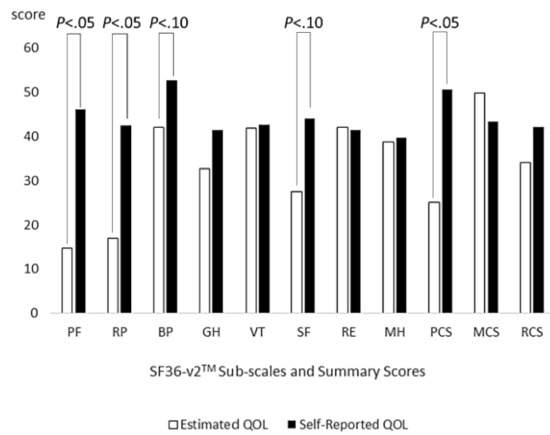

Figure 4– C81-96 (Differences between estimated QOL and self-reported QOL in lymphoma patients)

Discussion

Our findings showed that among the 3 summary scores of the SF-36v2^{TM} Health Survey, there were statistically significant differences in the Physical Component Summary (PCS) score between medical staff-estimated QOL and self-reported QOL in 2 of the 3 types of cancers analyzed. Although various studies have addressed patients suffering from these diseases, our study, surprisingly, indicated that the medical staff tended to underestimate patients' physical QOL. This difference in PCS scores between the medical staff and patient authors suggests that patients may tend to speak out explicitly regarding their pain. If so, patients may suffer from less pain than expected by the medical staff. In the near future, we would have more precise techniques to estimate the level of patient pain.

The other QOL summary scores (mental component and social component) did not show any significant differences between medical staff estimations and self-reporting. This suggests that the patient narratives contain much more information on mental and social activities, thereby enabling the medical staff to have a better interpretation of these aspects of QOL. As most patient narratives focus on their daily lives, it is reasonable that the medical staff were able to accurately estimate the mental and social aspects of patient QOL. In most cases, the QOL gap was due to underestimations by medical staff. In other words, medical staff rarely overestimated the patient

QOL scores. One of the possible reasons for this bias is that the medical staff may have been too intent on empathizing with the patients and sharing their feelings, which resulted in the gap.

Among the 3 cancer groups, the most precise QOL estimation was achieved in gastrointestinal cancer (Figure 2). In Japan, the mortality risk of gastrointestinal cancer is the second highest after lung cancer. This study showed that even in such a serious disease, there was little difference between the medical staff-estimated QOL and patient self-reported QOL; this suggests a degree of success in information sharing for this disease. In contrast, there were gaps between the 2 methods of QOL assessment in the other 2 cancer groups.

The results for breast cancer were not unexpected, as breast cancer has a relatively low mortality risk. In contrast, the mortality risk of lymphoma is higher than many other types of cancers. The reasons why the medical staff tended to underestimate the QOL for this disease require further study.

A surprising finding was that the self-reported QOL scores tended to be relatively high. For example, the Bodily Pain (BP) sub-scale in lymphoma patients was higher than the Japanese average (in this QOL scale, the average Japanese person has a score of 50 in each of the QOL scale components). In addition to the BP value, most of the other QOL sub-scales were over 40. This result suggests that cancer patients may be happier than we had expected.

Limitations

A limitation of this study is that the 2 aspects of the analysis were obtained from different media, which may have biased the results: Material A was acquired from autobiographical books and Material B from patients through SNS. However, we analyzed the same diseases in order to reduce the possible bias.

Conclusions

In this study, we compared medical staff-estimated QOL and patient self-reported QOL scores in 3 categories of cancer patients. Our findings demonstrate that the medical staff tended to underestimate the physical QOL of patients based on autobiographical text. In contrast, there were no significant differences between the 2 types of QOL assessments in the mental and social aspects. Care should therefore be taken when estimating QOL from illness narratives, particularly for the physical component of QOL. These results indicate a need to create support systems that can improve patient conditions by using the gaps in physical QOL assessment. In the future, if a technique for automated QOL estimation is developed, the result of this study will contribute to effective communication between patients and medical professionals.

Identifying Effective Approaches for Dissemination of Clinical Evidence – Correlation Analyses on Promotional Activities and Usage of a Guideline-Driven Interactive Case Simulation Tool in a Statewide HIV-HCV-STD Clinical Education Program

Dongwen Wang[a], Xuan Hung Le[a], Amneris E. Luque[a]

[a] *University of Rochester Medical Center, Rochester, NY, USA*

Abstract

Dissemination of the latest clinical evidence to community-based healthcare providers is a critical step to translate biomedical knowledge into clinical practice. We performed a study to analyze the correlations between the promotional activities and the usage of a guideline-driven interactive case simulation tool (ICST) for insomnia screening and treatment in a statewide HIV-HCV-STD clinical education program. For this purpose, we tracked users' interactions with the ICST and the sending of promotional email newsletters during a study period of 44 weeks. Results showed that promotional activities were strongly correlated with the number of audience as well as the intensity of use of the target resource. The strength of correlation varied in specific use contexts. Strong correlations were found between the sending of email newsletters and the intensity of resource use by promotion recipients, by new users, and through the most convenient access channel associated with the promotion. Selection of approaches for resource dissemination should consider the potentials and limitations of use contexts to make them more effective.

Information Dissemination; Clinical Practice Guideline; Evidence-Based Medicine; Interactive Case Simulation Tool; Insomnia; HIV; HCV; STD.

Introduction

Effective and timely dissemination of the latest clinical evidence to community-based healthcare providers is a critical step to translate biomedical knowledge into clinical practice. Dissemination and implementation research has become a national priority of the United States to harness the investment in biomedical research with the improvement in clinical care and public health [1]. The informatics research community has accumulated a critical mass of knowledge on effective approaches to disseminating clinical evidence, including use of online platforms to host clinical and educational resources and leverage of information and telecommunication technologies to promote them [2-3]. Nevertheless, few prior studies have reported on how promotional activities can improve the actual usage of online resources, and particularly, in what specific contexts the resource usage tends to respond to promotions.

In this paper, we report a pilot study to analyze the correlations between the usage of a guideline-driven interactive case simulation tool (ICST) and resource dissemination activities [4-6]. The results from this study will: (1) identify how dissemination activities can increase the usage of online clinical and educational resources; (2) characterize the profiles of use contexts that respond to promotions; and (3) direct the future development of effective approaches to disseminating clinical evidence.

Materials and Methods

Target Resources

The target resources for dissemination in this study were from the New York State (NYS) HIV-HCV-STD Clinical Education Initiative (CEI) online training program [7]. The CEI program is sponsored by NYS Department of Health (DOH) AIDS Institute, targeting primary care clinicians such as physicians, nurse practitioners, pharmacists, dentists, physician assistants, dental hygienists, case managers, social workers, counselors, and other team members providing care for HIV-HCV-STD patients. CEI aims to increase access to quality HIV-HCV-STD healthcare, to expand the base of clinicians who can effectively manage HIV-HCV-STD patients, to disseminate the latest clinical guidelines, and to foster partnerships between community-based care providers and HIV-HCV-STD specialists. Since 2008, CEI has initiated the online training program and developed various digital resources, including 235 multimedia learning modules, 93 online CME/CNE courses, and 12 guideline-driven ICSTs [8-9]. These resources can be accessed from multiple platforms, including a main website, a mobile website, Android and iOS mobile apps, online social networks and social media, RSS feeds, and newsletters sent through CEI email listserv. Over the five-year period since its launch, the CEI website has recorded 121,150 visits and 608,487 pageviews by audiences from 171 countries around the world [6,10]. It is now consistently ranked by Google and other search engines as a top site for HIV-HCV-STD clinical education.

ICST

ICSTs are online tools for clinical decision assistance and case simulation on individual patients [4, 11]. When used by healthcare providers, they serve as vehicles to dessiminate the latest biomedical knowledge. On the back-end, ICSTs are typically based on knowledge-bases adopted from clinical practice guidelines. For example, the *Insomnia Screening and Treatment* ICST selected as the resource for analyses in this study was based on a quick reference guide for HIV primary care clinicians, a simplified version of the full guideline developed by the NYS DOH AIDS Institute [4, 12]. On the front-end, ICSTs support user interactions such as review of patient management processes, examination of different

options for clinical decisions, and entry of case-specific data for individualized recommendations. In addition to user-defined patient cases, an ICST can include a list of pre-defined sample cases presenting the typical scenarios for clinical decision making as well as a text recommendation section with highlighted points adopted from the source guideline. These three sections, i.e., *recommendation*, *sample case*, and *user-defined case*, provide the complete user functions for an ICST [4]. The ICSTs can be accessed from the CEI website as well as mobile apps. Screenshots of the *Insomnia Screening and Treatment* ICST are shown in Figure 1.

CEI Resource Promotion

To ensure that its resources can reach out to the target clinicians and communities, CEI has been consistently engaging in program promotions through multiple channels. Among these, CEI newsletters sent to email listserv have been used most freqently. The CEI newsletters are regular updates of the latest CEI clinical and educational resources, such as the newly developed CME/CNE courses, multimedia learning modules, mobile tools, training events and news, etc. These newsletters contain hyperlinks pointing to the CEI website and other online platforms that host the various clinical and educational resources. For many years, we have been sending these newsletters to the CEI audience through email listserv every two to three weeks. The number of subscribers of this listserv is in the range of 2,200-2,600. When a listserv subscriber receives a CEI newsletter and finds interest in a specific item, he/she can click the hyperlink to check the details of that resource on the CEI website. He/she can also forward the email to colleagues or friends to further disseminate these resources through his/her professional and social networks [6, 13].

Study Design and Data Collection

To analyze the correlations between the ICST usage and promotional activities, we first collected the usage data from April 3, 2012 (when the *Insomnia Screening and Treatment* ICST was released) to February 4, 2013 (a period of 44 weeks) through tracking of user interactions with the system [4]. We focused on two usage measures: (1) episodes of use (reflecting the number of audience); and (2) frequency of visits to specific part of the ICST (reflecting the intensity of use) [4]. For this purpose, we built customized tracking functions to monitor the use of specific functions on different system user interfaces. System and user events, such as click of a button, check of a decision branch, and selection of a specific patient condition, as well as the timestamps of these events and user sessions, were stored in a tracking database for analyses. To control potential biases, usage by internal staff and for testing of app installation was excluded from the analyses [4].

To characterize the use context, we profiled user interactions by multiple dimensions:

1. Sections of ICST system function, i.e., *user-defined case*, *sample case*, *recommendation*, and *cross-box* (usage spanning over two or three of the previously listed sections);
2. *New* vs. *returned users*;
3. Access from *large-screen equipment* (desktops, tablets, etc.) vs. *small-screen hand-held devices* (smartphones, iPods, etc.);
4. Access through *web browsers* vs. *native apps*;
5. Audience from the *United States* vs. *non-US countries*;
6. Audience from the *NYS* vs. *out of the state*; and
7. Audience from *healthcare organizations*, *government agencies*, and *unknown settings*.

Additional technical details on tracking of user interactions, use contexts, and usage measures can be found in our previous publications [4, 13-14].

To collect the data of CEI resource dissemination through newsletters, we reviewed all the archived emails, selected those newsletters directly related to ICSTs, and recorded the date when they were sent.

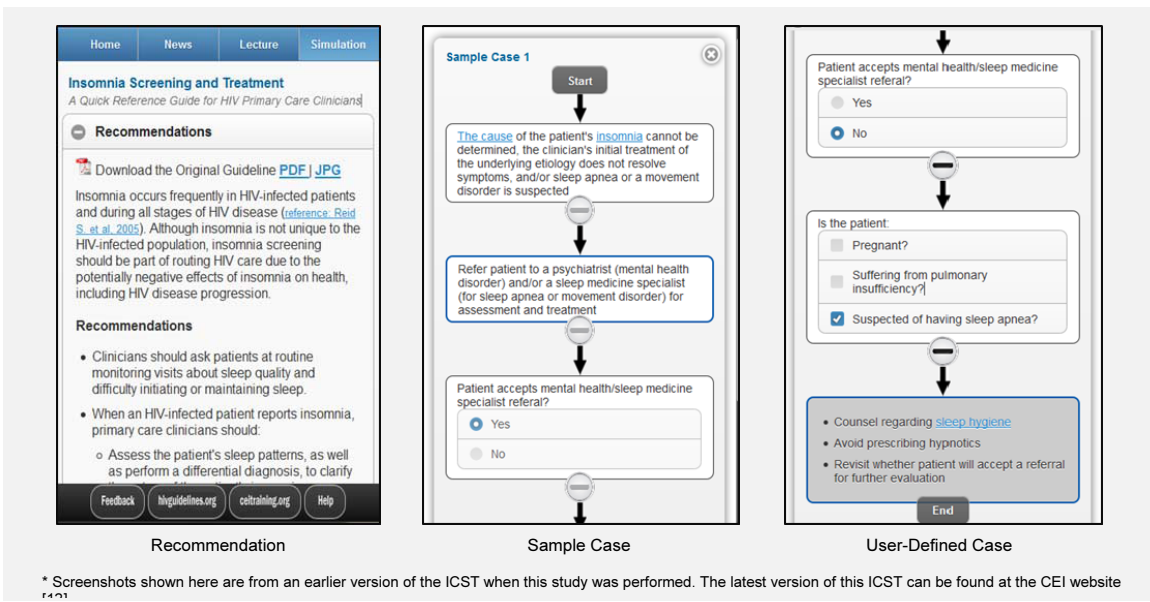

Figure 1 – Screenshots of the Insomnia Screening and Treatment ICST

Data Analyses

For data analyses, we segmented the total usage as well as the profiles of use context by the dimensions listed above as bi-weekly time-series. We plotted dissemination activities, i.e., sending CEI newsletters through emails, as a binary variable in a bi-weekly time-series with the same formulation. We then performed correlation analyses between each combination of usage profile/measure and the dissemination activities. We calculated Pearson correlation coefficient (r) to determine the potential correlations. We considered $|r| >= 0.5$ as a strong correlation, $0.5 > |r| >= 0.3$ as a moderate correlation, and $|r| < 0.3$ as a weak or no correlation [15]. For statistical analyeses, we used the SPSS software package [16].

Results

A total of 298 episodes and 1,415 rounds of interactions (visits) with the *Insomnia Screening and Treatment* ICST were recorded during the study period. Meanwhile, five CEI email newsletters were sent during this period to promote the ICSTs. The detailed distributions of the total ICST usage, its use in specific contexts, and the sending of email newsletters presented as bi-weekly time-series are shown in Figure 2.

Table 1 – Results of Correlation Analyses

Note: *r*: Pearson correlation coefficient; dark grey cells: strong correlation ($|r| >= 0.5$); light grey cells: moderate correlction ($0.5 > |r| >= 0.3$); white cells: weak or no correlation ($|r| < 0.3$).

Pearson correlation coefficients showed strong correlations between promotional activities and the following usage profiles:

1. Usage measured by episodes on *total usage*; and
2. Usage measured by frequency of visits on *recommendation*, by *new users*, through *web browsers*, by audience from *the United States*, and by audience from *healthcare organizations* and *government agencies*.

Meanwhile, Pearson correlation coefficients showed that there were moderate correlations between promotional activities and the following usage profiles:

1. Usage measured by episodes on *recommendation*, by both *new* and *returned users*, from *large-screen equipment*, through *web browsers*, by audience from *the United States*, by audience from both *inside* and *outside of NYS*, and by audience from *all settings*; and
2. Usage measured by freqency of visits from *large-screen equipment*, by audiences from both *inside* and *outside of NYS*, and on *total usage*.

Weak or no correlations were found between promotional activities and the following usage profiles:

1. Usage measured by episodes on *sample case* and *user-defined case*, from *small-screen hand-held devices*, through *native apps*, and by audience from *non-US countries*; and
2. Usage measured by freqency of visits on *sample case* and *user-defined case*, from *returned users*, from *small-screen hand-held devices*, through *native apps*, and by audience from *non-US countries*.

The detailed results of the correlation analyses, including *r* and p-value for each usage profile, are summarized in Table 1.

Discussions

The results have confirmed that there were moderate (measured by intensity of use) to strong (measured by number of audience) correlations between the *total usage* of the *Insomnia Screening and Treatment* ICST and the sending of CEI email newsletters. The strength of correlation in specific use contexts was not evenly distributed. Instead, certain usage profiles demonstrated strong or moderate correlations, while others only presented weak or no correlations. This is the first time a study has characterized the profiles of use context that do and do not respond to promotions. These identified usage profiles will direct future informatics research to develop effective and targeted approaches to disseminate clinical evidence, focusing on particular users, platforms, and settings.

Regarding the specific use contexts, here are the potential explanations on strength of the correlations:

1. The *recommendation* section of the ICST system function was the target of the promotional email (clicking the ICST hyperlink in the email would bring a user to this section). Therefore, its use demonstrated a strong correlation with the promotional emails. In contrast, the *sample case* and *user-defined case* sections presented only weak or no correlations.
2. The *new users* had not yet bookmarked the ICST webpage nor downloaded the mobile apps. Therefore, they were more likely to respond to email promotions.
3. Access through *web browsers* was the default channel when clicking the ICST hyperlink in the promotional email. Therefore, this use context recorded more responses. In contrast, access through *native apps* and *small-screen hand-held devices* (hosting the native apps) only showed weak or no correlations.
4. Most of the CEI newsletter subscribers were from *the United States*. Therefore, these audiences were more likely to respond to email promotions.
5. Most of the CEI program audiences were clinicians and public health professionals. Therefore, the audiences from *healthcare organizations* and *government agencies* demonstrated strong correlations.

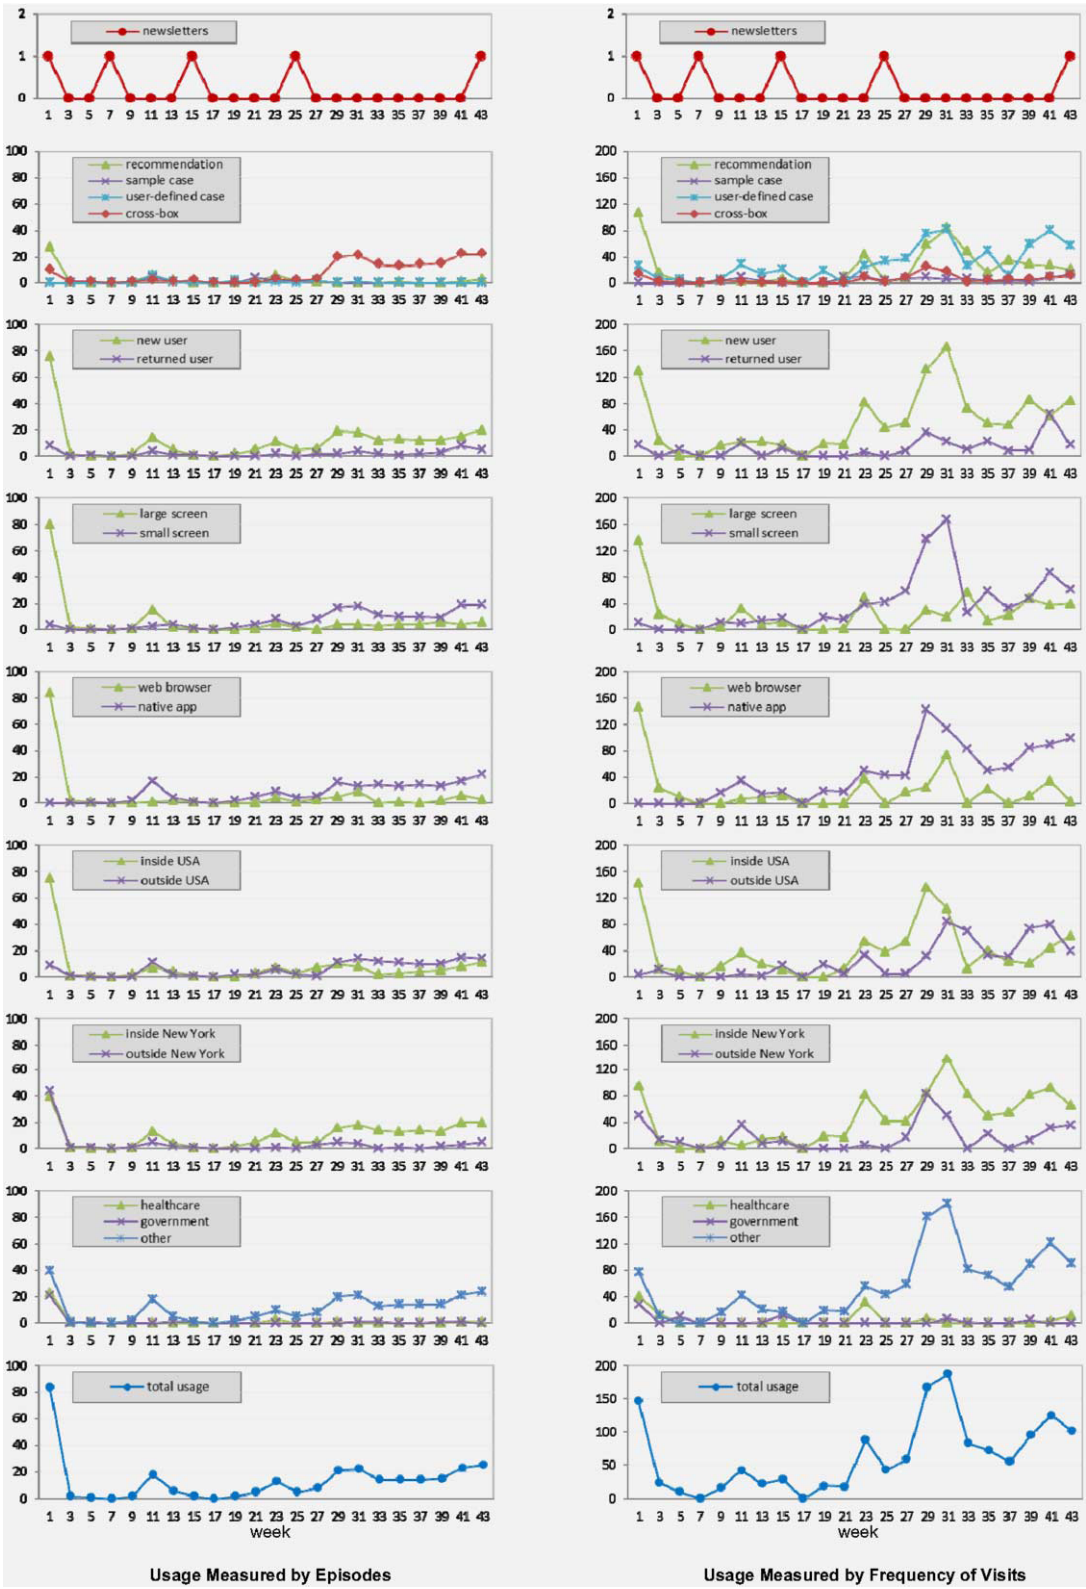

Figure 2 – Sending of CEI Email Newsletters, Total ICST Usage, and ICST Use in Specific Contexts during the Study Period

To plan for effective resource dissemination, the use contexts with strong correlations should be the focus. Regarding the use contexts demonstrating only weak or no correlations, resource usage is likely from a core group of loyal audiences (considering that we still recorded high level of usage in these use contexts) who do not need promotions.

There were two limitations in this study. First, we selected a single ICST as the target resource and only the email newsletter as the dissemination activity for analyses. There were many other resources developed by the CEI online training program, and these resources were promoted through multiple channels. Generalizability of the findings from this study, therefore, needs to be verified in future research. Second, this study focused only on correlations, which could be the first step to determine causality. For the use contexts with strong correlations, it may worth further investigating on the detailed pathways in which the dissemination activities can lead to the increasing use of clinical and educational resources.

Conclusion

Dissemination of clinical evidence through promotional activities is correlated with number of audience and intensity of use of online education resources. Strength of correlation depends on specific use contexts. Strong correlations were found between sending of email newsletters and intensity of resource use by promotion recipients, new users, and through the most convenient access channel associated with the promotion. Selection of approaches for resource dissemination should consider their potentials and limitations in specific use contexts to make them more effective.

Acknowledgments

This work is supported by NYS DOH AIDS Institute through contracts C023557, C024882, and C029086, and by the Agency for Healthcare Research and Quality (AHRQ) through grant R24 HS022057. Abstract

Current approaches for capacity building in Health Informatics (HI) in developing countries mostly focus on training, and often rely on support from foreign entities. In this paper, we describe a comprehensive and multi-dimensional capacity-building framework by Lansang & Dennis, and its application for HI capacity building as implemented in a higher-education institution in Kenya. This framework incorporates training, learning-by-doing, partnerships, and centers of excellence. At Moi University (Kenya), the training dimensions include an accredited Masters in HI Program, PhD in HI, and HI short courses. Learning-by-doing occurs through work within MOH facilities at the AMPATH care and treatment program serving 3 million people. Moi University has formed strategic HI partnerships with Regenstrief Institute, Inc. (USA), University of Bergen (Norway), and Makerere University (Uganda), among others. The University has also created an Institute of Biomedical Informatics to serve as an HI Center of Excellence in the region. This Institute has divisions in Training, Research, Service and Administration. The HI capacity-building approach by Moi provides a model for adoption by other institutions in resource-limited settings.

Keywords:

Health Informatics; Capacity Building; Developing Countries; Training.

Introduction

Health Informatics (HI) is rapidly being embraced in the developing world[1]. It is now commonplace to see comprehensive deployment and implementation of Electronic Health Record Systems (EHRs). As an example, countries like Rwanda and Kenya have rolled out EHRs at scale within Ministry of Health (MOH) facilities. Other health information systems, ranging from Health Information Management Systems, Laboratory Information Systems, Pharmacy Information Systems, and mobile Health Systems also have increased uptake. Beyond systems, there are multiple initiatives to develop and operationalize national Health Information System (HIS) strategies. At the same time, increasing numbers of evaluations are underway to increase the evidence-base of impact of HIS.

With increasing relevance of HI in developing countries comes the requisite need for comprehensive mechanisms to support these systems. At the very least, countries need appropriate institutional and human capacity in HI. Needed workforce in HI include: (a) Local level: Health IT professionals, eHealth specialized programmers, data managers, implementation managers, support specialists and reporting personnel; (b) Institutional level: Chief medical information officers; and health information management specialists, (c) Administrative: national and regional eHealth coordinators and eHealth monitoring and evaluation specialists, and (d) Other: Health information privacy and security specialists, HI researchers, among others. End users, managers and policy-makers also need appropriate training on relevant aspects of HI.

Over the years, various approaches have been undertaken to improve capacity in HI for developing countries. There are several examples of training programs. The American Medical Informatics Association has had the 10x10 program whose aim is to train 10,000 health care professionals in applied health and medical informatics within 10 years, with some coming from developing countries[2]. The Informatics Training for Global Health Program of the Fogarty International Center is another initiative that aims to improve informatics research training in developing countries[3]. Health Informatics Building Blocks (HIBBS) by the Global Health Informatics Partnership arm of AMIA also provides applied informatics training targeted to developing countries.

Beyond formalized training programs, other approaches to improving capacity have involved direct presence in developing countries of Western institutions, or significant North-South collaboration. Organizations like the International Training and Education Center for Health (ITECH) conducts extensive work and training in HI in multiple developing countries. Regenstrief Institute, Inc., Partners In Health, and numerous universities in the West now have formal relationships with developing country partners and ministries in HI. An exemplar case of institutional partnerships for HI capacity building involves collaboration between University of Washington, Seattle and Universidad Peruana Cayetano Heredia, Peru[4, 5]. The project, called AMUATA, has lasted for over a decade and led to significantly increased capacity through short-term courses, Masters and PhD-level HI training.

Unfortunately, few HI capacity building initiatives can mimic the success of programs like AMUATA. The problem is that most initiatives target narrow dimensions of a broader capacity building framework. It is quite common for individuals to be trained in HI within the Western setting, only to come back home and have no institutional base from which to operate. In fact, these individuals often receive little requisite recognition for their newly acquired skills. Numerous capacity building initiatives also lack buy-in from relevant governmental authorities, with efforts not necessarily aligned with larger national HI capacity-building goals. Some HI training programs also lack solid implementation partnerships to enable applied training in HI within real-world settings.

In this paper, we report on an HI capacity building initiative grounded by a comprehensive and multi-dimensional capacity building framework. We use this case-study approach to high-

light the necessity of a multi-faceted approach to HI capacity building, with the primary goal of realizing self-sustainable locally run HI programs in developing countries.

Materials and Methods

Capacity Building Framework

Lansang & Dennis describe a broad-based capacity building framework that takes into consideration both short- and long-term strategies for capacity building with an eye towards sustainability (**Table 1**)[6]. This framework incorporates various complementary approaches for capacity building, including: (1) graduate or post graduate training; (2) learning by doing; (3) institutional partnerships between developing and developed countries; and (4) centers of excellence. Building HI capacity at the institutional level requires an approach that touches on every aspect of the four dimensions in this framework. It should be noted that training, the most common modality currently used globally for HI capacity building, leads to a lower likelihood for sustainability if implemented in isolation.

Approach

The HI program described in this paper used the comprehensive framework by Lansang & Dennis to build a broad-based and sustainable HI Informatics Program within an institution in a developing country setting. The guiding principles for the HI program are outlined below:

- *Multi-Dimensionality:* The HI program should support various dimensions of HI, including: HI research, HI system development and implementation, and policy guidance.
- *Locally Led:* The program should aim for self-suffiency of the local institution, with little reliance from outside.
- *Strategic Partnerships:* The program should form public-private, North-South, and South-South strategic partnerships as needed to achieve its goals.
- *Government support and Integration:* The program should ideally operate within publicly-funded institutions, and work closely and in alignment with government-supported health and education sectors.
- *Accreditation:* Training programs should be formally recognized within the country, and follow well-accepted core competencies in HI training and education[7-9].
- *Affiliation with an Implementation Setting:* There needs to be an emphasis on applied and practice-based HI. As such, programs should collaborate closely with active care systems, and with larger national HIS ecosystem.
- *Economic sustainability:* Multi-modal approaches for finanacial sustainability, incorporating various business models, should be implemented to avoid excessive reliance on seasonal and time-limited grants or funding approaches.

Setting

The comprehensive HI program, guided by the Lansang & Dennis framework, has been implemented within Moi University in Kenya. Moi University is a public and government supported university located in Eldoret, Kenya[10]. The University was established in 1984 as the second university in Kenya through an Act of Parliament. It currently has 13 schools, 4 directorates and operates 6 campuses, namely: Main Campus, Eldoret West Campus, Odera Akang'o Campus, Mombasa Campus, Nairobi Campus, and Eldoret Town campus. Within the Town Campus is the College of Health Sciences that houses four schools, namely: School of Medicine, School of Public Health, School of Dentistry and School of Nursing. The College of Health Sciences has a student population of about 2,000 with a staff complement of over 500 of which 170 are academic staff. The College of Health Sciences hosts the HI programs.

Results

We describe the activities of the Moi University HI program along the four dimensions of capacity building framework outlined in the Lansang & Dennis framework, namely: (1) Graduate or post graduate training; (2) Learning by doing; (3) Institutional partnerships between developing and developed countries; and (4) Centers of excellence.

Graduate and Post Graduate Training

With support from the Norwegian Agency for Development Cooperation, and as part of the NORHED program, Moi University is leading the Health Informatics Training and Research in East Africa for Improve Health Care (HI-TRAIN) (Norad Project #: QZA-0484) project. This project, currently in its second of five years, has the following specific aims:

- Provide **post-graduate (Masters and PhD) level training in Health Informatics and research**. Targeted groups

Table 1. **Matrix of capacity-building strategies, likelihood of sustainability and research focus**

Entity targeted	Approach to capacity building			
	Graduate or post-graduate training	Learning by doing	Institutional partnerships between developing and developed countries	Centres of excellence
Individual[a]	+++	+	++	+
Institution	+++	++	+++	+++
Network	++	++	+++	++
National level	+	++	++	+++
Supranational level		++	+++	++
Financial investment[b]	++	+	+++	+++
Research focus →	Research skills ▫▫ → Programme, policy, systems			
Likelihood of sustainability[c] →	+ ——— +++			

[a] + indicates the entity is targeted sometimes; ++ it is targeted moderately often; +++ it is frequently targeted.
[b] Plus signs in this row indicate the extent of financial investment needed by national health research systems or funding agencies: + for low; ++ for medium; +++ for high.
[c] Plus signs in this row indicate the likelihood of sustainability of various approaches: + for fair; +++ for strong.

include health professionals and individuals with computer science background. Personnel trained in HI-TRAIN become core HI faculty at Moi University.

- Increase **number of women and marginalized populations in faculty-level training in Health Informatics and research**.
- Improve the **quality and quantity of Health Informatics research** conducted primarily by researchers based in the LMIC countries in collaboration Northern partners (*see Institutional Partnerships*).
- Provide **model curricula, educational programs and approaches for faculty-level HI training** that can be emulated by regional higher education institutions.

The two-year Masters in Health Informatics program is approved as a university program, and will train an average of 20 candidates per class. In total, 11 Masters candidates will get full scholarship support under HI-TRAIN program to pursue this degree. In return, these individuals will commit to serving as HI personnel and staff within the University. **Table 2** outlines the approved courses for the Masters program. Faculty for this program will come from various departments within Moi University, and from two other partner institutions for HI-TRAIN program, namely Makerere University, Uganda and University of Bergen (UiB), Norway.

	GRAND TOTAL OF ALL COURSES TAKEN		**57**

The HI-TRAIN program is also supporting four faculty members to receive full scholarship to undertake PhD training in HI at UiB in Norway, with research conducted within Moi University setting. As part of the scholarship, the faculty will have a binding agreement to serve within the HI programs at Moi to assure sustainability. Moi University has over the last several years also partnered with Regenstrief Institute, Inc. and Indiana University to also offer formal HI fellowship training at Regenstrief Institute. Individuals with fellowship training are now back to oversee new HI programs and research at home. With nine faculty members with fellowship or PhD training in HI, Moi University plans have its own locally run PhD program by 2016. The curriculum development and approval processes for this program start in early 2015.

While the Masters, Fellowship and PhD programs all aim to improve institutional capacity in HI, Moi University has also paid attention to improving capacity in direct response to government and implementation partner needs. Moi University is home to the Regional East African Center for Health Informatics (*REACH-Informatics*). This is project funded by Fogarty International Center as part of the Informatics Training for Global Health (ITGH) Program[11]. Since 2010, REACH-Informatics has offered 25 short courses to 469 participants. Courses have included data management, EHRs developer and implementer training, forms & concept dictionary training, and research database training.

Learning by Doing

Moi University's HI work has been grounded by the need to address real world challenges within the Kenyan setting. The University forms part of a larger care partnership, the Academic Model Providing Access To Healthcare (AMPATH)[12]. AMPATH is a collaborative between Moi University School of Medicine, Moi Teaching and Referral Hospital, and the AMPATH Consortium - a consortium of North American Academic Medical Centers led by Indiana University. Initiated in 2001, AMPATH has used a systems-based approach that closely links clinical care, prevention, research, and training. The program provides comprehensive care and treatment services through 544 MOH facilities and serves a catchment area of three million people.

From its inception, AMPATH recognized the need for comprehensive Health Information Systems to assure optimal care for the people it serves. AMPATH was the first implementation site for the open source electronic record system, OpenMRS, with the implementation called the AMPATH Medical Record System (AMRS)[13]. Success of AMRS helped to convince the Kenyan MOH to roll out OpenMRS in over 300 MOH clinics. Beyond eHealth, AMPATH has used mobile technology for: (a) data collection as part of a home-based counseling and testing for HIV program that has reached over a million individuals; (b) computerized clinical decision support for HIV and chronic disease management; (c) mobile store-and-forward teleconsulttion; and (d) mobile learning and counseling platforms, among others[14-17]. The AMPATH partnership with Moi University offers a real-world laboratory in HI, where trainees can work to complement foundational aspects of HI training. As an innovative arm of the MOH, AMPATH HI innovations largely inform the national conversations in HI.

Institutional Partnerships

A core component to Moi University's HI capacity building initiative is the formation of strong strategic partnerships. These partnerships include:

- *South-South Institutional Partnerships in HI*: Moi University has natural strength in applied Clinical Informatics. The Institution however recognizes that a big part of HI includes foundations of health informatics with a significant computer science component – competencies ranging from algorithms, visualization, analytics, natural language processing, security, to artificial intelligence. To this effect, Moi University has partnered with the School of Computing and Informatics Technology (CIT) of another

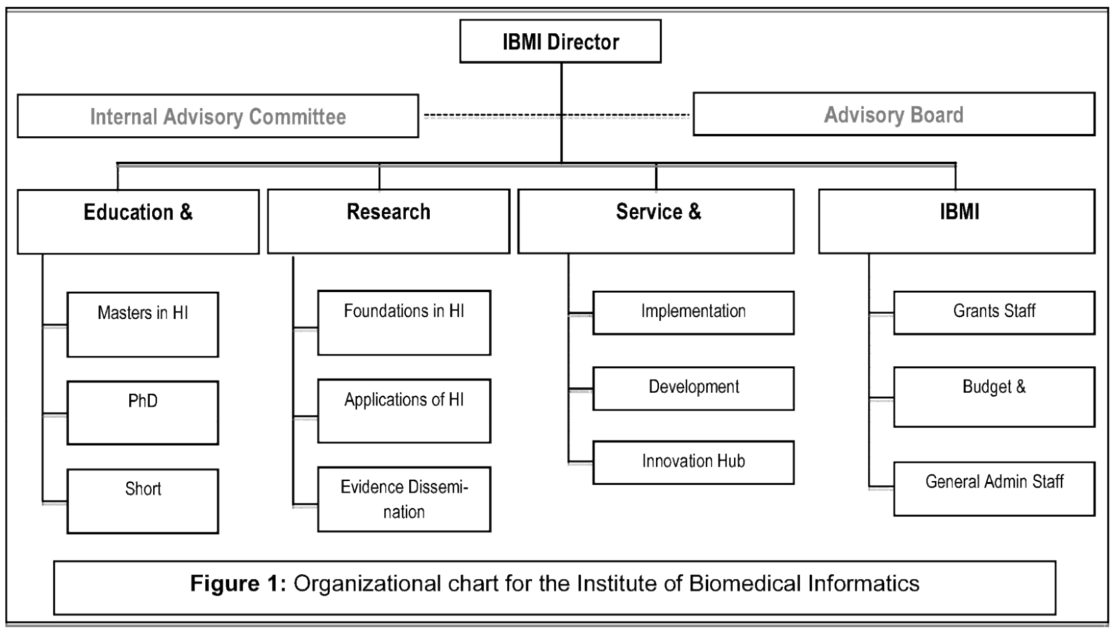

Figure 1: Organizational chart for the Institute of Biomedical Informatics

regional university, Makerere University (Uganda) for its HI initiatives. CIT has 22 PhD holders on the academic staff, with fully fledged academic departments in Information Systems, Computer Science, Information Technology and Software Engineering. Makerere is a member of the HI-TRAIN program, and will be sending students for Masters training in HI at Moi University, and making available faculty to teach in the HI degree courses.

- *North-South Institutional Partnerships in HI:* Over the years, Moi University has partnered with Regenstrief Institute, Inc. (RI) and Indiana University to advance global HI. Among the core achievements of this partnership is the development and implementation of OpenMRS. Moi University has also partnered with University of Bergen (UiB), with a particular emphasis on PhD-training of new emerging HI faculty. All Moi University candidates pursuing PhD-training in HI at UiB will have a Bergen University faculty supervisor in addition to a Moi University supervisor. The HI partnership involves the Center for International Health and Department of Informatics at UiB.
- *Public-Private & Public-Public Partnerships:* As a public institution, Moi University has formed strategic partnerships with organizations in both the public and private sector to ensure sustainability. Partnerships include work with ITECH-Kenya to train implementers on KenyaEMR, which is being rolled out broadly with Kenya. The University is also partnering with Jacaranda Health, a social enterprise for health, on mobile and e-learning platforms for health. Partnerships with counties are in the inception phases, with the goal of training county personnel in HI.

Centers of Excellence

It is well recognized that building centers of excellence offers the best chance for sustainability and long standing capacity building efforts[6]. Centers provide academic homes for highly trained faculty in HI and allow for consolidation of numerous approaches to capacity building. To this end, Moi University has established an Institute of Biomedical Informatics (IBMI), to serve as a regional HI Center of Excellence. The IBMI at Moi is made up of: (a) *Education & Training Division* – hosting the Masters program, PhD program, and short courses; (b) *Research Division* – serving as the research and dissemination arm; (c) *Service & Extension Division* – providing consulting, development and implementation services to MOH and partners in the region; and (d) *Administration Division* – overseeing all administrative aspects of the IBMI (**Figure 1)**. IBMI is an integral part of the University, with core funding coming from the government of Kenya to assure sustainability. Additional sources for Institute financial sustainability come from student tuition, research grants, and service-based fees.

Discussion

Existing approaches to HI capacity building within resource-limited settings remain largely non-comprehensive. In this paper, we present a case study of a publicly-funded higher education institution in a developing country that has taken a multi-dimensional HI capacity building approach guided by a comprehensive framework. This approach incorporates training, learning by doing, partnerships and a center of excellence. The approach can serve as a model for adoption by other institutions in similar resource-limited settings.

There are multiple reasons why the described capacity-building model needs to be the goal for institutions aiming to improve HI capacity in developing countries. To improve HI capacity, countries need highly trained individuals to serve as teachers and trainers. These individuals should ideally be locally-based, and should have a supportive home-institutional environment within which to work. The work should be grounded by the country HI capacity needs and strategies, and by interaction with real-world healthcare settings to inform innovations and evaluations. In a resource-limited setting, chances of self-sufficiency and sustainability can only happen when strategic partnerships are formed to reduce burden to individual institutions. Ideally, core support should come from the country's ministries of education and health, as this will provide an excellent foundation for sustainability, and for alignment with country's HI systems strategy.

The described capacity building approach has its limitations. To implement all dimensions for capacity-building, a significant amount of financial investment is needed. It is fair

to say that this capacity-building model is not necessarily practical for all institutions. It is one best suited for select institutions tasked with a larger role of leading each country's HI capacity building initiatives. It should also be noted that each component of the model can be used to generate financial resources for sustainability. Tuition will be charged for training and degree programs, service fees can be incorporated into the learning-by-doing experience and into centers of excellence activities. Partnerships can also be strategically used to alleviate the financial burden to the institution.

To actualize the proposed comprehensive approach takes time. It would be unrealistic to expect institutions to implement all dimensions at once or within a short period. At the very least, institutions should have a roadmap that would eventually see the actualization of all dimensions over realistic timelines. Alternatively, multiple institutions with complementary strengths can collaborate to create a comprehensive partnership that has every dimension of the model, without necessarily having all components fall under a single institution. As an example, an institution with strengths in HI training can partner with another institution with a HI Center of Excellence.

Funding organizations should pay attention to the models for capacity building they are supporting. The NORHED capacity building initiative by NORAD is a program that is already looking at capacity building initiatives at very comprehensive level. In addition to encouraging all dimensions, the NORHED program also emphasizes gender equity, as females are often underpresented in the Sciences. Other programs that can have impact in this area include ITGH and the Rockefeller's Digital jobs initiative. The goal should be sustainable HI capacity initiatives beyond a grant period.

Conclusion

It is possible to build comprehensive, locally-run HI capacity building initiatives that are sustainable, in line with country capacity building priorities, and which offer high quality and accredited HI training.

Acknowledgments

This work was supported in part by NORHED program (Norad: Project # QZA-0484) and the REACH-Informatics Program (Fogarty Institute: Grant # D43 TW008447-01S1). Special thanks to the Vice Chancellor, Moi University (Prof. Richard K. Mibei); Dean, School of Information Sciences (Prof. Justus Wamukoya); and core HI partner institutions, namely Makerere University, Regenstrief Institute, Inc., and University of Bergen.

Health Informatics: Developing a Masters Programme in Rwanda based on the IMIA Educational Recommendations and the IMIA Knowledge Base

Graham Wright[a], Frank Verbeke[bc], Marc Nyssen[bc], Helen Betts[a]

[a] *CHIRAD, University of Fort Hare, East London, South Africa*
[b] *Department of Biostatistics and Medical Informatics, Vrije Universiteit, Brussel, Brussels, Belgium*
[c] *Regional e-Health Center of Excellence, University of Rwanda, Kigali, Rwanda*

Abstract

Since 2011, the Regional e-Health Center of Excellence in Rwanda (REHCE) has run an MSc in Health Informatics programme (MSc HI). A programme review was commissioned in February 2014 after 2 cohorts of students completed the post-graduate certificate and diploma courses and most students had started preparatory activity for their master dissertation.

The review developed a method for mapping course content on health informatics competences and knowledge units. Also the review identified and measured knowledge gaps and content redundancy. Using this method, we analyzed regulatory and programme documents combined with stakeholder interviews, and demonstrated that the existing MSc HI curriculum did not completely address the needs of the Rwandan health sector. Teaching strategies did not always match students' expectations. Based on a detailed Rwandan health informatics needs assessment, International Medical Informatics Association (IMIA)'s Recommendations on Education in Biomedical and Health Informatics and the IMIA Health Informatics Knowledge Base, a new curriculum was developed and provided a better competences match for the specifics of healthcare in the Central African region. The new approved curriculum will be implemented in the 2014/2015 academic year and options for regional extension of the programme to Eastern DRC (Bukavu) and Burundi (Bujumbura) are being investigated.

Keywords:

Education; Medical Graduate; Teaching; Curriculum; Knowledge.

Introduction

The International Medical Informatics Association (IMIA) is the international organization for health and biomedical informatics. IMIA acts as a bridging organisation, bringing together the constituent regional and country health informatics associations and their members. The IMIA General Assembly has approved a number of endorsed documents:

1. Recommendations of the International Medical Informatics Association (IMIA) on Education in Biomedical and Health Informatics; First Revision (2010)
2. IMIA Knowledge Base (2011)

The Recommendations of the IMIA on Education (1)

Rather than reproduce all the recommendations, the first 6 illustrate the nature of the recommendations:

Biomedical and Health Informatics Core Knowledge and Skills

1.1 **Evolution of informatics** as a discipline and as a profession

1.2 **Need for systematic information processing** in health care, benefits and constraints of information technology in health care

1.3 Efficient and responsible **use of information processing tools**, to support health care professionals' practice and their decision making

1.4 **Use of personal application software** for documentation, personal communication including Internet access, for publication and basic statistics

1.5 **Information literacy**: library classification and systematic health related terminologies and their coding, literature retrieval methods, research methods and research paradigms

1.6 Characteristics, functionalities and examples of **information systems in health care** (e.g. clinical information systems, primary care information systems, etc.)

The IMIA Knowledge Base (2-4)

In 2011, IMIA also published a knowledge base structuring the knowledge of the Health Informatics domain into 14 topics (listed below). The base was subdivided into 245 knowledge units. This unit list served in the review process as a tool for measuring the coverage of Health Informatics knowledge by the MSc HI curriculum:

1. Computer Science for Health Informatics (ICT for Health)
2. Health & Social Care Processes
3. Health (care) Records
4. Health and Social Care Industry
5. Health Informatics Standards
6. Knowledge Domains and Knowledge Discovery
7. Legal and Ethical
8. People in Organisations
9. Politics and Policy
10. Technologies for Health
11. Terminology, Classification and Grouping
12. Uses of Clinical Information
13. Using Informatics to Support Clinical Healthcare Governance
14. Computer Systems Applications in Health (Toolkit)

Figure 1 – Section of the IMIA Knowledge Base

In February 2014 in Kigali with a team of 3 international reviewers, the University of Rwanda, College of Medicine and Health Sciences (CMHS) commissioned a curriculum review of the MSc in Health Informatics (MSc HI) programme. The team used an Action Research method to review and rewrite the curriculum based on the two IMIA endorsed documents above.

The review activities consisted of:

- A study of national regulations and documents relevant for the MSc HI programme.
- A study of the MSc HI programme documents.
- A study of international standards, recommendations and literature on health informatics postgraduate education programmes (6,7) especially those that had been endorsed by the IMIA.
- A mapping of the existing MSc HI curriculum content on to international standards and regulations.
- A field study of needs and competences in Rwanda in the area of health informatics (5), mainly through a number of interviews with relevant stakeholders, including Ministry of Health (MoH) staff, NGOs, public and private health facilities, education & training institutions, health software development companies and research organisations.
- An evaluation of how students, teaching staff and CMHS faculty perceived the existing MSc HI curriculum.

Information obtained from the MoH clearly showed a growing need for people with combined skills covering Information Technologies (IT), Information Systems (IS), Information Management (IM) and Health System (HS) knowledge. Generally speaking, there is a shift from IT and IS towards IM and HS needs: internal MoH software and systems development activities are progressively phasing out in favour of private sector outsourcing. Consequently, the MoH requires new management skills related to contracting, people management, and project management. Health facilities identified competences related to health care research (mainly for university teaching hospitals), data mining, and statistical and epidemiological reporting based on Electronic Health Record (EHR) content. Public and private hospitals described the urgent need for Chief Information Officer (CIO) profiles that again must be capable of combining IT, IS and IM knowledge and skills.

Based on competence needs and employment perspectives, the following human resource profiles can be identified for MSc HI graduates:

- Health Information Managers (mainly IM and HS knowledge and skills needed in public sector)
- Clinicians proficient in IT, IS and IM (health facilities)
- Information System Implementers and System Integrators (e.g. for EMR-HMIS integration)
- Information System Evaluators (Health Informatics Interventions impact measurement and Information Systems quality evaluation)
- Education staff (Academic staff and Information Systems training staff / functional experts)
- Researchers (Health Informatics domain and other Health Care domains)

All of the competences identified by the Rwandan stakeholders were covered by the IMIA recommendations on Education.

Methods

The IMIA recommendations were mapped to the IMIA Knowledge Base and the learning outcomes produced would underpin the identified human resource profiles. This mapping then lead the team to develop an SQL database.

IMIA competences - knowledge base mapping

In the first exercise, 40 competences identified in the "IMIA recommendations for health informatics education" were mapped on 0 or more knowledge units in the IMIA knowledge base. This resulted in a total of 400 mappings, clearly demonstrating the IMIA Knowledge Base units synergy with the IMIA competences.

IMIA competences - existing programme mapping

Each module title of the existing MSc HI programme was then mapped onto a number of IMIA competences (replacing the original programme objectives). This showed that a total set of 38 IMIA competences (out of 40) were covered by the existing programme. The existing programme modules did not have consistency within or between modules in terms of content. There were gaps in the content and poorly distributed weightings of the content. However, the module titles and objectives gave a good starting point to automatically populate these modules using the IMIA recommendations and the IMIA Knowledge Base. The computer based exercises took 5 days using a three dimensional SQL Querying method devised by Dr. Verbeke.

IMIA knowledge - existing curriculum mapping

Based on the mapping between existing MSc HI module titles and IMIA competences combined with the previously performed mapping between IMIA competences and IMIA knowledge units, an automatic mapping between existing MSc HI modules and IMIA knowledge units was generated. This demonstrated that 219 (out of 245) knowledge units were covered by the existing titles and structure.

Development of a reference curriculum

The automatically generated mapping table between existing curriculum modules and IMIA knowledge units was then cleaned for redundancy (assigning each knowledge unit to only one single module) and for completeness (modifying module content in order to cover previously missed knowledge units). This provided a set of modules with 100% knowledge coverage whilst avoiding any redundant or repetative teaching.

In a final phase, a number of modules were (partially) merged in order to come to an equally distributed module weight of 10

credits for each module, with 6 modules in the post-graduate certificate year and 6 modules in the post-graduate diploma year.

Results

An Example of Module Aims, Outcomes and Content Introduction to Health Informatics

Brief description of aims and content

This module introduces the discipline of health informatics and the details of the programme. The module covers a number of basic concepts in health informatics and ensures that students from different backgrounds have the opportunity to share perceptions of health and medical informatics.

Learning outcomes (competences) from IMIA Recommendations

1.1 Evolution of informatics as a discipline and as a profession

1.4 Use of personal application software for documentation, personal communication including

Internet access, for publication and basic statistics

3.1 Basic informatics terminology like data, information, knowledge, hardware, software, computer, networks, information systems, information systems management

3.2 Ability to use personal computers, text processing and spreadsheet software, easy-to-use database management systems

3.3 Ability to communicate electronically, including electronic data exchange, with other health care professionals, Internet /intranet use

3.4 Methods of practical informatics/computer science, especially on programming languages, software engineering, data structures, database management systems, information and system modelling tools, information systems theory and practice, knowledge engineering, (concept) representation and acquisition, software architectures

3.6 Methods of technical informatics/computer science, e.g., network architectures and topologies, telecommunications, wireless technology, virtual reality, multimedia

Indicative content (units) from IMIA Knowledge Base

- Access to information
- Computer literacy (ECDL)
- Computer systems
- Computing methodologies
- Data management and storage
- Databases
- Demystify IT for users
- Explains health informatics
- History of methods of gathering information in the clinical workplace
- Human Computer Interaction (HCI) principles
- Information sources
- Information Storage and Retrieval
- Internet, intranets and associative technologies
- Networking
- Web technologies
- Wireless technology
- Prototype system for a department

The curriculum content was also weighted according to the recommended student workload in European Credit Transfer and Accumulation System (ECTS) credits for the knowledge and skill areas of a two year biomedical and health informatics master (BMHI) programmme.

Table 1 - European Credit Transfer and Accumulation System (ECTS) credits

Knowledge/Skill Area	Credits
1. BMHI Core Knowledge And Skills	80
2. Medicine, Health And Biosciences, Health System Organisation	20
3. Informatics/Computer Science, Mathematics, Biometry	40
Total ECTS credits	120

The teaching components of the programme total 120 credits. These components are divided between the Certificate and Diploma levels. However the number of ECTS recommended by the IMIA team are 140; therefore, 20 of the credits will be included in the Research Thesis.

Post-graduate certificate

The post-graduate certificate programme essentially focuses on IT and IS after an introduction to the Health Informatics domain. The development of practical skills and essential knowledge of the Rwandan health informatics context are core components of the programme.

Introduction to Health Informatics: includes an introduction to the discipline of Health Informatics and the scope of the programme. The course covers a number of basic concepts in Health Informatics and ensures that the students have the opportunity to share perceptions of Health and Medical Informatics (8).

Healthcare Management and Organisation: covers the concepts of Healthcare Management in relation to Health Informatics. The Health Informatics concepts underpinning management, organisational culture and socio-technical aspects are explored (8).

Knowledge Management in Healthcare Delivery: covers Health Informatics topics, in particular the processing of Data into Information, and then into Knowledge. The use of this knowledge is explored in Decision Making and Education.

Management Information Systems: explores the connection between information systems (IS) and business performance. It also explores the issues of security, transparency, traceability and Return on Investment.

Electronic Health Records Management and Hospital & Health Information Systems: assists students to understand the complexities of managing individual and community based health information. Students will be able to understand different approaches of health record modeling; purpose based structuring of health information and the principles of integrated health information management (9).

Health Informatics Applications including PACs, MIT, Telemedicine and mobile technologies: explores the concepts of ubiquitous computing technologies to provide positive support in the population. It explores the use of telemedicine and e-Health solutions for medical support. This is underpinned by an exploration of wireless technologies.

Post-graduate diploma

The post-graduate diploma year is designed to add more IM knowledge and skills, leading the student to a broader comprehension of the complete health informatics domain and its place in the health system ("the big picture"). It also adds

essential project management skills and elements of critical thinking enabling well-considered evaluation of different options. Research skills and scientific reasoning are formally included in the programme.

The following modules are part of the diploma programme:

Software Based Clinical Decision-making and Support Systems: explores the concepts of information to support health professionals in their decision-making and development of therapeutic strategies. The module covers clinical pathways and guidelines and biomedical modeling and simulation as well as the principles of data representation and cognitive aspects of information processing.

Public Health Informatics includes Patient Information Kiosks, Websites and Public Health Systems for Epidemiology, Epidemic Control and GIS: explores the concepts of data representation and information analysis. The module includes information tools to support education for the public and health professionals, epidemiology and public health.

Social-Cultural, Legal and Economic Impact of Health Informatics: explores ethical, legal, and social issues arising in the use of computer-based technology and information systems in the delivery of health care. The module also includes health informatics ethics and regulatory frameworks.

Project Management and IT Introduction in Health Care Delivery, Case Studies in Health Informatics: students learn the principles of project management and using information management within projects. Through exploration of health information projects, students gain a real-world understanding of how to manage biomedical informatics projects taking into account the socio-technical aspects of implementation.

Research, Monitoring and Evaluation in Health Informatics: explores an introduction to research in the areas of health informatics and covers a wide range of methods and techniques. The topics range from epidemiology data and analysis and mapping to measures of patient outcomes following medical interventions. Evaluation and monitoring of programs of care and clinical audit are also included (9).

E-health Enterprise Architecture: explores the details of healthcare information technology (HIT) interoperability and standards. The evolution of technology in healthcare, along with the impact on clinical information systems, is studied. The benefits of integrating healthcare information systems are investigated (9), as are the challenges of integrating systems across disparate organisations, healthcare disciplines, and technologies. The value proposition of a standards-based approach to integration is presented (10).

Discussion

This curriculum has been validated and plans to start in January 2015. The curriculum is the first in Africa to be based on the IMIA recommendations.

The new MSc HI programme has been tailored to the Central African context (8) and options for regional extension of the program to Eastern DRC (Bukavu) (10) and Burundi (Bujumbura) are being investigated.

Conclusion

The 3-dimensional mapping of IMIA competences, IMIA knowledge base units and curriculum module titles provided a useful method for validating biomedical and health informatics domain coverage of a competence based MSc HI curriculum in Rwanda. The same method could be applied to other MSc HI programmes seeking compliance with IMIA biomedical and health informatics education standards. Unfortunately there is insufficient space to include details of the SQL queries in this article. The authors intend to publish this in a technical paper.

Many of the content gaps found by our analysis might have been revealed earlier had more robust evaluation and monitoring processes been in place. In addition to the work discussed in this paper, the review also explored the teaching and assessment strategies employed. The programme content gaps and teaching strategy issues discovered during the curriculum review demonstrated the importance of periodical external curriculum reviews.

Abstract

As part of the Open Government Initiative, the United States federal government published datasets to increase collaboration, transparency, consumer participation, and research, and are available online at HealthData.gov. Currently, HealthData.gov does not adequately support the accessibility goal of the Open Government Initiative due to issues of retrieving relevant data because of inadequately cataloguing and lack of indexing with a standardized terminology. Given the commonalities between the HealthData.gov and MEDLINE metadata, Medical Subject Headings (MeSH) may offer an indexing solution, but there needs to be a formal evaluation of the efficacy of MeSH for covering the dataset concepts. The purpose of this study was to determine if MeSH adequately covers the HealthData.gov concepts. The noun and noun phrases from the HealthData.gov metadata were extracted and mapped to MeSH using MetaMap. The frequency of no exact, partical and no matches with MeSH terms were determined. The results of this study revealed that about 70% of the HealthData.gov concepts partially or exactly matched MeSH terms. Therefore, MeSH may be a favorable terminology for indexing the HealthData.gov datasets.

Keywords:

MeSH; Data; Standards; Indexing; Data Storage and Retrieval.

Introduction

The United States federal government collects and stores massive amounts of data, yet that data has largely been inaccessible to the American people [1]. In an effort to change the culture regarding governmental transparency and information sharing, then Presidential-candidate Barack Obama pledged to create a transparent and connected democracy [2]. On January 21, 2009, the day President Obama was sworn into office, the "Memorandum for the Heads of Executive Departments and Agencies: Transparency and Open Government" was signed [3]. This Memorandum outlined the Obama Administration's "Open Government Directive" that detailed actionable steps and deadlines that federal agencies were required to take to promote the principles of transparency, participation and collaboration. This directive initiated the Data.gov website [4] for publishing and disseminating federally-sponsored datasets. The memorandum specified that each federal agency must identify and publish in an open format at least three high-value data sets and register those datasets via Data.gov [5].

High value information was defined as "information that can be used to increase agency accountability and responsiveness; improve public knowledge of the agency and its operations; further the core mission of the agency; create economic opportunity; or respond to need and demand as identified through public consultation" [5]. In the U.S. National Action Plan, a policy was instated regarding "smart disclosure," or releasing high quality, complex information in standardized, machine-readable formats that can improve decisions and aid scientific research. The action plan noted the government's intent to develop Federal guidelines on scientific data [6]. Federal agencies were encouraged to release a variety of "smart disclosure" data that was accessible, machine-readable, standardized, timely, adaptive and innovative to markets, in an interoperable, and deidentifed format [7].

Publicly Available Data

Data.gov is an online data repository that includes tools and resources, communities, and education on how to utilize the site and its data. A community portal, HealthData.gov [8], was specifically developed to support the dissemination of healthcare data including Medicare and Medicaid cost reports, public health registries, medication treatments, and county-level determinants-of-health [8]. The overall impact of the Open Government Initiative on healthcare data resulted in the release of almost 2000 high value data sets on HealthData.gov.

In both Data.gov and HealthData.gov, users have the ability to filter datasets by subject, description, publisher, keywords, and other relevant meta-data (Table 1). Although the dissemination of publically available data is a step forward in promoting governmental transparency, there exist significant limitations in actually acquiring the datasets. Specifically, the limitations in the annotation principles adopted by HealthData.gov may result in suboptimal results from data searches.

Data.gov and HealthData.gov adopted a data management system constructed by Comprehensive Knowledge Archive Network (CKAN), an open-source data portal software [9]. The CKAN search application programming interface (API) is based on keyword searches for querying and accessing data. The searches are based on metadata that is supplied by the data publisher. To the best of our knowledge, the performance of the CKAN search API has never been formally evaluated.

Public Data Challenges

There are obvious reasons why the federal government is making high quality healthcare data available for research and use by the public, including benefits related to the goals of

collaboration, transparency, participation, and research. The overarching benefit of these data is the potential to improve decisions based upon knowledge [7]. However, the impact of the open government initiative on supporting research has been minimal. A primary reason why the open government initiative is failing to support research is due in part to the fact that transparency and access standards are inconsistently applied within federal communication policymaking [10]. Thus, the lack of consistency may be inhibiting citizen engagement in utilizing these resources for scholarly purposes [11]. In fact, studies have shown that although the government is adopting technology to increase transparency, these tools have been ineffective in engaging citizen participation [12-15].

Table 1 - Primary Meta-data Fields that are required for all Datasets in HealthData.gov

Field	Description
id	The unique identifier for the dataset
title	The title name for the dataset
notes	The description of the dataset
author	The name of the federal agency that submitted the dataset
tags	Tags associated with the dataset

Although the websites Data.gov and HealthData.gov have the potential to support governmental transparency, the success of these sites rests upon how well they can accommodate consumer accessibility [16]. Robinson and colleagues [17] discussed how full compliance and coordination with government-wide policy requirements present challenges for federal websites. Chang and Kannan [18] and Dawes and Helbig [14] suggested that more research is needed to explore the needs of citizens in order to enhance data tools. Similarly, others have suggested that there needs to be a more integrated approach to investigate data accessibility and dissemination tools and inventory resources and solutions to any problems [15, 18].

Information accessibility remains a challenge for citizens regardless of the growth of Data.gov and HealthData.gov. Research is needed to investigate practices that can accommodate consumers in accessing and using publically available federal data. Studies have suggested that the government should allow third party, private entities to play larger roles in the delivery of data and information [15, 17]. Feasibly, other federal efforts can be leveraged to support accessibility and usability of publicly available data. In Europe, several initiatives have begun to support the sharing of data. OpenPHACTS is one example of a partnership between public and private stakeholders from academia, pharmaceutical companies, and other enterprises that is funded through the Innovative Medicine Initiative to support common standards and sharing of data for more efficient drug development and patient treatment [19]. The European Medical Information Framework (EMIF) is another initiative that aims to create an environment for the re-use of existing health data. The EMIF Platform allows researchers to browse available patient-level data in Europe to support research. A data repository known as tranSMART is currently being developed to provide a schema for a variety of data types [20].

As Data.gov and HealthData.gov expand, the ability for end-users to find relevant data sources will become paramount for the sustainability of the websites and the Open Government Initiative. Particularly, the data extraction methods that were adopted in the construction of Data.gov and HealthData.gov need to be evaluated so that the most relevant data is queried while also avoiding irrelevant data. Additionally, proactive indexing of datasets should be systematic, structured, and not too labor-intensive to allow for long-term sustainability and usability of publically available data.

Medical Subject Headings (MeSH)

In the 1960s, the U.S. National Library of Medicine (NLM) dealt with information retrieval issues around biomedical literature due to poor indexing and search mechanisms for articles in MEDLINE. Due to problems in retrieving relevant medical literature, NLM produced MeSH. The goal of MeSH is "to provide a reproducible partition of concepts relevant to biomedicine for purposes of organization of medical knowledge and information" [21].

MeSH is one of several biomedical vocabularies that are available in the Unified Medical Language System (UMLS) Metathesaurus. The UMLS Metathesaurus is a large, multi-purpose, and multi-lingual vocabulary database that contains information about biomedical and health related concepts, their various names, and the relationships among them [22].

Tools were developed that utilize the UMLS Metathesaurus. MetaMap is a natural language processing (NLP) tool that was developed to map biomedical text to the UMLS Metathesaurus [23]. Input text is processed by MetaMap using lexical/syntactic analyses, followed by variant generation, candidate identification, mapping construction, and word sense disambiguation. There are processing options that allow users to limit the UMLS Metathesaurus to a specific vocabulary, such as MeSH.

MeSH is based off of a concept-oriented framework. The framework has a three-level structure: descriptor class, concept, and term. A concept is a common idea or meaning expressed by synonymous words or terms. A concept is a term for each of these synonymous terms. A term is a way of describing the concept. The concept will often have a preferred term, which has been adopted as the name of the concept in the MeSH framework. The descriptor is a class of one or more related concepts where the name of the descriptor is the preferred concept.

The main headings and entry terms are the names of the concepts in a descriptor class. In MEDLINE, the descriptor name is often attached to the citation record. An entry term may be the descriptor name or a concept in that descriptor class. The role of entry terms is to provide a guide for choosing proper concepts. Therefore, searchers most often use entry terms for determining the most appropriate concept class.

Interestingly, there are very few studies evaluating the performance of the MeSH framework for retrieving resources other than medical literature [24, 25]. Of particular interest is the possible influence of the MeSH vocabulary in indexing and retrieving publically available healthcare data that is published under the Data.gov community site, HealthData.gov.

Indexing Public Data with MeSH

The metadata that is available in CKAN offers similar information that is available within biomedical literature published on MEDLINE, including a title, author, description/abstract. CKAN recommends that publishers provide specific metadata to describe the datasets (Table 1). However, CKAN does not currently support a standardized vocabulary for indexing purposes. Tags, also known as keywords, are a metadata element provided in CKAN that is self-prescribed by the authors of those datasets. In constrast, MEDLINE uses MeSH entry terms for indexing biomedical literature. Currently, MeSH entry terms are assigned to each

article that is accessible through MEDLINE by trained indexers hired by the U.S. NLM. However, efforts for automating the indexing process in MEDLINE have shown promise.

The Medical Text Indexer (MTI) was developed for the sole purpose of offering MeSH concepts by automatically processing the MEDLINE metadata [26]. Research suggested that biomedical literature in MEDLINE was successfully indexed with MTI when only a title and abstract were provided [26]. Interestingly, the auotmated indexing engine, MTI, was shown to have similar accuracy as a human indexer, but with far greater efficiency [26]. Therefore, MTI was shown to be a substitute to human indexing, which supports a more efficient indexing process. The MTI may also prove to be an efficient and accurate tool for indexing datasets that are available through HealthData.gov. However, before an automated indexing engine can be adopted and applied to the HealthData.gov metadata, there is a need to evaluate the alignment of MeSH entry terms to the concepts that are present in the HealthData.gov metadata.

To support the adoption of MeSH for indexing and retrieving healthcare data, a formal evaluation is needed to determine if MeSH is an appropriate vocabulary for data indexing and retrieval. The purpose of the proposed study is to test this thesis. MeSH should only be adopted if the vocabulary offers consistent and adequate coverage of the concepts that are available in HealthData.gov. This study will explore the coverage of terms by parsing out the noun and noun phrases from the HealthData.gov metadata and mapping these terms to the MeSH vocabulary.

Methods

Extracting Nouns and Noun Phrases from HealthData.gov

The complete HealthData.gov metadata catalogue from datasets that were published from May 2012 to May 2014 were queried from the CKAN engine using an HTTP GET script. There was a total of 1,003 datasets published during this time. The HealthData.gov metadata was exported from CKAN in a JSON file format. The *json* Python library was used to parse the JSON file to extract the notes (*i.e.,* the descriptions) from the metadata. The extracted metadata were written to a CSV file.

The metadata CSV file was mapped to the UMLS Metathesaurus by using MetaMap to identify the nouns and noun phrases. The supplied text was parsed into simple noun phrases using the SPECIALIST minimal commitment parser [27]. Variants were generated for each phrase using the SPECIALIST lexicon. Variants consisted of phrase words together with their acronyms, abbreviations, synonyms, derivational variants, and meaningful combinations of these, including inflectional and spelling variants [28]. A candidate set of all Metathesaurus strings containing at least one of the variants was retrieved. Each candidate was evaluated against the input text by mapping the phrase words to the candidate's words and then calculating the strength of the mapping using a linguistically principled evaluation function [29].

To determine the overall frequency of all nouns and noun phrases that occured in the HealthData.gov notes, all UMLS concepts were indexed with MetaMap and the output was selected to reveal noun phrases, nouns, and acronyms/abbreviations. The MedPost/Semantic Knowledge Representation (SKR) part-of-speech tagger broke the original notes for each dataset into sentences, tokenized each sentence and then further tagged tokens as nouns, verbs, prepositions, adjectives, and punctuations. Candidates were identified from the list of variants for each concept. Once the nouns and noun phrases were identified, MetaMap provides UMLS concept candidates with concept unifier identifiers (CUIs), preferred names and semantic types. All of the mapping results were printed and exported in a machine-readable output. The machine-readable output was further processed by extracting nouns from the summary while omitting verbs, prepositions, adjectives, and punctuation using a regular expression function in the R statistical software package. The frequency of nouns, noun phrases, and distinct nouns and noun phrases that were present in the HealthData.gov metadata were then reported.

MeSH Coverage of Nouns

The complete MeSH library was downloaded as an XML file from the U.S. NLM webpage [30]. The XML file was parsed using the Python-based Element Tree XML API to create a Python dictionary of all the MeSH concepts, related concepts, and entry terms. The dictionary was written to a CSV file and uploaded to R to calculate MeSH term coverage.

In order to determine the level of coverage that MeSH offered for indexing the HealthData.gov metadata, the nouns that were extracted from the metadata using MetaMap were mapped to MeSH entry terms. The nouns were mapped to MeSH by developing a query in R to search for partial or exact matches between the nouns extracted using MetaMap and the complete MeSH library. The frequency of partial, exact, and no matches between the MeSH terms and the extracted MetaMap nouns were calculated. If a noun was contained in part of a MeSH entry term, it was considered a partial match. A noun that exactly matched a MeSH entry term was considered an exact match. Any noun that was not part of a MeSH entry term was considered not matching.

Further analysis was conducted by restricting the comparison of MeSH terms to the nouns extracted using MetaMap for those nouns that accounted for 75% of all of the identified nouns. The 75% threshold was determined based on the observation that this accounted for nouns that occurred at least 10 times in the HealthData.gov metadata. This was completed in order to evaluate the efficacy of indexing the data with MeSH while minimizing the effects of nouns that do not occur frequently in the HealthData.gov metadata. The frequencies of partial, exact and no matches were calculated to determine the efficacy of MeSH for indexing the most common occurring nouns in HealthData.gov.

Common MeSH Concepts in HealthData.gov

A final analysis was carried out to determine the most common MeSH concepts that occured in the HealthData.gov metadata. The HealthData.gov metadata CSV file was processed a second time using MetaMap, but restricting the library source to only MeSH. The phrases that were mapped to MeSH were returned along with the MetaMap summary, which was exported to show the associated MeSH candidate concepts that map to the noun phrases. A mapping score was provided that revealed the level of agreement between a noun phrase and the MeSH candidate concept. A mapping score of 1000 indicated an exact match. In addition to the MeSH concept, the MeSH category was also provided. The MetaMap summary was uploaded to R and a regular expression function was used to extract the noun phrases, mapping scores, candidate MeSH terms, and MeSH categories. MeSH terms were only included in the analysis if the mapping score was greater than or equal to 900. The frequency that each MeSH concept and category occurred in the HealthData.gov metadata was calculated.

Statistical Analysis

The R statistical software package was used to determine if the frequency of matching types (partial, exact, and no match) were significantly different between the mapped nouns and MeSH entry terms. The frequency of the partial matches was calculated as the number of nouns that matched at least part of a MeSH entry term. Exact matches were the frequency of nouns that exactly matched a MeSH entry term. The frequency of no matches was calculated as the sum of the nouns that did not appear in a MeSH entry term. Chi-squared tests of independence, with pairwise comparisons and a Bonferroni correction, were used to determine if there were significant differences in the frequency of terms in the matching groups.

Results

There were 30,132 nouns identified from 17,677 noun phrases from the 1,003 datasets using MetaMap, of which 2,975 nouns and 9,772 noun phrases were considered unique. When restricted to the MeSH library, there was a total of 18,839 concepts identified of which 1,336 were unique. The number of unique MeSH concepts that had a mapping score greater than or equal to 900 was 947. The 10 most frequent MeSH concepts and the accompanying categories that had a mapping score greater or equal to 900 are shown in Table 2.

Table 2 - Most frequent MeSH Concepts in HealthData.gov

Concepts	Categories	Frequency (Percentage)
Use (Utilization)	Functional Concept	238 (3.6%)
Medicare	Governmental or Regulatory Activity	134 (2.0%)
Collections	Intellectual Product	87 (1.3%)
Reported (Report)	Intellectual Product	84 (1.3%)
Programs	Intellectual Product	83 (1.3%)
File (Filing)	Occupational Activity	74 (1.1%)
United States	Geographic Area	74 (1.1%)
Medicaid	Governmental or Regulatory Activity	68 (1.0%)
Measures	Quantitative Concept	61 (0.9%)
Published (Publishing)	Occupational Activity	59 (0.9%)

Table 3 shows the frequency of nouns that matched partially, exactly, or did not at all match a MeSH entry terms. In addition, Table 3 indicates the frequency of these matching groups when the nouns were restricted to those covering 75% of all nouns, totally 480 nouns.

Table 3 - Matching HealthData.gov nouns to MeSH terms

Match Type*	Medical Subject Headings (MeSH)	
	All Terms Frequency**	*Restricted to top 75%* Frequency**
No Match	851 (28.6%)	47 (9.8%)
Partial	1533 (51.5%)	301 (62.7%)
Exact	591 (19.9%)	132 (27.5%)
Total	**2975 (100%)**	**480 (100%)**

**No match is the frequency where the noun is present in the HealthData.gov metadata, but not covered by the MeSH library. A partial match is the frequency of nouns that partially match a MeSH term. An exact match is the frequency of nouns that exactly match a MeSH term.*

*** There were significant differences in the frequency of each of the matching types (df=1; p-value<0.001).*

There were significant differences between the matching types (χ^2=477.3, df=2, p-value<0.001). Pairwise comparisons demonstrated that there were significantly fewer nouns that did not match to MeSH terms when compared to partial (χ^2=195.1, df=1, p-value<0.001) and exact matches (χ^2=46.9, df=1, p-value<0.001). There were significantly more nouns with partial matches to MeSH entry terms compared to nouns that exactly matched MeSH entry terms (χ^2=417.8, df=1, p-value<0.001).

These differences were observed when the nouns were restricted to the top 75% (χ^2=209.0, df=2, p-value<0.001). Pairwise comparisons demonstrated that there were significantly fewer nouns that did not match a MeSH terms compared to partial (χ^2=185.4, df=1, p-value<0.001) and exact matches (χ^2=40.4, df=1, p-value<0.001). Also, partial matches were significantly greater than exact matches (χ^2=66.0, df=1, p-value<0.001).

Discussion

There were significantly greater nouns that partially or exactly matched MeSH entry terms than nouns that didn't have any matches to MeSH entry terms. This is evidence that MeSH may offer adequate coverage of the concepts that are present in the HealthData.gov metadata. Although additional research is needed, this study suggested that MeSH may be a suitable controlled vocabulary to adopt for indexing HealthData.gov datasets.

As federal agencies and independent researchers acquire data, there is a general need to organize the data for later indexing and queries. One study found that very few publications that were registered at ClinicalTrials.gov actually published their datasets [31]. It was suggested that the lack of existing policies around standardization do not ensure availability of results and data from clinical research. Another study [32] discussed the need to develop data models and dictionaries that can support sharing of biomedical data, and suggested that the development of terminologies and ontologies could support this goal. Based on the results of the present experiment, the use of MeSH has the potential to support these demands for data sharing and data searching of a United States data portal, HealthData.gov.

Future research should evaluate if indexing with MeSH supports consumers in retrieving relevant datasets. If MeSH does offer a more effective search strategy, a method needs to be developed to automatically index the CKAN metadata. A limitation of this study is that new datasets are frequently published in HealthData.gov. This study only examined datasets that were published during a 2-year timeframe. Future research will need to be conducted to investigate the sustainability of coverage that MeSH. Finally, future research can investigate the term coverage of other terminologies, such as SNOMED CT.

Conclusion

This study demonstrated that MeSH may be a suitable vocabulary for indexing the data that is available through HealthData.gov. Better indexing would help the the Open Government Initiative, enacted by the United States federal government, achieve its goal of providing accessible published datasets. Adopting a standardized vocabulary such as MeSH for indexing the HealthData.gov metadata, the search and retrieval methods may be better supported. In order to ensure that MeSH can be used effectively for indexing, MeSH needs to have adequate coverage of the concepts in the HealthData.gov metadata. By extracting the nouns from the

metadata using MetaMap, a significant number of the nouns mapped partially or exactly to MeSH entry terms.

Recruit - An Ontology Based Information Retrieval System for Clinical Trials Recruitment

Diogo F. C. Patrão[a], Michel Oleynik[a], Felipe Massicano[a], Ariane Morassi Sasso[a]

[a] *International Center for Research (CIPE) - A. C. Camargo Cancer Center*

Abstract

Clinical trials are studies designed to assess whether a new intervention is better than the current alternatives. However, most of them fail to recruit participants on schedule. It is hard to use Electronic Health Record (EHR) data to find eligible patients, therefore studies rely on manual assessment, which is time consuming, inefficient and requires specialized training. In this work we describe the design and development of an information retrieval system with the objective of finding eligible patients for cancer trials. The Recruit system has been in use at A. C. Camargo Cancer Center since August/2014 and contains data from more than 500,000 patients and 9 databases. It uses ontologies to integrate data from several sources and represent medical knowledge, which helps enhance results. One can search both in structured data and inside free text reports. The preliminary quality assessments shows excellent recall rates. Recruit proved to be an useful tool for researchers and its modular design could be applied to other clinical conditions and hospitals.

Keywords:

Information Retrieval, Ontology, Clinical Trial, Patient Selection

Introduction

A clinical trial is designed every time a new intervention needs to be tested and compared with its current alternatives in an effective way. This type of study usually specifies two groups of research subjects: control (patients receiving regular treatment or placebo) and treatment (patients receiving new treatment). To statistically back up the conclusions, there should be enough participants (the recruiting target) and all of them should have similar clinical characteristics (in order to meet the inclusion and exclusion criteria). Currently, only half of all clinical trials reach their recruiting target, and half of those reach the target in a timely manner [1]. The usage of existing search tools (such as data warehouses) over Electronic Health Record (EHR) data can lead to significant increases in recruitment rates [2–5], however, there are still important challenges to be faced.

Firstly, the clinical data is notoriously difficult to represent formally [6–8]. The complex nature of medical practice, its specialties and sub-specialties led the industry to develop specialized software. Thus, it is common that the hospital context involves usage of several systems for different aspects of clinical practice, and the patient information is scattered through different databases, usually using different data models. Both structured forms and reports containing free text may coexist in one database. Therefore, in order to use EHR data to find patients based on clinical features, it is necessary to apply data integration techniques [9].

In Computer Science, ontologies represent knowledge formally, and have been used to derive new knowledge from facts by a process called logical inference [10]. Ontology based data integration employs the descriptive power of ontologies to harmonize semantic mismatches between source databases, particularly on the biomedical domain [11]. Additionally, the field of Information Retrieval has been developed at a fast pace [12], with continuous improvements to the algebraic models (such as latent semantic indexing) as well as to the probabilistic models, many of them empowering natural language processing. However, the availability of language models trained on the medical subdomain is still sparse mainly due to ethical concerns when publishing corpora, a fact that hinders the development of the area.

Several systems have tried to overcome these difficulties with customized search engines. Most of them [13] map free-text data onto concepts taken from terminologies such as SNOMED CT, upon which a structured search is then performed. The translation of eligibility criteria into computable definitions is usually done by the searcher, but can be aided through machine language [14,15], especially useful on cross-language environments.

In this paper, we present Recruit, an information retrieval system with the target of finding patients based on clinical criteria using EHR data. It uses ontologies to reconcile heterogeneous databases, as well as merge data from structured forms and free text for pathology and image reports. We will describe its requirements, design, deployment and preliminary quality assessments.

Materials and Methods

Requirements

We classified requirements for Recruit in two types: data and functional. Data requirements are clinical information that the system must be able to find, and functional are tasks that the user must be able to perform when using the system. The first source for data requirements was the Medical Informatics Laboratory ticket system. We analyzed the patient reports requested during the past 12 months and identified the most common clinical criteria. We interviewed the clinical trial support team, who described the most important concepts.

In particular, the system should implement the ethics regulations regarding patient data access. System usage should be monitored by analytics tools, to assess usage patterns.

Design

Based on the verified requirements, we elaborated an UML use case diagram to describe the interactions between the user

and the system, and a mock-up of the user interface. File formats and software used should be open source.

We chose to use ontologies to represent both patient information and knowledge about the domain. The data model should be as simple as needed for creating an index of concepts for patients. Existing ontologies can be reused, as long as they are provided with a free license and are within the desired expressive power. Classes and properties will be annotated in Portuguese, to allow easy understanding to both the technical team and Recruit users.

Quality Assessment

In order to evaluate the quality of Recruit we created a methodology to build gold standards that could be replicated and that would help us measure the impact of interventions in the system. The standards are constructed based on the classification of the results from predetermined queries as relevant or non-relevant in a chosen scenario. Therefore, we can obtain the precision (defined as the ratio of retrieved patients that are relevant) and recall (defined as the ratio of the relevant patients that were retrieved) measures for each one, which combined generates the weighted harmonic means F_1 and F_2. These scores allow us to assess the quality of the result sets produced by Recruit.

First, we realized that it is important to choose queries in which the professionals from the institution have scientific interest for and also that brings a reasonable amount of cases. In this way, it is possible to collaborate with researchers in the construction of the gold standards and the results can be assessed in a short period of time.

Second, each result from the chosen queries had to be classified as relevant or non-relevant, by using a 3 point scale in which (2) means relevant, (1) unsure and (0) non-relevant. Therefore, if there is certainty about the presence of the clinical condition, we would classify the subject as relevant (2), usually by confirmation from a pathology report. Besides, if there is doubt, either because there is lack of electronic clinical documents to support the presence of the condition or, by the own doubt of the health professionals, we would classify the case as unsure (1). Finally, if the hypothesis of the patient meeting the clinical criteria is rejected by the physicians or, if it is impossible to find the information even in non-electronic format (e.g. the case is too old), we would classify the case as (0) non- relevant.

The next step is to convert the 3 point scale into a binary one, thus we prefer to consider only relevant cases as (1) and the all others as non relevant (0). Finally, it is recommended to look into documents not searched by the system to recover and analyze other cases related to the queries. That will allow the generation of the described set of measures for each standard, namely precision (P), recall (R), F_1 and F_2, which will further help the system's quality evaluation.

Results

Requirements

After the interview with the clinical trials support team and review of requests on the ticket system, we compiled the data requirements (Table 1). After that, we identified in which database each information could be found and Table 2 compiles the characteristics of each one.

Table 1 – Data Requirements

% Tickets	Description
33,07%	Diagnosis (ICD-10) , date and age of diagnostic
33,07%	Tumor Topography (ICD-O)
33,07%	Tumor Morphology (ICD-O)
13,39%	Treatment type (Surgery, Chemotherapy, Radio-therapy)
13,39%	Sample collected in biobank (by type: frozen tissue, blood, RNA, DNA)
11,02%	Chemotherapic drugs used
9,45%	Demographics (Date of birth, current age, gen-der)
8,66%	Department
6,30%	Cancer status (under diagnostic, not cancer, cancer, metastasis, remission)
6,30%	Alive/deceased, date of last information, death by cancer or other reasons
4,72%	TNM Clinical Stage (e. g. CS III)
3,94%	TNM Variables (e. g. T0, N2, M1)

Table 2 – Source Databases

Database	Technology	Information	Time span	Structured / free text
EHR	Oracle 10i	TNM, ICD-10, Chemotherapy, Surgery, Radiotherapy	2007-2014	Structured
AP Reports	Interbase	Pathology Reports	2006-2014	Free text
AP Reports-legacy	Oracle 8i	Pathology Reports	2000-2006	Free text
AP Reports-legacy-2	DBase III	Pathology Reports	1992-2000	Free text
Image Reports	Oracle 10i	Image Reports	2006-2014	Free text
Image Reports-legacy	Oracle 8i	Image Reports	2002-2006	Free text
Registry	Excel	ICD-10, ICD-O, TNM, follow up, treatment	2000-2012	Structured
Biobank	MySQL 5.1	Frozen tissue, blood, DNA/RNA sample	1999-2014	Structured
Index	SPSS	ICD-10, ICD-O	1953-2000	Structured

Design

The Recruit software is divided in two parts: the backend, responsible for extracting, transforming and indexing data; and the frontend, the web interface with which the end user interacts. We designed a single use case (depicted on Figure 1) to represent the user authentication, search and retrieval of results on screen or on a CSV file.

The backend is a workflow that produces an index combining unstructured and structured data contained in the original databases. This index will be processed by the search engine Apache Solr which will be queried by the frontend. We adapted the structure described in [16]: instead of view integration, we created a data warehouse based on ontology, and then loaded this data as structured metadata in an indexing server, along with unstructured report texts.

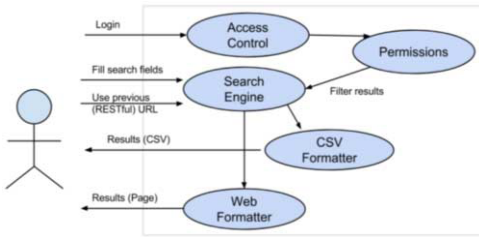

Figure 1 - UML use case diagram

As the first step, we integrated data from several structured databases into only one triple store endpoint, namely Openlink Virtuoso (Figure 2). The mapping from relational data to RDF graphs was done with the help of Ontop, thus generating several RDF files which were loaded in memory using ARQ (configured with inference profile OWL Micro Reasoner). Then, all inferenced triples were materialized into a single RDF file, later loaded into the triplestore endpoint. Finally, a set of handcrafted SPARQL queries was executed at the endpoint in order to enrich it with information not feasible by the inference process due to absence of closed world reasoning. Therefore, the resulting dataset contained consolidated information, such as the ICD-10, ICD-O and the date of the diagnosis and also the age of the patient at the diagnosis.

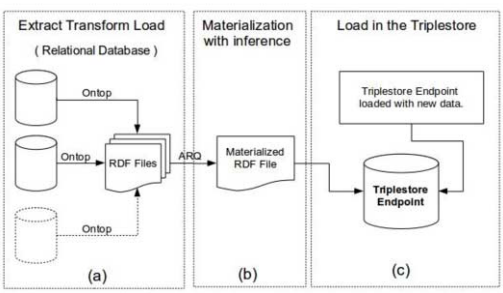

Figure 2 - Integration process data flow

In a second step, we published the inference-rich facts together with unstructured data into a search engine (Figure 3). We extracted the textual content of pathology and image reports and then associated it with the triple store endpoint data using the patient identifier. The results of this process were published in the search engine using its API.

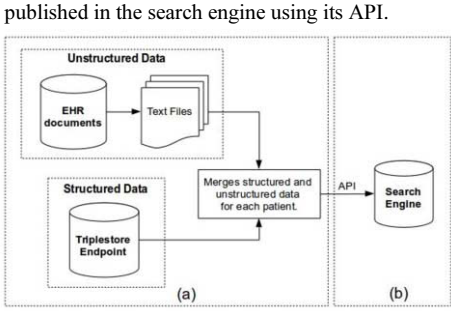

Figure 3 - Search engine publishing data flow

Knowledge representation and structured data mapping

We decided to represent structured data as an ontology, as it has been used for database integration and semantic harmonization, and also for its inference capabilities. This consolidated data will be used to feed the search engine and to display result details in the user interface. Due to the large data volume, we decided to use a very simple model, that would allow for a reasonably fast (for weekly updates) inference, while powerful enough to make required reasoning tasks.

In our ontology, patients are represented as instances of NamedIndividuals (as defined in OWL2 [17]) and structured search criteria as classes directly attributed to instances. For instance, a patient with breast cancer would belong to class C50 (the ICD-10 [18] code for this disease). The patient URI is based on the patient identifier, used in all databases. The ICD-10 ontology was reused from NCBO [19], the ICD-O was semi-automatically obtained from an existing relational database. Other ontologies (treatments, chemotherapy, cancer staging [20]) were manually created. Data properties were created for identification data and diagnostic dates. Properties with unique values for a patient were marked as *owl:functional* to allow sorting on them. All properties and classes were created with URIs in Portuguese and annotated with the *skos:prefLabel* property. Besides the class hierarchy, inference axioms were created to enhance results, specially on clinical staging data. See excerpts of the ontology axioms on Figures 4 and 5.

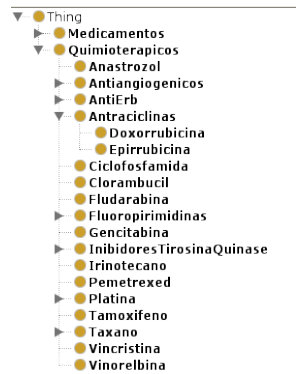

Figure 4 - Class hierarchy for chemotherapic drugs

SQL Mapping

In order to translate data from the relational databases into an ontology, we created one SQL query that maps a production database to instances of the corresponding class. We used Ontop software to test and extract data into N3 format. Similar information represented in different ways in the same database was normalized in this step using regular expressions (such as '^IV|IV$|^4$' for clinical stage IV). Moreover, we associated a patient ICD-10 code with his/her diagnostic status, a structured field with three possible values: patient in diagnostic, patient without cancer, or patient with a confirmed cancer diagnostic.

Figure 5 -Rules for inference of TNM clinical stage for specific topographies

Quality Assessment

The first query we chose to apply our methodology on was related to the phyllodes tumor, a rare breast neoplasm. With the help of a research nurse we built a list of synonyms in Portuguese for that clinical term and they were expressed in the following query: "filode OR filoides OR phyllodes OR phylloides OR phylodes OR phyloides". Then, we presented it to Recruit, which retrieved a set with 266 patients and, to it we added more 91 that were found by looking into documents not searched by Recruit but that belong to the patients' electronic health record. That was done in order to reproduce a more real search universe and finally, we divided the cases between two authors of this paper and one research nurse, who classified them as relevant (2), non-relevant (0) or unsure (1). There was a final meeting to guarantee that everyone had the same understanding about each classification option and so, the measures highlighted in table 3 were obtained. The evaluated recall is high (97.16%), which fulfill the health professionals expectations. However, the obtained precision was 51.50%, probably due to the search engine not being specific for the healthcare scenario. F_2 (82.53%) is higher than F_1 (67.32%), since the former gives more weight to recall while the latter considers both measures to have the same weight.

Table 3 – Quality Evaluation

Variable	(%)
Precision	51.50
Recall	97.16
F_1	67.32
F_2	82.53

We noted some signs that may indicate whether a case is relevant or not, for example, if the patient has an unknown name or if the case is too old, it usually is less relevant due to lack of electronic records and the possibility of the patient being dead or have lost follow-up. It is also a sign of non-relevance the presence of terms that negates the searched condition such as 'absent' or the existence of relevant documents only in paper or microfilm. If the patient possesses a considerable amount of electronic records, or if the clinical criteria appears in an anatomic pathology report and the latter is recent, the chance of the case being relevant is higher.

Discussion

We designed Recruit to be easily maintainable, modularizing the data extraction in a large number of queries, each mapping to specific classes, or group of classes within the same category or property, on a particular database. Adding another database or removing a problematic query simply implies adding or removing a mapping file. We verified this in practice, when developing the mapping files incrementally.

Our database is large (more than 500,000 patients), and our mappings generated a reasonable amount of RDF triples which took a significant time (>6 hours) to be extracted. Most of this time was spent on a couple of queries that used regular expressions to detect patients with specific molecular test results. The inference materialization step took more than 2 hours and required almost 20GB of RAM in a single process. This could be optimized by using a customized program to extract specific axioms, such as class instances, instead of using a general SPARQL query to extract all possible inferences. Parallel inference is a current topic of study, and could greatly enhance the inference performance. Overall, the preparation step took more than 8 hours, hindering the application to be updated on a daily basis. The addition of concepts, axioms or mappings should be carefully planned, as running time and memory required can grow exponentially.

Our modelling also directly connects the diagnostic to the patient. Although the inference takes less time this way, it would be impossible to correctly assign the date of a diagnostic when a patient has multiple tumours. The creation of a new entity for the diagnostic would allow this, but the inference resources would be higher, and it would require a different usage of the indexing engine as well.

Since its release on August/2014 until December/2014, the system has been continuously accessed by at least 15 different users per week. Therefore, it is becoming a established tool for researchers in A. C. Camargo Cancer Center.

Recruit achieved a high recall rate, considered good by the research nurses, since they usually look into all the results, thus not giving much weight to precision. Although we understand the importance of the former measure, the latter has a significant role, since it can diminish the time a researcher needs to look for relevant patients. Also, the search engine being used by Recruit is capable of dealing with cases of inflection in Portuguese but not specificities from the healthcare field. We believe that Recruit would have its performance enhanced if it was imbued with a clinical health terminology in Portuguese, which would allow users to discover the synonyms for terms such as "phyllodes".

Despite having just one gold standard, we believe that it gave us some insight related to the quality of the search and to the signs needed to enhance it. Therefore, if we build more standards to evaluate the searches made by Recruit we can improve our list of signs and use it to make interventions in the system, which will have its results measured and compared to the standards. Also, each intervention has a different difficulty level: in order to increase the weight given to terms found in anatomic pathology reports, for example, one would need to detect if the searched condition is followed by a word or phrase that negates it. All that must be taken into consideration in order to plan the next maintenance projects and consequently improve Recruit's quality.

We could have used extraction and classification techniques to improve free-text data with structured concepts and thus improve recall rates [21]. However, due to unavailability of public language models and annotated corpora in the medical domain in Portuguese, we chose not to apply experimental results at this moment while further research is ongoing.

Other works [3–5] rely on search and integration tools already implemented for performing the search; in particular, these tools were designed with other objectives than searching for patients for clinical trials, therefore they may not include all needed search criteria, or may not be customized to do so and keep their main objective. Recruit, being designed exclusively for patient selection, can be customized as needed for the sole purpose of finding potentially recruitable patients. Also, as it relies on open source software and file formats, it does not impose artificial limits or require expensive licenses, which is particularly relevant for research projects. Recruit integrates data from structured and unstructured sources, which, at least to our knowledge, has not been done in this field.

Recruit is now a production level tool being used at A. C. Camargo Cancer Center, but further improvements are

needed. A comprehensive set of gold standards should be created in order to guide further enhancements on mappings, and evaluate the general quality of results. Data extraction and inference should be optimized as to be more frequently updated. The ontology model should be improved by creating an instance for each diagnosis and relating the diagnostic classes and date to it. This would allow specifying date of diagnostic for patients with multiple cancers. Also, other types of documents should have free text indexed, such as outpatient clinical notes. A preliminary evaluation showed that doctors employ a large number of acronyms and do not use proper phrases, instead using a list of diagnostics, therapies and other applicable concepts, and that should pose a major challenge.

Conclusion

We have successfully implemented an ontology based information retrieval system for clinical criteria based patient selection. It uses EHR data, represents medical knowledge as ontologies, integrates several databases and allows search for structured data and free text. The preliminary quality assessments show excellent recall rates. It is not only an important asset for A. C. Camargo Cancer Center researchers, but the principles here presented can be used on a larger range of information retrieval problems.

Acknowledgments

Marcelo Sagayama contributed on the prototype construction, data mapping and other technical tasks. Fábio Rampazzo Mathias provided technical assistance. Helano Carioca Freitas and Tatiana Iafuso provided system requirements. Silvana Soares dos Santos assisted on the gold standard construction.

Abstract

Relation extraction typically involves the extraction of relations between two or more entities occurring within a single or multiple sentences. In this study, we investigated the significance of extracting information from multiple sentences specifically in the context of drug-disease relation discovery. We used multiple resources such as Semantic Medline, a literature based resource, and Medline search (for filtering spurious results) and inferred 8,772 potential drug-disease pairs. Our analysis revealed that 6,450 (73.5%) of the 8,772 potential drug-disease relations did not occur in a single sentence. Moreover, only 537 of the drug-disease pairs matched the curated gold standard in Comparative Toxicogenomics Database (CTD), a trusted resource for drug-disease relations. Among the 537, nearly 75% (407) of the drug-disease pairs occur in multiple sentences. Our analysis revealed that the drug-disease pairs inferred from Semantic Medline or retrieved from CTD could be extracted from multiple sentences in the literature. This highlights the significance of the need of discourse-level analysis in extracting the relations from biomedical literature.

Keywords:
Relation extraction; Discourse-level analysis; Literature-based discovery; Semantic Medline.

Introduction

Information extraction (IE) aims to automatically extract information from text. To understand and extract information from text, IE systems should look at the text as whole and not only sentences separately. Researchers in the discourse domain agree that usually sentences/clauses are not understood in isolation [1]. Researchers in IE have studied discourse-level analysis [2] in applications such as question answering and dialogue generation. Of course, discourse-level analysis is built on top of sentence-level analysis and its performance somehow depends on sentence level. One of the well-studied parts of discourse-level analysis is identifying relation between sentences (clauses), called discourse relation. These types of relations could be contrast or explanation-evidence [1].

Two main tasks in IE are named entity recognition (NER) and relation extraction. In relation extraction, IE systems identify the relation between two or more entities where the entities could be located in one or multiple sentences. Identifying the latter type of relations needs discourse-level analysis such as coreference resolution which can be challenging.

The goal of this paper is to asess the need of discourse-level analysis for relation extraction and indirectly evaluate the amount of information that IE systems are missing if they just focus on sentence level. First, to perform this experiment, Semantic Medline [3] is used to generate a list of potential literature-based discoveries. The potential discoveries are limited to drug-disease relations as potential drug repositioning candidates. Then, we implement two kinds of searches on top of Medline abstracts to find any evidence of these discoveries, 1) Sentence-level search: we looked for pairs in the sentence 2) Discourse-level search: the whole abstract was searched. Comparing the results of these searches indirectly evaluates the amount of relations that IE systems can extract from sentence-level v.s. discourse-level analysis.

Background

Relation Extraction

The IE pipeline usually begins with NER which has been very well studied and various types of methods such as dictionary-based, rule-based, and machine learning algorithms have been applied to NER [4], [5]. After NER, the main task in IE is identifying relations among the entities. Relations could be binary or they could involve more than two entities. Most of relation extraction systems focuson relations in a single sentence [6]. It is imperative for a relation extraction system to extend beyond clauses and sentences and handle complex discourse-level analysis.

The importance of discourse-level analysis is well known and the analysis has been studied in several applications such as: question-answering systems [7]–[9], automatic dialogue generation [10], etc. Besides, there are several studies on extracting discourse-level relations. Marcu and Echihabi [1] developed an unsupervised approach to classify four types of relations between sentences/clauses. The goal here was extracting the relation between two or more entities that are mentioned in multiple sentences. Bach and Badaskar [6] reviewed some of these types of relation extraction systems and their applications. The methods for extracting such relations, often range from a simple distance based criteria to a more complex one that employs statistic and linear algebraic approaches [11] to extract explicit and implicit semantic relations from text.

In the biomedical domain, researchers developed various IE systems to extract different types of biomedical relations [12]–[16]. Quan et al [13] proposed two systems, unsupervised and semi-supervised to extract protein-protein interactions and

gene-suicide associations. Their systems employed dependency parsing. Bundschus et al [14] developed biomedical relation extraction using conditional random fields. Their system identified relations between diseases and treatments; also relations between genes and diseases. All these systems just focused on relations within a single sentence and often ignored relations involving entities across sentences. In general, extracting relations that involve entities mentioned in two separate sentences is a complex one and requires special NLP techniques such as coreference resolution and complex semantic analysis.

Literature-based discovery

Literature-based discovery (LBD) aims to find a connection/correlation between concepts using scientific literature. Therefore, LBD is one kind of special relation detection we are interested in. Many LBD systems have been developed in the biomedical domain to generate new hypotheses that potentially could lead to new discoveries. Swanson [17] first introduced this approach and applied it to find a correlation between migraine and magnesium. After that, a number of studies followed his approach and had interesting discoveries. The important part of LBD is how to decide that two concepts are correlated. The most commonly used approaches are co-occurrence analysis [18], Association Rules [19], TF-IDF, Z-Score, and Mutual Information Measure [20]. Yetisgen-Yildiz and Pratt [20] briefly discussed these approaches and meanwhile Andronis et al. [21] reviewed literature mining systems which identify potential drug repurposing candidates. Another approach to identify correlated concepts is using semantic relations [22]. Hristovski et al. proposed [22] using semantic predications to enhance LBDs. In this study, semantic predications are used to create a list of potential LBDs (drug-disease pairs). The generated LBDs in this study are potential drug repurposing candidates.

Semantic Medline, semantically enhanced with predicates extracted by SemRep [23] from Medline titles and abstracts, contains approximately 70 million semantic predications. Predications are triplets of *Subject*, *Predicate*, and *Object* where the subject and object are biomedical entities (drug, gene or disease in our study), and predicate shows the type of relation between the entities such as inhibits, interaction with, associated with, etc. The predications are stored in a relational database called Semantic Medline Database (SemMedDB). It has been used in many studies to facilitate knowledge discovery [24], [25].

In this study, we plan to assess the need of going beyond sentences for extracting relations. Our goal in this study is to highlight the need and asess the amount of relations, relation extraction systems that are potentially missing if they just focus on sentence-level analysis. For this purpose, following Swanson's model, a list of potential drug-disease relations is generated from literature. The extracted LBDs are assumed as relations between drugs and diseases that could be mentioned implicitly or explicitly in literature. Two kinds of searches are conducted to identify any evidence of these relations in the sentence level or discourse level of Medline abstracts.

Methods

Our study contains two steps: 1) generating a list of drug-disease pairs based on LBDs and 2) using the discoveries to evaluate the drug-disease relation extraction by comparing the extractions from a single sentence to the one from multiple sentences.

Generating LBDs

In the first step, we generated a list of potential relations between drugs and diseases. We followed Swanson's model [17] to generate a list of LBDs. According to Swanson's model if one scientific study notes a correlation between concept A (Starting concept) and concept B (Linking concept), and another study mentions a correlation between concept B and concept C (Target concept), then there might be a correlation between concept A and C. In our study, drug is the starting concept and disease the target concept, gene serves as a conceptual link between the two leading to the generation of a list of potential drug-disease relations.

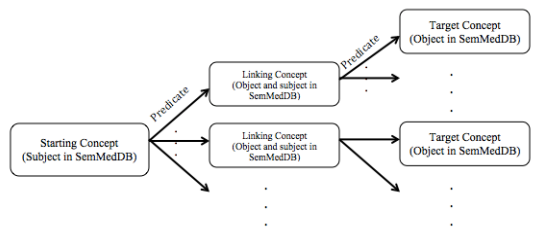

Figure 1 - Architecture of our LBD system. In this system, the starting concept is drug, the linking concept is gene, and the target is disease that leads to drug-disease discoveries. Our system uses Semantic predications as evidence of correlation between the concepts.

In contrast to commonly used approaches such as document-level or sentence-level co-occurrence of entities or concepts to generate LBDs, we used semantic predications as evidence for correlation between entities [22]. For example, from the following two predications from SemMedDB:

- Flecainide (Drug) *INTERACTS WITH* SCN5A (Gene)
- SCN5A (Gene) *ASSOCIATED WITH* Heart Failure (Disease)

The system generates *Flecainide-Heart Failure* as a potential new drug-disease pair. Figure 1 shows the architecture of our LBD process.

There are two major reasons for our choice of using semantic predication to generate LBDs 1) semantic predication takes biological meaning into consideration 2) the semantic type of the interaction and the contextual information about the interaction such as *NEGATION* allow us to filter unnecessary predications: *NEGATIVE TREATS*, *NEGATIVE ASSOCIATED WITH*, etc. At this point, we do not consider any threshold based on a frequency measure to further eliminate drug-disease pairs. We believe that using a frequency measure will eliminate potentially novel relations from our initial list.

In order to further refine the drug-disease pairs to be relevant for LBD, we used Timeline profiles to narrow down the drug-disease pairs with literature evidence. We only considered drug-disease pairs where the first literature evidence appeared after their related drug-gene and gene-disease pairs. Equation (1) clarified our Timeline profile:

$$Max\begin{pmatrix} Min(Y_{sp}(Drug-Gene)), \\ Min(Y_{sp}(Gene-Disease)) \end{pmatrix} \leq Min(Y_c(Drug-Disease)) \quad (1)$$

where Y_{sp}(Drug-Gene) indicates the publications' date of all Medline abstracts that contain at least one semantic predication between Drug-Gene. For Drug-Disease, we considered publications that contain at least one co-occurrence of the entities. For example, assume two studies in 2003 and 2005 reported an association between Drug A and Gene B; and three studies in 2006, 2008, and 2009 mentioned an association between Gene B and Disease C. The left hand side of the equation would be Max (Min (2003, 2005) , Min(2006, 2008, 2009)) = 2006. So if Drug A and Disease C appeared together in any publication before 2006, we do not consider Drug A-Disease C as a potential discovery.

Evaluating sentence and discourse-level relation extraction

After generating LBDs, we used the drug-disease pairs identified earlier to evaluate their co-occurrence in literature, thereby estimating the need for discourse-level analysis in relation extraction. So, we have a list of drug-disease relations that potentially could be mentioned in the scientific literature. In the second step, we searched Medline abstracts tofind any co-occurrence (evidence) of drug and disease pairs. We categorized the drug-disease pairs with at least one evidence in Medline, into two groups, i) sentence-level relation and ii) discourse-level relation. For a given pair, if the drug and the disease appeared in a single sentence in at least one of the abstracts, we classified it as a sentence-level relation, otherwise we considered it as a discourse-level relation.

In order to assess the true validity of the drug-disease pairs we used the Comparative Toxicogenomics Database (CTD) [26], manually curated biological relations as our reference standard. CTD contains annotations of biological relations from various categories such as chemical-disease, gene-disease, drug-gene associations along with the corresponding PubMed citation. We compared the drug-disease pairs identified by the system against the chemical-disease associations in CTD. We considered our pair to be valid only if there was a match in the PubMed citation in addition to the drug-disease pairs.

Results

Retrieval of LBD relations

In order to generate potential LBD pairs, we started with 1,710 approved drugs from DrugBank [27]. We extracted 4,096 drug-gene (A-B) unique pairs where the drugs were restricted to our chosen list of 1,710 along with the semantic predicates from SemMedDB. For all the genes mentioned in A-B pairs we further retrieved 2,741 gene-disease (B-C) relations from SemMedDB. With gene being the common link between Drug-Gene and Gene-Disease, we inferred 71,842 drug-disease (A-C) relations. Further analysis revealed that only a small fraction of (118) of the 71,842 drug-disease pairs had an overlap in terms of abstracts from which the drug-gene (A-B) and gene disease (B-C) pairs were identified. We also found 14,451 drug-disease pairs catalogued in SemMedDB since they co-occurred in the same sentence. We have 57,391 drug-disease pairs also indirectly inferred through the Swanson's model of LBD and not present in SemMedDB. The results of our study is illustrated in Figure 2.

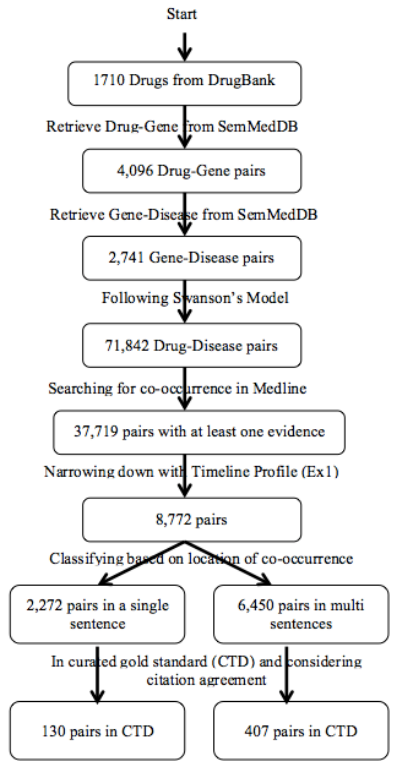

Figure 2 – Results of our study

Comparison of sentence level and discourse level

We further attempted to assess the level of textual extraction required to identify the drug-disease relations (A-C pairs). We searched Medline using "Drug AND Disease" as the query, to find any evidence of the identified pairs in the first step. We found only 37,719 (52.05%) of the 71,842 drug-disease pairs with at least one literature evidence.

Timeline analysis (Eq1) further narrowed down the number of drug-disease pairs to 8,772 (23.25%) from 37,719. 6,450 drug-disease relation pairs (73.52%) out of 8,772 identified earlier transcend sentence boundaries, demanding the requirement of discourse-level analysis for textual extractions.

We performed additional analysis on the remaining 2,322 drug-disease relational pairs, which had at least one literature evidence as sentence-level co-occurrence. For these 2,322 pairs, we found 89,805 literature evidences, which indicated that there were more than one literature evidence for each pair. Further composite analysis revealed that there were far more literature evidences across sentences than from a single sentence as shown in Figure 3.

We further carried out an assessment to validate the 8, 322 drug-disease pairs against a curated resource (CTD). We found that only 537 (6.4%) of them matched the gold standard. The low match was due to the fact that in addition to the match in the drug and disease names we also considered an agreement in the cited literature. Further analysis revealed that only 130 (24.20%) of the 537 that matched the gold standard occurred in a single sentence while the rest (75.80%) appeared across different sentences. If we ignored the match in the literature citation then we found 17,094 drug-disease pairs in CTD, which was significantly higher than the earlier one.

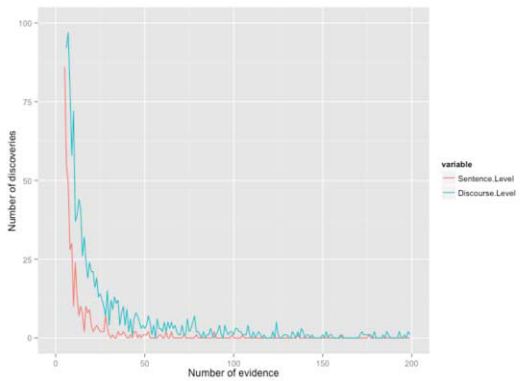

Figure 3 – Comparison of frequencies of drug-disease relations' co-occurrence in a single sentence versus multiple sentences

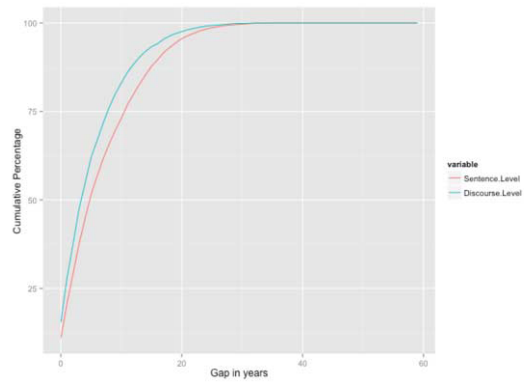

Figure 4 - Comparing the time gap between the first co-occurrence of discovery and the causal pairs (Sentence level versus discourse level)

Discourse-level analysis may impact Time lag of LBD

We performed another interesting analysis to study whether discourse-level analysis would have a positive impact on the time lag due to the reporting of causal pairs (drug-gene/gene-disease) and the appearance of drug-disease pairs in the scientific literature. Figure 4 plots the cumulative percentage which represents a cluster of drug-disease pairs observed at a time zone at both sentence level and discourse level. The trend shows that performing discourse-level analysis would significantly advance the identification of the drug candidate for a specific disease.

Discussion

In this paper, we attempted to assess the need for performing discourse-level analysis to extract biological relations that might potentially lead to serendipitous discovery. We found that biological relations quite often transcend clausal sentences and hence demand mechanisms to connect information across such boundaries. Using drug-disease relation discovery as an example, the description of 23,268 potential drug-disease relations across sentence boundaries against the 14,451 relations within sentences indicates the importance of a discourse-level analysis requirement to extract these relations from biomedical literature.

Across all experiments we observed a consistent trend that drug-disease relations that occurred across sentences outnumbered the ones within sentences. Our evaluation against a curated resource such as CTD also reinforces this fact. Results from two experiments need attention 1) Frequency of drug-disease relation co-occurrence at sentence level against the discourse level (Figure 3) was skewed towards the latter than the former. 2) The time lag analysis where the discourse-level analysis would have significantly reduced the time lag between the scientific reporting of causal pairs (drug-gene/gene-disease) and drug-disease relational pairs. This shows the need for advance discourse-level analysis approaches to extract information from literature in time and its ability to hasten the pace of discovery.

Another significant observation is the amount of potential false-positive drug-disease relations identified through literature mining. We observed a substantial reduction in the number of drug-disease relations when we compared the literature based drug-disease pairs with that of curated resource CTD. The reduction among the discourse-level pairs is far greater (3.3 times) when compared to the ones from the sentence level (2.5 times). As a note of caution discourse-level analysis might potentially extract more false positives, provided one does not explore sophisticated linguistic/statistical approaches to handle them.

As a final note we would like to mention that the way we generate the seed pairs of drug-disease relations in this study, coupled with our timeline based restriction analysis reinforces that the goal of our study is centered on LBD of novel relations. However we also understand the limitations of this study. Simple sentence-level or document-level co-occurrence information does not imply any biological relation between entities. As pointed out earlier, simple discourse-level analysis has the danger of extracting more false positives. In certain tangential areas of research such as drug repurposing certain techniques [28], [29] were explored to reduce the false positives.

Conclusion

In this paper, we investigated the extent of the need of discourse-level analysis for drug-disease relation extraction from biomedical literature. We used Semantic Medline to extract LBDs and then, based on co-occurrence analysis, we collected any evidence of the discoveries in Medline abstracts. We categorized the evidence into two categories, sentence level and discourse level. From subsequent analysis we infer that there is a potential to miss more than 70% of drug-disease relations when we extract information from the sentence level. This clearly demonstrates the need for deeper discourse-level analysis, which may translate to significant improvement in the state of the art of NLP techniques.

In the near future, we plan to explore much more sophisticated NLP approaches, a significant departure from the co-occurrence based extraction which may lead to significant improvement in the state of the art.

Abstract

Objective*. The aim of this paper was to present a practical InfoRoute algorithm and applications developed by CISMeF to perform a contextual information retrieval across multiple medical websites in different health domains.* ***Methods.*** *The algorithm was developed to treat multiple types of queries: natural, Boolean and advanced. The algorithm also generates multiple types of queries: Boolean query, PubMed query or Advanced query. Each query can be extended via an inter alignments relationship from UMLS and HeTOP portal.* ***Results.*** *A web service and two web applications have been developed based on the InfoRoute algorithm to generate links-query across multiple websites, i.e.: "PubMed" or "ClinicalTrials.org".* ***Conclusion.*** *The InfoRoute algorithm is a useful tool to perform contextual information retrieval across multiple medical websites in both English and French.*

Keywords:
Algorithms; Information Storage and Retrieval; Medical Informatics Applications.

Introduction

The Internet and in particular the Web has become an extensive health information and knowledge repository. As described in the survey published by Podichetty et al. [1], a majority (72%) of physicians affirmed that they used the Internet on a regular basis for medical research and 51% of them confirmed that the Internet influenced their healthcare practice. However, as mentioned by De Leo *et al.* [2] the vast majority of physicians (92%) indicated that they access a target site rather than utilize a search engine to gather medical information. A comparison study by Freeman *et al.* [3] concluded that PubMed appears to be more specific than Google Scholar; which was the same conclusion reported by Anders *et al.*[4] "PubMed is more practical to conduct efficient and valid searches on clinical topics than Google Scholar".

With the explosion of available health information and the number of biomedical websites in different medical fields including: literature databases, clinical trials databases, and drug databases; knowledge and information retrieval (IR) have become more complex and more time consuming. In the medical field some problems have obstructed the IR [5],[6] including the following:

- **Inadequate expression of information needs:** many information needs cannot be appropriately expressed: query syntax, medical terminologies or languages.
- **Lack of the relevant information:** Due to the inadequate terms used to search information, as medical databases and IR systems are indexed according to specific health terminologies which are different: lexically (different terms referred to the same medical concept) and structurally (different relationships between same concepts).

The aim of this work is to propose an algorithm named "InfoRoute" to perform a contextual and cross-lingual information retrieval across multiple websites in different health fields. This algorithm is devoted to French-speaking health professionals, who can read English but who prefer to perform queries in their native language. InfoRoute builds and generates various IR query on websites such as: PubMed, ClinicalTrials.org. Besides the algorithm, a web service and multiple web applications have been developed to help physicians and students to express the adequate IR query including medical terms in English and French based on more than 56 health terminologies.

Materials

The UMLS Metathesaurus

The UMLS Metathesaurus [7], developed by the US National Library of Medicine (NLM®), integrates 2,930,638 concepts in its 2014 release from 168 biomedical vocabularies. In the "MRCONSO"[1] table, which lists all UMLS concepts, only four terminologies, of all UMLS terminologies, are included with their French version in the UMLS Metathesaurus: the MeSH thesaurus, the World Health Organization Adverse Reaction Terminology (WHO-ART), the WHO International Classification of Primary Care (ICPC2), and the Medical Dictionary of Regulatory Activities (MedDRA). However, five (5) Biomedical Terminologies and Ontologies (BMTO) that have an existing official French version, are included in the UMLS but without their French version: the International Statistical Classification of Diseases (ICD10), the Systematized NOmenclature of MEDicine (SNOMED Int), Logical Observation Identifiers Names and Codes (LOINC), the International Classification of Functioning, Disability and Health (WHO-ICF) for handicap and the International Classification for Nursing Practice (ICNP). Furthermore, the CISMeF (French acronym for "catalogue and index of online medical resources in French") team has partially translated the BMTO included in the UMLS only in English: 24,563 synonyms and 689 ambiguous acronyms of the MeSH Descriptors, 163 synonyms of the MeSH Qualifiers, 20,887 MeSH Supplementary Concepts, and, 847 MEDLINEPlus terms and 12,700 FMA terms.

[1] The name of the concepts table in the UMLS metathesaurus

The Health Multiple Terminologies and Ontologies Portal (HeTOP)

A generic meta-model was designed in order to fit all 56 terminologies into one global structure.

The HeTOP[8] is connected to this meta-model to search concepts from all the health terminologies available in French (or in English and translated into French) included in this portal and, to browse it dynamically. This allows to:

a) Manual or automatic indexing of resources for the catalogue;
b) Retrieval of resources;
c) Teaching or performing audits in terminology management.

Some terminologies and classifications are included in the UMLS Metathesaurus (N=17) but the majority are not (N=39), i.e. the Human Rare Diseases Ontology (HRDO). Currently, HeTOP integrates 1,743,772 concepts in English, 1,031,230 in French, and 9,255,438 relationships.

The HeTOP portal integrates multiple terminological relationships and they can be classified as:

1. **Intra Terminological relationships:** terms linked with this type of relationships are in the same terminologies. For example, the MeSH term "suicide" is linked according to the Intra MeSH relationships **"See also"** with the MeSH term "suicide, attempted".
2. **Inter Terminological relationships:** these relationships link terms from different terminologies. In HeTOP, four (4) main inter-relationships were integrated and/or created (see *Table 1* for examples):
   a. **UMLS alignment ($UMLS_{alignment}$) :** This conceptual relationship described previously by Merabti *et al.*[9]. Two terms in HeTOP are linked under this relationship if they share the same UMLS concept in the Metathesaurus.
   b. **Manual inter-alignment ($CISMeF_{manual}$):** This relationship is added manually in HeTOP by CISMeF physicians or terminological specialist to link between two similar terms described in the same medical concept.
   c. **Exact inter-alignment ($CISMeF_{exact}$):** This relationship is obtained automatically using the lexical approach previously described by Merabti *et al.*[9]. Two terms are linked using $CISMeF_{exact}$ if they are lexically similar at the preferred term or at the synonym level, in French or English.
   d. **Exact supervised inter-alignment ($CISMeF_{supervised}$):** There are several $CISMeF_{exact}$ relationships validated by CISMeF physicians and tagged as $CISMeF_{supervised}$. In terms of efficiency this relationship is equivalent to $CISMeF_{manual}$ relationship.

Methods

Websites categorization

A total of twelve (12) categories were created to classify multiple medical websites (see Table 2). The selection of websites was performed by librarians according to the needs of health professionals, students and patients. Moreover, some websites were considered as the most important: e.g. PubMed, US Clinical Trials and EU Clinical Trials. Therefore, specific functions for these websites were developed. For example, in the following sections we described a PubMed query which is a specific querying on PubMed. The websites selected are important since it conditions the input and output of the algorithm developed.

Table 1 –examples from each 4 inters relationships integrated and their number in HeTOP (2014 released)

	Source Term (Terminology)	Target Term (Terminology)	Number of relations in HeTOP
$UMLS_{alignment}$	*Myocardial Infarction (MeSH)*	*Myocardial infarction, NOS (SNOMED Int)*	*644,982*
$CISMeF_{manual}$	*Riedel thyroiditis(HRDO)*	*Riedel's thyroiditis (MedDRA)*	*41,673*
$CISMeF_{exact}$	*appetite stimulants (ATC)*	Appetite stimulated (WHOART)	*653,709*
$CISMeF_{Supervised}$	*gonadotropin-releasing hormone (MeSH)*	*Luteotropin-releasing factor (FMA)*	*251,995*

InfoRoute Algorithm

InfoRoute is defined as an algorithm that automatically generates multiple search queries across many medical websites and exploiting the entire range of French and English Medical terminologies included in the HeTOP and some terminologies from the UMLS Metathesaurus.

The input

The InfoRoute algorithm takes in input three (3) kinds of queries:

1. **Natural Input Query (NI_{Query}):** this type of query assumes that the input text is composed of multiple terms in English and French in the natural language without using Boolean or restricted operators.
2. **Boolean Input Query (BI_{Query}):** query is based on the CISMeF Boolean query syntax shown in an equation 1. Where:
   a. **RO:** corresponds to the restricted operators (ROs)[2] as defined by the CISMeF such as "mr" for reserved words, "ti" for title or "tc" as all fields. These ROs can be useful to accurately translate the query to PubMed.
   b. **TERMINO:** the terminologies assigned to each term.

In addition to these ROs, the following terms can be connected using Boolean operators: AND, OR and NOT.

For example, the query **"asthma.mr[TER_MSH] AND child.tc"** corresponds to the query "search resources indexed by asthma as a reserved MeSH term and with the term child in all fields (title, abstract, etc.).

3. **Advanced Input Query (AI_{Query}):** this type of query is composed of at least one natural or Boolean query

$$(\text{Term}(.\text{RO}([\text{TERMINO}])^*)^+((\text{AND}|\text{OR}|\text{NOT})(\text{Term}(.\text{RO}([\text{TERMINO}])^*)^+)^* \quad (1)$$

and some options such as: age, country, gender. These options are used to translate the query to clinical trial websites: ClinicalTrials, Clinical Trials Register.

[2] Restricted operators used in the CISMeF search engine: http://doccismef.chu-rouen.fr/aides/aidedcacronyme.html [Nov 2014]

In addition to the query, the algorithm is a terminology depending, therefore, according to the terminology assigned in an input, and the results change whether query terms are included or not.

The Mutli-Terminological Automatic Indexing Query (MTAIQ)

This part of algorithm is very important, since in this query stage the input is indexed to extract the most similar medical terms in the query. The MTAIQ is a multi-terminological-bilingual indexer [9]. It uses the HeTOP databases and natural language processing tools [9] to analyze and normalize the query. In the case of the natural query, MTAIQ maps the query to the most similar term(s) depending on terminologies assigned in the input. For example, if the query is **"childhood asthma"** then MTAIQ detects "asthma in children" term, since the "childhood asthma" is a synonym of the MEDLINEPlus term "asthma in children". Nevertheless, if only the MeSH terminology is assigned then the most similar term detected will be "**asthma**", since "childhood asthma" and childhood are not MeSH terms.

The query Translation

In order to query all the websites, the InfoRoute algorithm performed multiple query translation from the one of the three queries types to at least four (4) possible kinds of queries:

1. **Boolean Output Query (BO_{Query}):** the query generated is composed by terms indexed using the MTAIQ and separated with Boolean operators. For example, if the query is **"furlong syndrome"** and the terminology selected is MeSH then the query generated will be "(**Furlong syndrome) OR (marfanoid disorder with craniosynostosis, type 2".** In this example the entry and the input languages were in English but it is possible to translate the result into the corresponding French Boolean query: **(syndrome de furlong) OR (furlong) OR (craniosynostose marfanoide)**".
2. **Extended Boolean Output Query (EBO_{Query}):** the Boolean query generated can be extended using the inter terminology relationships: $UMLS_{alignement}$, $CISMeF_{manual}$ and $CISMeF_{supervised}$ relationships described above. The aim was to obtain a new query with additional synonyms not included in the original user query. In this case, synonyms are all terms preferred or synonyms related to the query terms in the same language and according to the medical terminologies assigned.
3. **PubMed Query ($PubMed_{Query}$):**

Most of the research efforts were concentrated on PubMed queries because PubMed is of utmost importance for health professionals, students and patients. Some improvements have already been performed by CISMeF on PubMed query (vs. the PubMed query by default) since 2009[11],[12]. The first study was testing the added value of MeSH synonyms (MeSH Entry Terms) [11] and the second study was testing the added value of UMLS synonyms (same CUI) [12]. The PubMed query is a Boolean query combined MeSH terms (preferred and synonyms) and search options from PubMed: [MH]: Main Headings, [TI]: Title or [TW] for text words. This query was generated from natural or Boolean query. In addition to the simple PubMed query, in CISMeF two additional PubMed extended queries and one PubMed manually build query were developed:

a. **PubMed UMLS-Extended Query ($PubMedUmlsE_{Query}$):** As the EBO_{Query} query and as described in [12]. The PubMed query was extended by adding synonyms from UMLS representing terms which are in relation with the MeSH terms in the query and translated into English.

b. **PubMed Inter Extended Query ($PubMedInterExt_{Query}$):** Like the $PubMedUmlsE_{Query}$, the PubMed query was extended by adding synonyms which are in related to the MeSH terms according to two (2) inter relationships: $CISMeF_{manual}$ and $CISMeF_{supervised}$. Furthermore, for some BMTO included in HeTOP a PubMed generator query was developed based on these relationships. This generator extracted only the MeSH terms (MeSH descriptor and MeSH Supplementary concepts) for "no MeSH terms" which were related to it and build automatically a PubMed query using these MeSH terms. For example, for the HRDO term "Marfan syndrome" will be extended to the MeSH term "marfan syndrome" and all its synonyms.

c. **PubMed Manual Query ($PubMedManual_{Query}$):** In some cases where the automatic generated query was not effective (for the drug terms as an example), a manually PubMed query for each term was created in order to be more accurate. In a previous study[13], the "ATCtoPubMed" application to access PubMed via any Anatomical Therapeutic Chemical Classification (ATC) code was described. For each ATC code, a predefined query was created and could be entered on PubMed.

4. **Advanced Clinical Query ($Advanced_{Query}$):** This query is based on the AI_{Query} since it generates a "Boolean" query combined with the AI_{Query} Options selected. Currently, options have been selected based on two clinical trials websites: http://clinicaltrials.gov (US clinical trials) and http://www.clinicaltrialsregister.eu (EU clinical trials). Moreover, one name options were used as input and the $Advanced_{Query}$ mapped options in input to the adequate name option in the query search for each clinical websites. For example, the option "SEXE=female" will be mapped to: "gender=female-only" in EU clinical trials and to "gndr=Female" in the US clinical trials.

Table 2– Principals Websites classified by categories and language.

Categories	Website	
	English	**French**
Clinical Trials	1. ClinicalTrials: http://clinicaltrials.gov 2. Clinical Trials Register: http://www.clinicaltrialsregister.eu	1. ANSM: http://ansm.sante.fr

$PubMedManual_{Query}$	allergens	*ATC*	"desensitization, immunologic"[MH] AND "allergens"[MH]"

Results

The InfoRoute Web Service

The web service can be used by third-party web services or web-based applications. For example, The HeTOP portal used the InfoRoute to access PubMed from any BMTO's terms. In the CISMeF catalog, a specific website link which can be refreshed after any CISMeF query is integrated. The website category corresponds to the "search engine category" from the twelve (12) categories introduced above: PubMed, Intute, NCBI GQuery, etc.

InfoRoute Web Applications

Two web applications were devloped based on InfoRoute:

1. The InfoRoute General Website Tool

The application at http://inforoute.chu-rouen.fr/ir, visualises the input and the search results of the InfoRoute algorithm described in this paper. The input query allows the end-user to enter a term or an expression in French or English. All terminologies are assigned to the query by default. However, it is possible to specify the terminology(ies) input. Term or expression can be expressed using NI_{Query} or BI_{Query} described above. Search results can be obtained from all the twelve (12) category websites. Each category will be displayed separately and websites in each category will be separated according to their languages (French or English).

2. The InfoRoute Clinical Trials Access

The application at http://inforoute.chu-rouen.fr/irec, can be considered as a subtype of the InfoRoute general website tool described above. Tha aim of this application is to perform an effective access especially in French but also in English for two clinical trial websites: http://clinicaltrials.gov (US clinical trials) and http://www.clinicaltrialsregister.eu (EU clinical trials). Additional options will be added to this application compared to the general application based on AI_{Query} to generate and $Advanced_{Query}$ described in the query translation section.

Discussion

The aim of this study was to present the InfoRoute algorithm, which uses multiple BMTO and multiple relationships to generate IR health queries from natural or Boolean queries in French or English. The InfoRoute algorithm permits to answer the two questions presented in the introduction:

- **Inadequate expression of information needs:** the use of multiple kinds of queries (natural, Boolean and advanced), helps users to express their needs in multiple forms in two languages. Furthermore, the algorithm permits the user to express their queries according to multiple BMTO directly from specific biomedical terms or indirectly when applied the MTAIQ to extract biomedical terms.
- **Lack of the relevant information:** As described for PubMed and some clinical websites; the algorithm has been improved to retrieve the more accurate information for these specific websites. For example, in Thirion *et al.*[11] the optimized query is significantly more precise than the current PubMed query (54.5% vs. 27%). In [12], the expansion of the PubMed query on UMLS synonyms increase recall and proportion of queries retrieving. However, the expansion of the user query according to multiple synonyms can decrease precision because the description of the same medical concept differ between BMTO. Besides UMLS synonyms, the $PubMedInterExt_{Query}$ which based on synonyms terms expanded using $CISMeF_{manual}$ and $CISMeF_{supervised}$ relationships will be evaluated in further work. Further studies will be performed to exploit hierarchical inter relationships to expand results query.

The InfoRoute algorithm is the first algorithm developed which used French terms and/or French BMTO to generate and reformulate IR queries according to multiple health websites such as: PubMed or ClinicalTrials. The use of two languages is due to the bilingual BMTO included in HeTOP and thanks to multiple automatic and manual translations performed on multiple BMTO such as: MEDLINEPlus, MeSH SC, FMA, etc. Currenlty InfoRoute is integrated in the two main CISMeF tools: CISMeF search engine (http://doccismef.chu-rouen.fr/dc/) and HeTOP (http://www.hetop.eu/hetop/) to retrieve health infrormations from many sources. The next step is to integrate InfoRoute in real clinical information systems and develop a "French InfoButtons" as described in [14].

Conclusion

To conclude, the InfoRoute algorithm is a useful tool to perform contextual information retrieval across multiple medical websites in both English and French.

Abstract

Medical Cyber-Physical Systems (MCPS) are currently a trending topic of research. The main challenges are related to the integration and interoperability of connected medical devices, patient safety, physiologic closed-loop control, and the verification and validation of these systems. In this paper, we focus on patient safety and MCPS validation. We present a formal patient model to be used in health care systems validation without jeopardizing the patient's health. To determine the basic patient conditions, our model considers the four main vital signs: heart rate, respiratory rate, blood pressure and body temperature. To generate the vital signs we used regression models based on statistical analysis of a clinical database. Our solution should be used as a starting point for a behavioral patient model and adapted to specific clinical scenarios. We present the modeling process of the baseline patient model and show its evaluation. The conception process may be used to build different patient models. The results show the feasibility of the proposed model as an alternative to the immediate need for clinical trials to test these medical systems.

Keywords:

Baseline Patient Model; Statistical Analysis; Simulation; Testing; Medical CPS.

Introduction

In the health care domain, traditional clinical scenarios are seen as *closed-loop systems* in which the caregivers are the *controllers*, medical devices act as *sensors* and *actuators*, and patients are the "*physical*" *plants*. *Medical Cyber-Physical Systems* (MCPS) modify this vision by introducing additional computational entities that help the caregiver control the "*plant*", i.e., decision support [1].

Due to the insufficient understanding of human body dynamics in response to any treatment, MCPS development is more complex than traditional systems [1]. Since patient safety is the main concern of an MCPS, they must be carefully tested before being released to the market. However, to allow a MCPS to be directly tested with real patients, it is necessary to have an alternative solution for developers to identify critical errors and prevent serious harm to test patients. Therefore, a pre-validation step must be added to the validation process to anticipate the identification of these errors.

Nowadays, MCPS designers, more specifically the manufacturers of medical devices, use documents provided by regulatory agencies related to health, such as the FDA[1]. They specify standards for safety and performance to minimize design risks and to ensure the effectiveness of products.

The importance of having a formal patient model is the capability of generating relevant test cases to validate an MCPS. This process aims to examine if the therapies provided by these systems are adequate and ensure patient safety by adapting their behavior given the patient's current state [2].

The concept of a *virtual patient* described by Agur [3] is related to a complex set of mathematical models and a set of parameters that represent the dynamics of biological, pharmacological, and pathological processes in the body of a patient under medication. In the literature, we can find some related work about computational modeling of patients. For instance, Jiang et al. [2] provide an environment for closed-loop testing, whose patient model, specifically a formal model of the human heart, is the control center of a cardiac pacemaker system. The goal is to evaluate the device's operation safety and effectiveness based on the patient condition.

Other recent research is presented by Van Heusden et al. [4], which proposes an artificial pancreas model for patients with type 1 diabetes mellitus based on control theory. Its goal is to improve glucose control in such patients. One of its advantages is that it incorporates the patient's medication (insulin) reaction.

Lastly, Khan et al. [5] present a glucose control system to prevent hypoglycemia as a consequence of medication administration. In this work, the patient model (i.e., an artificial pancreas) establishes a relationship between certain vital signs such as heart rate and skin impedance in the blood glucose level control.

The aforementioned patient models either focus on variables of interest for specific clinical scenarios or neglect the relationship between the four human being's vital signs: heart and respiratory rates, blood pressure, and body temperature. Therefore, the absence of these aspects contradicts the actual behavior of human beings. So, these models have limited applicability to other scenarios.

In this paper, we propose a formal patient model to be used as a basis for developers to validate MCPS solutions without risking compromising patients' health if the system fails. Our model provides parameters to define patient profiles, and correlates the main vital signs to simulate the patient's health condition. The vital signs are represented by statistical regression models which were integrated to provide the patient's model dynamics.

[1] United States Federal Food and Drug and Administration - http://www.fda.gov/

The key feature of the baseline patient model is the ability to be adapted to various specific clinical scenarios, promoting reuse. The main contribution of this paper is to present the conception process used to develop the baseline patient model of the model-based architecture proposed by Silva et al. [6].

Materials and Methods

The vital signs and physiological parameters provided by our patient model are based on thresholds. They are generated by regression models. We established the parameters that defined the thresholds in accordance with Clinical Guidelines, such as [7-9]. These clinical guidelines also were used to help identify the probable regression model predictor variables for each vital sign considered in our baseline patient model. Also, we applied some rules on the real patient data obtained from the *MIMIC II Clinical Database v2.6*, whose access was authorized by the PhysioNet.org [10]. This data set contains clinical data from Intensive Care Unit (ICU) patients and the rules were applied to characterize the population of interest for study. The baseline patient model conception process consists of: (1) Statistical analysis and (2) Computational modeling.

Statistical Analysis

We used the same database to characterize a population of individuals. We applied inferential statistical techniques such as a *Generalized Linear Model* (GLM) to obtain regression models. These models are used to predict the observed signs to be incorporated in the baseline patient model.

In the GLM, is assumed that the response variable follows the exponential family distribution, and the predicted values are calculated from a link function [11].

The population contained 38,141 observations from 2,245 patients, in which approximately 37.4% were female and 62.6% male. From this population, we obtained a sample with one observation of each patient in the moment they were admitted to the ICU. We present a summary of the process to characterize the population of interest and sampling procedure in Figure 1, whose sample size represents only approximately 0.001% of total population. Table 1 presents descriptive statistics about the data set extracted from this process.

Table 1 – Statistics of the Population of Interest

Variable	Mean	Std. Dev.	CV [a]	Min.	Max.
hr	86.863	14.473	0.167	42.00	150.00
sbp	115.447	20.403	0.177	62.00	205.00
rr	17.552	5.619	0.320	8.00	38.00
pt	36.926	0.879	0.024	31.70	41.44
gl	129.631	30.444	0.235	47.00	188.00
weight	83.727	20.826	0.249	33.00	200.00
height	169.781	10.427	0.061	124.50	231.10

[a] Coefficient of Variation; Std. Dev. = Standard Deviation, Min = minimum, Max. = Maximum.

We selected eight variables for the statistical analysis: *gender*, *weight* and *height* as demographic variables; heart rate (*hr*), respiratory rate (*rr*), systolic blood pressure (*sbp*), and body temperature (*pt*), as vital signs; and blood glucose level (*gl*), as a physiological parameter. It is worth mentioning that a variable for diastolic blood pressure was not used in this analysis because it depends on *sbp* variable. The strong correlation between these variables may cause a multicollinearity problem [12].

Given that the population of interest was defined and one sample was obtained, we extracted four regression models, one for each vital sign in study. The regression models were evaluated using the following statistical measures: (a) determination coefficient (R^2); (b) square of the linear

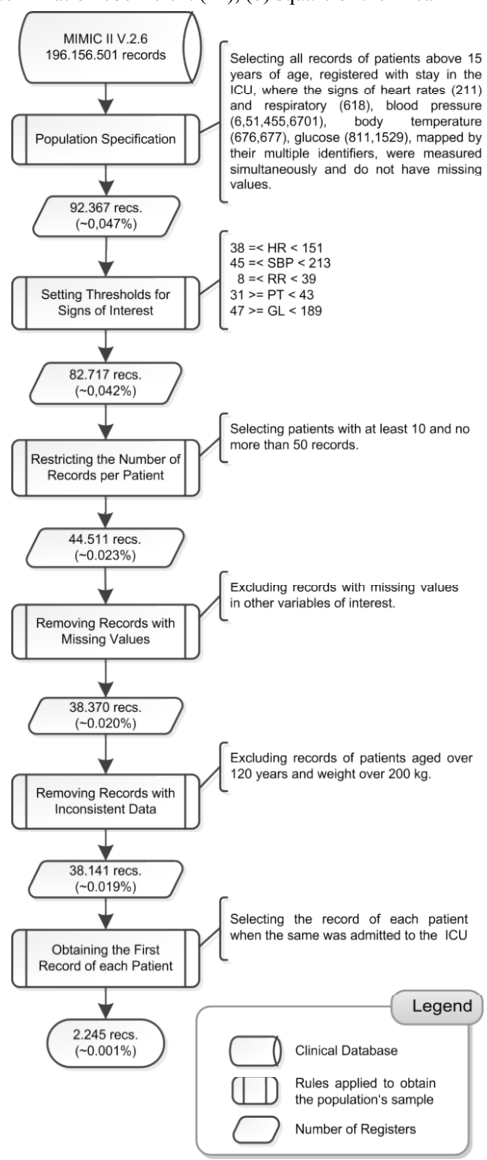

Figure 1 – Process to characterize the population of interest

correlation coefficient (R^{2*}) between response variable and adjusted values. Both measures were used to indicate the data variability explained by the regression model. Table 2 presents the results for each model, with confidence level of 95%.

Table 2 – Metrics to Evaluation of the Regression Models

Regression Model	R^2	R^{2*}
GLM_HR	0.310	0.332
GLM_SBP	0.477	0.511
GLM_RR	0.414	0.489
GLM_PT	0.480	0.480

R^2 = Determination Coefficient, $R^{2*} = COR(y, \hat{\mu})$

As human beings have many variables to be observed, and different individuals react differently to the same drug [13], we believe the results are satisfactory.

It is noteworthy that to predict the respiratory rate we used a *Normal Inverse Model* in the form of Equation (1) with canonical link function defined in Equation (2):

$$\hat{\mu} = \hat{\eta}^{-\frac{1}{2}} \quad (1)$$

where μ is the mean frequency of respiratory rate that we want to model and

$$\hat{\eta} = \hat{\beta}_0 + \sum_{i=1}^{4} \hat{\beta}_i X_i + \sum_{j=2}^{4} \hat{\beta}_{5j} X_{5j} + \sum_{i=6}^{7} \hat{\beta}_k X_k . \quad (2)$$

is the systematic component where β_0 corresponds to the intercept and $\beta_{1\text{-}7}$ to the coefficients of the variables *hr*, *sbp*, *pt*, *gl* and *group*, as well as the interactions between *hr*·*sbp* and *hr*·*gl*, respectively. The *group* variable is used according to the patient classification, given the values of the other predictor variables. Therefore, the X_{5j} variable assumes the value *1* according to the *j* value that specifies the patient group, and the value *0* for all other possible *j* values.

The usage of the *Normal Inverse Model* means that the higher the value of the systematic component, the lower the value of the average estimated respiration rate. Hence, higher values of variables with positive coefficients lead to lower values of *rr*. On the other hand, higher values of variables with negative coefficients, lead to higher values of *rr*.

For the remaining regression models, we used a *Gamma Linear Regression Model* given by Equation (3), whose variance function is more restrained than the *Normal Inverse Model*:

$$\hat{\mu} = \hat{\eta}^{-1} \quad (3)$$

Where μ is the mean frequency of vital signs that we want to model; in this case *hr*, *sbp* and *pt*. Since the workflow to create regression models for all vital signs is similar, these regression models were omitted.

Computational Modeling

To design the baseline patient model we used the AOD paradigm, i.e., a design methodology based on components called *actors* [14]. This methodology represents a formal model of concurrency in which an *actor* is a computational agent that has an independent thread of control and communicates through asynchronous message exchange. We used the *Ptolemy II* modeling tool, which is an extensible AOD-based software framework that supports experimentation, to build the models. Its emphasis is in concurrent components, using well-defined computation models that govern the interaction among these components [15].

The baseline patient model considers the four main vital signs: heart rate (*hr*), respiratory rate (*rr*), arterial blood pressure (*bp*) and peripheral body temperature (*pt*). This patient model consists of the integration among the regression models that represent each one of these vital signs. Such regression models in the AOD paradigm may be modeled as shown in Figure 2, whose regression model is for respiratory rate (*GLM_RR*).

We integrated the regression models to the baseline patient model (see Figure 3) to allow interaction among them and provide the behavioral dynamics to the patient's model. Thus, the user may change the value of a specific vital sign during simulation and automatically the values of other vital signs will be modified according to their respective regression models.

We present part of the elaborated model that incorporates the patient characteristics and the regression models of the four vital signs in Figure 3a. We have highlighted the following key elements: **(1)** the patient model configuration parameters,

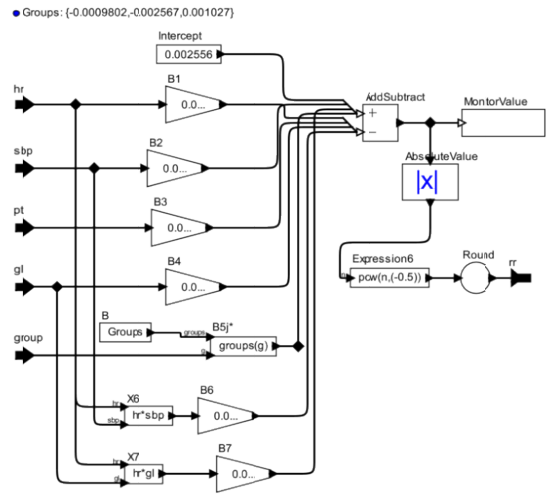

Figure 2 – GLM_RR for the Patient Model

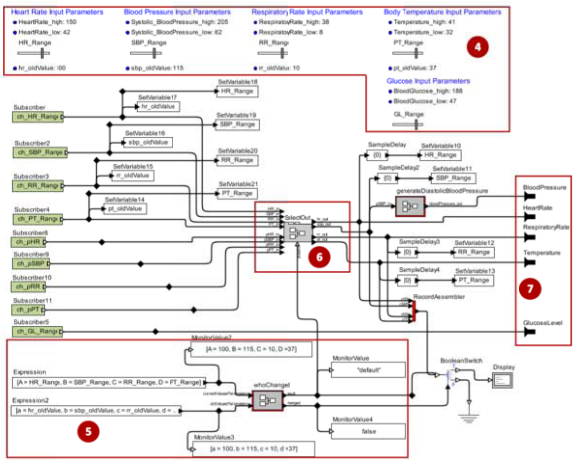
including the *Continuous Director* element that determines their execution semantics; **(2)** the substructure of the model that specifies the vital signs' initial values and physiological parameters represented in the model; **(3)** the elements labeled by the *GLM_<vital_sign>* pattern that denote the regression models for each vital sign modeled. The model parameters are the basis for generating the values for the vital signs provided by the patient model. Moreover, the specifications of the thresholds of each vital sign allow the developer to manipulate them during the simulation, to represent different health conditions for the patient's model. Consequently, the behavior analysis of the MCPS may be carried out for various situations.

We present the second part of the baseline patient model in Figure 3b. The highlighted elements are: **(4)** the parameters that define thresholds for each signal so that these signals remain within the range of values considered in the conception of regression models; **(5)** the logic used to identify which vital sign was changed by the user at a given time during the model simulation; **(6)** the component developed to select the model's correct output according to user intervention; and **(7)** ports that provide the patient model communication interfaces with the medical devices models for data acquisition from these devices.

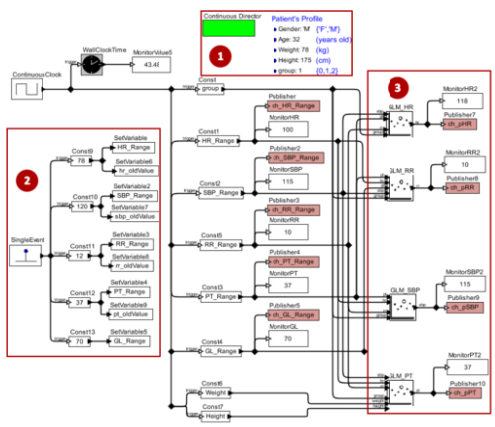
Notice that the patient model only has *output ports* for vital signs and physiological parameters. To receive *feedback control actions* from actuator models, *input ports* must be added to the patient model through the *Ptolemy II* framework. Additionally, the patient model must be adapted to represent the pharmacokinetic model's dynamic behavior corresponding to the drug type to be administered.

Results and Discussion

We used *Diagnostic Plots* to assess the regression models. In Figure 4 we present the envelope (*Normal Q-Q Plot*), leverage points, influential points and residuals versus fitted values plot for *rr*. Due to space constraints, we omit the results from the other vital signs.



(a) Regression models to estimate vital signs data



(b) Submodel to provide information to the medical devices' models

Figure 3 – Baseline Patient Model

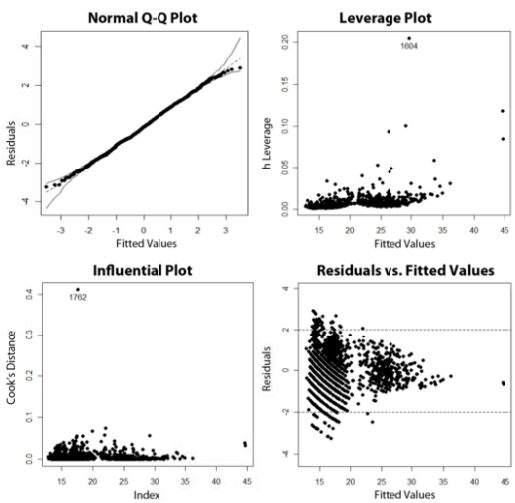


Figure 4 – Diagnostic Plots for the GLM_RR

Envelope plots are useful to check the regression models' fit. Leverage points may interfere in adjusted values close to them and regression coefficients estimate. Influential points may interfere in the model parameters' estimated values. The residuals versus fitted values plot is useful to assess the assumptions of the regression model (e.g., any visible trends would show a dependence of errors on the predictor variable).

After analyzing the diagnostic plots of each regression model, we concluded that the obtained models reasonably explain the vital sign they represent. Thus, the regression models were statistically validated. This means that the synthetic data generated by the patient computational model are compatible with the sample used in statistical analysis. The simulation of the proposed patient model in a specific clinical scenario is out of the scope of this paper.

Conclusion

In this paper, we presented a formal model to provide context information (e.g., profile and vital signs) of a patient, the so-called baseline patient model. We used regression models to generate a set of vital signs (heart rate, respiratory rate, blood pressure and body temperature) that compose the patient model.

The use cases of this patient model are to simulate patients' health conditions to support testing of MCPS. With its extension, it will be possible incorporate it to the context of specific clinical scenarios. This will provide the developer an important tool to identify failures in the system, and will also assist health experts in the strategy planning in the treatment of patients. However, its extension depends on the experience of the MCPS developer, as well as the knowledge of the medical expert that may help in this process.

Our solution can adapt and be used in a variety of clinical scenarios. These scenarios can simulate different medical contexts, helping in the validation process of medical systems. The approach applied to build the baseline patient model may be used to create different patient model types, but will require the use of different samples or clinical data sources. Furthermore, it might be necessary to define other patient use cases to validate the MCPS given that the patient model presented was built using only data of ICU patients.

A potential limitation of this patient model is its restriction to the input values for predictor variables. Whenever these values exceed their thresholds, the accuracy of the regression models used to generate the synthetic data for vital signs might decrease.

In the future, we will show how to extend the patient baseline model for specific clinical scenarios. This will require the incorporation of dynamics of the action of drugs in the patient's body to the model. Thus, the medical device models may act on patients' behavior, causing it to react to such actions. Lastly, we will request that health experts perform external validation of the patient model.

Acknowledgments

The authors would like to thank to CAPES, PPgCC-COPIN and IFPB for the financial support of this research, as well as LANEST-UFCG for the statistical consultancy service.

Leveraging Electronic Tablets and a Readily Available Data Capture Platform to Assess Chronic Pain in Children: The PROBE system

Vibha Anand[a,b], Steven J. Spalding[a]

[a] *Center and Department of Pediatric Rheumatology, Pediatric Institute, Cleveland Clinic*
[b] *Department of Quantitative Health Sciences, Lerner College of Medicine of CWRU, Cleveland, OH, USA*

Abstract

The Patient Risks Outcomes and Barriers Evaluation (PROBE) system is developed using a readily available data capture platform (REDCap) and iPads. PROBE performs complete and consistent assessment of pain at every patient visit in pediatric rheumatology practices of our very large healthcare system. Using evidence based clinical guidelines, it combines the following essential elements for care: 1) screening for behavioral risks for chronic pain such as anxiety, sleep deprivation, or painful conditions affecting a caregiver living in child's home, 2) capturing disease activity related measures and enabling 3) clinical decision support. In this demonstration project we describe PROBE and evaluate it for usability in practice. Using PROBE, we observed significant differences for behavioral risk factors in children with juvenile idiopathic arthritis in those who report chronic pain vs. not.

Keywords:
Electronic Tablets; iPad; REDCap; PROBE; CDSS; JIA; Pain; Children

Introduction

Pain is the most distressing aspect of disease in children and can play a predominant role in their everyday lives. Despite pain's impact on both children and their families, the medical community has only recently begun to focus its resources on the investigation and treatment of pain. The field of pediatric rheumatology is not alone in this delay. In June 2011, the Institute of Medicine (IOM) released a landmark report, Relieving Pain in America: A Blueprint for Transforming Prevention, Care, Education, and Research. This report addresses the US healthcare system for its deficiencies in the assessment and management for pain in the United States[1]. The report calls for progress in the collection and reporting of data on pain. It also emphasizes the need to provide complete and consistent assessment of pain as well as the necessity for expanding opportunities in pain research. Children and families who live with juvenile idiopathic arthritis (JIA) can ardently verify the findings of this IOM report.

Children with JIA who experience pain regularly perceive themselves to be more disabled and are more likely to restrict their activity[2-5]. Their pain related to disease commonly persists into adulthood and can significantly impact their productivity and quality of life[6-8]. However, the relationship between disease activity and pain in children and adolescents with rheumatic disease is known to be inconsistent [3,9] but certain behavioral risk factors have shown to influence the pain experience in children with JIA[10-12]. These include sleep deprivation, anxiety, or painful conditions affecting a caregiver in the child's home. Because early identification of risks may help in improving long term patient outcomes, numerous studies have shown that healthcare providers need to implement complete and consistent assessment of pain in their everyday practice[13-18]. Besides, many evidence based guidelines exist for screening and assessing pediatric chronic pain. However, it remains a formidable challenge for most practices to implement these guidelines in routine care [12,19,20] let alone initiate any intervention following screening. Difficulty in implementing guideline components within the workflow and constraints of the clinical workflow are often cited as potential hurdles. In our previous work in general pediatric practices, we have shown that computerized clinical decision support systems (CDSS) can automate screening in waiting rooms [21,22] and alert the providers based on screening. CDSS can be effective tools for case finding [23] and for improving physicians' use of and adherence to care guidelines[23-27]. More recently, we have also shown that electronic tablets are desirable mediums for implementing screening in the waiting rooms, and using these devices, CDSS can gather more complete patient data for making care decisions[28].

Therefore, to address complete and consistent assessments of pain in children and adolescents with JIA at every visit, we have developed an electronic data capture and clinical decision tool - *Patient Risks, Outcomes and Barriers Evaluation (PROBE)*. PROBE is currently being used in three pediatric rheumatology practices of our large health care system. It screens patient families for pain and associated behavioral risk factors in the waiting room using an electronic device (iPad) that communicates with the PROBE back end server in real-time. The objective of this pilot study is to demonstrate - 1) the feasibility of using a readily available data capture platform and electronic tablets for complete and consistent assessment of pain during routine care in pediatric rheumatology practices; 2) that differences are observed on screening in patient reports of chronic pain; and 3) that PROBE can evolve into a viable Health IT platform for pediatric pain management and patient engagement.

Materials and Methods

The PROBE System

The PROBE system consists of three data capture forms, a central server and electronic tablets such as iPads. Access to the data forms is provided using secure wireless network via a

web browser interface. The data forms capture information from patients or caregivers in the waiting room and clinical data from the clinical team in the exam or the work room. The three PROBE forms are - the Patient Screening Questionnaire (PSQ), the Patient Nursing Form (PNF) and the Provider Work form (PWF). Below we describe a workflow using PROBE. Please refer to Figure 1 for details of the workflow.

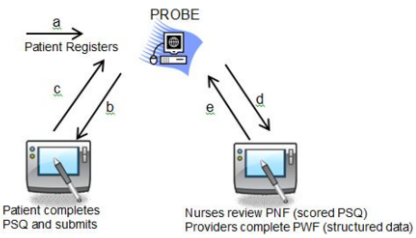

Figure 1 - PROBE Workflow

Workflow: At each patient registration visit (step a) patients or their caregivers are instructed to answer questions on PSQ using an electronic tablet device in the waiting room. Answers to each page of questions are securely recorded in the PROBE central server in real time (b), and no data is ever recorded on the electronic device (c). When responses to screening questions are submitted (d) the nursing form (PNF) is automatically populated with patient answers and scores (e). Inside the exam room, either the provider or the nursing staff completes the PWF (f).

Pain and Behavioral Risk Screeners: Children, adolescents and young adults, ages 3 to 23 years are screened. The following validated screening instruments are implemented using PSQ: *1) Mood disorder screening:* Childhood Depression Index and Screen for Child Anxiety Related Emotional Disorders (SCARED)[29]; *2) Sleep assessment:* Bedtime problems, Excessive daytime sleepiness, Awakening during the night, Regularity and duration of sleep and Snoring (BEARS)[30]; *3) Parental Pain History Questionnaire* (PPHQ)[31]: which is directed towards the caregiver; and *4) Pain Coping Questionnaire:* consisting of *Pain coping efficacy* and *Brief pain inventory scales*[32]. The latter measures weekly pain level on a 0-10 VAS scale, with 0 being the lowest and 10 the highest pain level. Please see Figure 2 below. The *Chronic pain (CP)* report is screened as pain greater than 3 days per week for more than 3 months.

Implementation: PROBE is developed using a readily available electronic data capture platform, the Research Electronic Data Capture (REDCap)[33] platform in collaboration with the Department of Quantitative Health Sciences (QHS) at Lerner Research Institute, Cleveland Clinic. REDCap is a secure data capture tool for research purposes and is supported in our environment. For the PROBE implementation, a REDCap project was created and an anonymous surveys consisting of validated screening questionnaires (*SCARED, BEARS, Brief Pain Inventory Scale, Parental Pain History and Pain Coping and Efficacy* as described above) were implemented for PSQ. The patients do not need login credentials but the front-desk staff enters patients' identifying information into PSQ before handing out the electronic tablet device. At each visit, the front desk staff confirms that the patient is an established JIA patient (from registration) and records the patient's medical record number, age and gender (of the child) and selects the provider and visit type (i.e. for infusion or provider) from a menu item in PSQ. No patient information for race/ethnicity or insurance category is currently recorded in PSQ. Additionally, if the child is between 3 and 12 years of age, the front desk asks the parent or the caregiver to complete the PSQ. Adolescents and young adults (12 – 23 years) complete their own PSQ. The screeners implemented in PSQ have both a parent and a child version, and based on the age entered by the front-desk staff, the appropriate one is automatically presented in PSQ. We use the branching logic capabilities of the REDCap software to implement age-based questions. Using REDCap database functionality, PROBE also automatically assigns a unique system identifier for all three data capture forms and together they constitute a record for the patient's visit. PROBE was initially implemented for a pilot test in one pediatric rheumatology clinic at our main hospital in March 2014. We currently have three practice sites, including two community sites using PROBE. Each site has at least two electronic tablet devices for patient use and they all communicate with the PROBE central server in real-time.

Clinical decision aid tool: PROBE implements clinical decision support via scoring screening questionnaires. When the PSQ form (Figure 2) is submitted by the patient, numeric scores (e.g. anxiety screening) are computed in real-time by the system and displayed to the clinical staff on the nursing form (PNF). Please see Figure 3 for PNF. The providers can access patients' PNF to view scores or any screening information via a secure login to the REDCap website either using an exam room computer or an electronic tablet device. At the conclusion of a visit, providers or their staff document current labs, medications, and disease activity scores. Please see Figure 4 for PWF documentation. More structured data item additions are planned for PWF in the near future. These include orders (labs, medications, imaging) and results from other investigations (e.g. eye exam) to support clinical decision-making. The following types of documentation notes are also planned as additions in the near future for PWF - psycho-social, and sleep evaluation, nutrition, physiotherapy and occupational therapy referrals**.**

At each visit, data from all the three forms are available to the providers and their nursing staff for any further action. However, currently no reminders or prompts to providers or their clinical staff are provided using PROBE. These are planned as future additions as well. Although information for orders, labs and referrals may exist in our electronic medical record (Epic Systems), they may mostly exist as free-text notes, so PROBE offers the capture of structured data items and the ability to use these data for follow up visits using a computer-based clinical decision support system that is also planned for development in the near future.

Analyses: As part of this study, we report descriptive statistics, i.e. number of visits since deployment and patient visit characteristics. We also condcuted bi-variate analyses for an outcome of the self-report of chronic pain with a self-report of anxiety symptoms, sleep impairment issues and parental history of pain as explanatory variables. For purposes of the statistical analyses, we dichotomized (yes or no) the explanatory variables according to the screener scoring thresholds (e.g. anxiety) and questions that were answered in affirmative (e.g. sleep and parental history).

Statistical analyses were performed using Stata Software version 12 (StataCorp, College Station, TX). The study was approved by the Cleveland Clinic Institutional Review Board.

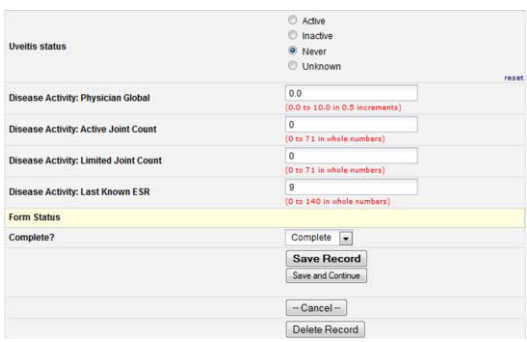

Figure 4 - Provider Work Form (PWF)

Results

Initial results: Over a three-month initial period, PROBE recorded 21 patient visits in the main hospital, our first pilot site. From these visits, we found that patients reporting chronic pain are more likely to report higher average pain scores (>=5) in the last week. They show symptoms of anxiety on as many as 17 of the 41 items screened using three point SCARED scale and are more likely to report sleep issues, e.g. problems falling asleep at bedtime, or feeling sleepy a lot during the day, in school or while driving when compared to those who do not report chronic pain. The patients reporting chronic pain are young adolescents (> 12 years) and more likely to be females with a parental history of pain.

Descriptive Results: As we observed these differences in one practice during routine care, we extended the use of PROBE to the other two practices at our community sites. Subsequent results presented here are from all three practice sites. At the time of this writing, there are 192 patient visits recorded in PROBE. Please see Table 1 below for patient visit characteristics. Please note that in Table 1 there may be missing data for explanatory variables (e.g. sleep) as the patient or the caregiver need not answer all questions at every visit. Similarly, as the system was being deployed and the front-desk staff was getting acquainted with the procedures for recording patient identifying information, there may be some missing values for socio-demographic variables (age, sex). A majority of visits are for female patients (77%) and over 12 years of age (~70%). Patients reported chronic pain in almost half of all visits (49%).

Table 1 – Patient Visit Characteristics

Sex (n=191)	
Female	148 (77.5%)
Age(n=183)	
3 to 7 years	17 (9.3%)
8 to 11 years	39 (21.3%)
12 to 18 years	107 (58.5)
18 to 23 years	18 (9.6%)
Chronic Pain Report (n=181)	
No	92 (50.8%)
Yes	89 (49.2%)
Anxiety Report (n=192) §

No	25 (16.2%)
Yes	129 (83.8%)

scoring or interpretation according to § SCARED; ¥ BEARS; £ PPHQ

Bi-variate Analyses: Using the chi-square test, the report of one or more sleep impairment issues was significantly associated with the report of chronic pain ($X^2 = 15.7$, p-value < 0.0001). The total score on anxiety symptoms were not significantly associated with the report of chronic pain, as was the parental history of pain report from this pilot study data.

However, we observed differences based on specific anxiety symptoms reported on the SCARED screening tool. In the bivariate analysis, the presence of panic disorder or significant somatic symptoms (score of 7 or more), separation anxiety (score of 5 or more), and significant school avoidance (score of 3 or more) on specific questions are significantly associated with the patient report of chronic pain (X2 = 4.24, p-value = 0.039) and (X2 = 7.11, p-value = 0.008) respectively.

Similarly, we observed differences in responses to pain coping questions for patients reporting chronic pain versus no chronic pain. In general, those reporting chronic pain reported higher pain score levels (4 to 5 on a 10 point VAS) as opposed to 2 to 3 on a 10 point VAS and lower coping levels (e.g. "When hurt or in pain for a few hours or a few days how often do you think you can do something to change it?" The responses were never, or hardly ever for patients reporting chronic pain versus often or very often for those reporting no chronic pain).

Discussion

We have demonstrated that by using a readily available data capture platform and by leveraging electronic tablets such as iPads as an interface, we can create a tool for complete and consistent assessment of pain at every visit in children and adolescents. Furthermore, our analyses show that there are differences in behavioral risks for patients who report chronic pain versus those who do not and we have demostrated this in a real-world clinical setting.

In this pilot work, we have also shown that the PROBE system can effectively screen patients or their caregivers in pediatric rheumatology waiting rooms. Our results show that impaired sleep is a strong predictor for a chronic pain report in children and adolescents with JIA. However, as we write this, we are collecting more data to develop and evaluate a comprehensive prediction model for chronic pain in this population. Simultaneosuly, we are working on developing PROBE into an automated computer-based clinical decision support system. We hope to evaluate it in near future for patient and system based interventions for pain management in clinical studies.

Because the use of PROBE in routine care can help identify patients' risk factors, i.e. chronic pain vs. no chronic pain group patients, we hypothesize that it can be used to support patient engagement activities, for example to ask more detailed questions about a patient's painful condition, their coping style and/or to provide educational content. Potentially, these activities can promote patient-clinician interaction and lead to informed clinical decisions such as a referral for sleep medicine, psycho-social evaluation or cognitive behavioral therapy (for example for pain coping). Therefore, PROBE based clinical decision support can be used to manage patients who are at higher risk of chronic pain prospectively, however all this needs to be studied in well-designed clinical trials.

As with all such work, there are limitations to ours too. First, the PROBE system is limited by use of REDCap and its built-in programming functionality (e.g. unable to query data on a survey form in real-time). In that respect, the current system is a prototype or demonstration project. Secondly, because of the above limitations, we have not built automated clinical decision support (e.g. prompts and reminders) functionality into the current system. Therefore, our future work would involve migrating PROBE to a more robust data capture and query platform so that we can build robust patient engagement tools, and provide clinical decision support. Lastly, our bi-variate analyses of pilot data may suffer from sample and confounding bias. Regardless, our demonstration project highlights the importance of using eHealth enabled tools in pediatric specialty care practices.

Acknowledgments

The authors would like to thank the front-desk and nursing staff at the Pediatric Rheumatology clinics at Cleveland Clinic. A special thanks to Carmen Howard for assistance with the initial pilot. The authors would also like to thank QHS, especially Heather Kren for assistance with programming and supporting the PROBE system in REDCap.

Normalization of Phenotypic Data from a Clinical Data Warehouse: Case Study of Heterogeneous Blood Type Data with Surprising Results

James J. Cimino

Laboratory for Informatics Development, the Clinical Center of the US National Institutes of Health, Bethesda, Maryland, USA

Abstract

Clinical data warehouses often contain analogous data from disparate sources, resulting in heterogeneous formats and semantics. We have developed an approach that attempts to represent such phenotypic data in its most atomic form to facilitate aggregation. We illustrate this approach with human blood antigen typing (ABO-Rh) data drawn from the National Institutes of Health's Biomedical Translational Research Information System (BTRIS). In applying the method to actual patient data, we discovered a 2% incidence of changed blood types. We believe our approach can be applied to any institution's data to obtain comparable patient phenotypes. The actual discrepant blood type data will form the basis for a future study of the reasons for blood typing variation.

Keywords: Clinical Data Repositories, Phenotype Detections, Blood Typing

Introduction

Clinical data warehouses are becoming a common tool for providing access to electronic health record data for various forms of reuse.[1] However, the reuse of historical data can be problematic, especially when data are pooled from multiple sources for which minimal documentation and metadata exist.[2] A challenge for clinical research informatics is to provide users with ways to reconcile such heterogeneous data.[2] For example, if one source codes gender as "male or female" and another source codes gender as "male, female, or other", summarizing gender data across sources becomes problematic.

While normalzation procedures are standard for genetic sequence data,[3] they have been less well defined for phenotypic data, typically involving ad hoc mappings between patient characteristics.[4] The purpose of this paper is to present a method for normalization of heterogeneous data by reducing them to specific, well-characterized phenotypic traits. We take as our example common ABO and Rh blood typing such as is typically tested in blood bank laboratories.

Background

The Biomedical Translational Research Information System

The Clinical Center of the US National Institutes of Health (NIH) is a hospital in Bethesda, Maryland that has served as a site for clinical research since 1953. Over the years, data from clinical studies at NIH have been captured in a variety of clinical trials data management systems, as well as two electronic health records – one in operation from 1976 to 2004 and one in operation since 2004. These data, on over 500,000 human subjects from over 50 source systems are collected into a single database that forms the core of the NIH's Biomedical Translational Research Information System (BTRIS).[5] All terms from source systems are assigned unique concept identifiers in BTRIS's Research Entities Dictionary (RED), which is a unified ontology that includes hierarchical classifications of similar terms (such as tests that measure the same substance or medications that contain the same ingredients). BTRIS users select specific terms or classes of terms from the RED to use in retrieving identified data on their own clinical studies, as well as de-identified data across all clinical studies.[5]

Case Study : ABO and Rh Blood Type Antigens

Human red blood cells express a wide variety of antigens. Three in particular (A, B and Rh) are commonly identified in clinical laboratories for purposes such as cross-matching blood for transfusion. Blood donors and blood recipients are characterized as having A, B, AB or O blood and as being Rh positive or negative. Except in rare instances, an individual's blood type does not change over his or her lifetime.

Today, most blood banks report these antigens together as the result of a single test; e.g., A+, B-, AB+, O-, etc. However, in the past, these results were reported across two tests: the ABO test to report types A, B, AB and O, and the Rh test with the possible results "positive" and "negative". Even earlier, the ABO test results were reported as two separate tests for the A and B antigens. A patient could have a positive results for both of these tests (type AB), one of these tests (type A or B), or neither of these tests (implying type O).

This heterogeneity has been well-documented as a challenge for dealing with pooling data from, or sharing them between, multiple health care sites.([6], also: Huff SM, personal communication; inspiring [7]) As a repository of data from multiple sites over 40 years, BTRIS often presents users with this type of challenge. We chose it as a case study for the normalization of heterogeneous data, since proper normalization should result in patients having consistent blood types over time, in effect serving as their own gold standards.

Methods

Approach to Phenotype Normalization

Our approach to phenotypic characterization involves reducing complex findings to their most atomic forms and them assembling them in canonical ways into more complex phenotypic patterns. In the case of blood typing, we consider that each test provides evidence for the presence or absence of at

least one red blood cell antigen. This can range from a single antigen (A, B, or Rh) to all of them (for example, type "AB+" indicates the presence of all three and type "O-" indicates the absence of all three).

Preliminary Analysis of Result Types

The first step in our normalization process was to identify the relevant tests panels, individual tests and actual results reported by those tests. We used the BTRIS Limited Data Set function[8] to retrieve de-identified data from BTRIS, using appropriate terms selected from the RED.

The second step was to review each unique panel-test-result triple to determine the antigenic evidence it provides. Each result was tagged with the letters A, B and R, with presence indicated by an upper-case letter and absence indicated by a lower case letter. Thus, the a B-Antigen test with the result "Positive" was labeled as "B" and a Type and Crossmatch test with the result "O+" was labeled as "abR". A MUMPS data structure (PC-MUMPS, DataTree Inc., Waltham, MA), was created for each result and its assigned antigens.

Analysis of Patient Data for Phenotype Consistency

In the third step, the relevant data of individual patients were characterized based on the assigned antigens. Pooled evidence for the presence or absence of each antigen was stored for each patient in a second MUMPS global, such that a patient would typically have three letters (one each of "A" or "a", "B" or "b", and "R" or "r"). In the fourth step, we reviewed the results for each patient to determine situations where an individual did not have exactly one of each letter.

All data were obtained with oversight of the NIH Office of Human Subjects Research Protection (Agreement Number BTRIS_2014_835_CIMINO_J_CC). Only those data that did not require permission for reuse from the original investigators, as per NIH policy, were retrieved. The patients' birthdates and test dates were included in the data but all other potentially identifying information was removed, as per NIH policy for limited-use data sets.

Results

Preliminary Analysis of Result Types

A search of the RED for tests with names containing the phrase "blood group" identified 644 terms, including three appropriate term classes as shown in Figure 1: *ABO Grouping and/or Rh Antigen Phenotyping Intravascular Test*, *Blood Group Antigen Blood Typing Blood Bank Test*, and *RH Blood Group System Antigen (Rh Factor) Test*. When BTRIS was queried with these three terms, 593,637 test results were found on 43,485 patients (see Figure 2). The data included results from 139 tests in 66 test panels, with 334 unique panel-test pairs that reported 3946 unique results (Figure 3).

Review of all panels and tests identified 21 panels and 59 tests within those panels that provide information on ABO and Rh blood typing. The data set included 1452 unique test results for these tests (many of which were misspellings, as in [6]). Each was reviewed manually to assign antigenic evidence. Table 1 shows a sample of panels, tests, results and assigned antigenic evidence.

Assignment of Phenotype Based on Antigenic Evidence

After removal of irrelevant panels and tests, the patient data included 165,981 panel events with 307,884 test results for 43,485 patients. Pooling of all antigenic evidence for each

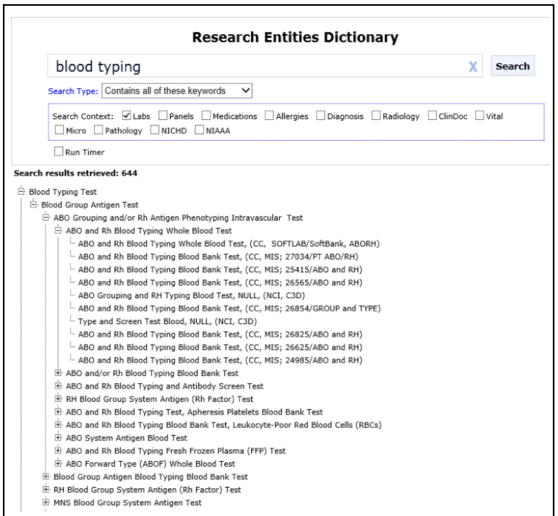

Figure 1: Blood type terms in the Research Entities Dictionary. A search for the phrase "blood typing", restricted to the laboratory domain identified one class ("Blood Typing Test") that subsumes 643 additional terms. The hierarchy is partially expanded.

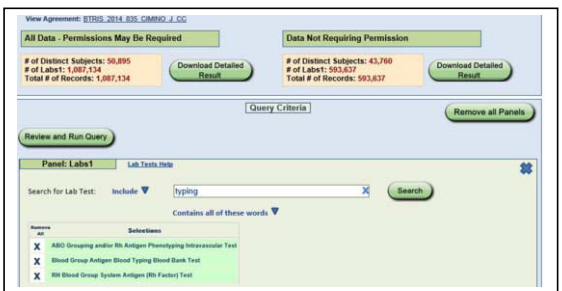

Figure 2: Query screen of BTRIS Limited Data Set application, showing three search terms at bottom and query summaries at top. Only data from the right ("Data Not Requiring Permissions") were downloaded.

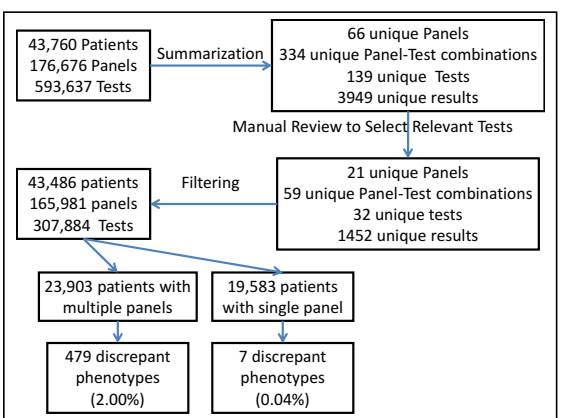

Figure 3: Summary of analysis of initial data set.

Table 1: Panel/test/result combinations with interpretations

Panel	Tests	Result	Interpretation
ABO GRP-RH TYPE	ABO GRP-RH TYPE	O POSITIVE	abR
ABO GRP-RH TYPE	ABO GRP-RH TYPE	0 POS	abR
ABO GRP-RH TYPE	ABO GRP-RH TYPE	A POSITIVE	AbR
ABO GRP-RH TYPE	ABO GRP-RH TYPE	A NEG	Abr
ABO GRP-RH TYPE	ABO GRP-RH TYPE	A NEGATIVE	Abr
ABO GRP-RH TYPE	ABO GRP-RH TYPE	AB NEG	ABr
ABO GRP-RH TYPE	ABO GRP-RH TYPE	B POS	aBR
ABO Group and Rh Type [ABORH]	ABO Group and Rh Type [ABORH] - A	0	a
ABO Group and Rh Type [ABORH]	ABO Group and Rh Type [ABORH] - A	1+	A
ABO Group and Rh Type [ABORH]	ABO Group and Rh Type [ABORH] - A	2+	A
ABO Group and Rh Type [ABORH]	ABO Group and Rh Type [ABORH] - A	3+	A
ABO Group and Rh Type [ABORH]	ABO Group and Rh Type [ABORH] - A	4+	A
ABO Group and Rh Type [ABORH]	ABO Group and Rh Type [ABORH] - A	M4	A
ABO Group and Rh Type [ABORH]	ABO Group and Rh Type [ABORH] - B	0	b
ABO Group and Rh Type [ABORH]	ABO Group and Rh Type [ABORH] - B	4+	B
ABO Group and Rh Type [ABORH]	ABO Group and Rh Type [ABORH] - Rh	NEG	r
ABO Group and Rh Type [ABORH]	ABO Group and Rh Type [ABORH] - Rh	POS	R

Panels are collections of one or more tests, each of which is associated with a result. We interpret the results to correspond to specific phenotypic characteristics: A=Antigen present; B=B antigen present, AB=A and B antigens present; a=A antigen absent; b=B antigen absent; ab=Neither A nor B antigens present ("Type O"); R=Rh antigen present ("Rh Positive"), r=Rh antigen absent ("Rh Negative"),

patient identified 32 different phenotypes, of which 8 were complete (ABO and Rh designations), 6 were incomplete (ABO or R designation only) and 18 were discrepant (multiple ABO and/or Rh designations). Table 2 shows the antigenic evidence, and counts for each phenotypic designation.

Review of Aberrant Phenotypes

In all, 531 of the 43,485 patients (1.22%) had aberrant phenotypes, based on discrepant laboratory results. Some examples of their test results are shown in Table 3. Given that random, patient-independent laboratory errors could account for some of these discrepancies, and that the frequency of errors would be proportional to the number of tests run, we examined the frequency aberrant phenotypes versus number of test panels performed (Figure 4). The Pearson coefficient for this association is 0.7127 (P<.00001); however, the slope of the regression line is only 0.04.

Initially, we did not consider patients with a single test panel, since we were looking for discrepancies between panels. Doing so would result in discrepancies in 479 of 23,903 patients (2.00%). However, we were surprised to find that seven of 19,583 patients (0.004%) with a single test panel had discrepancies, so although rare, this situation was not impossible. This led us to examine intra-panel discrepancies. We found that 109 patients (including the seven mentioned above) had 588 intra-panel discrepancies (see Table 3).

Discussion

Informatics Implications

As previously noted, heterogeneity of data syntax and semantics in clinical repositories complicates analysis of data aggregated from multiple sources over long time spans. The approach described here recasts clinical findings in terms of atomic phenotypic characteristics that are institution- and laboratory-independent. The case here concerns the presence or absence of specific human red blood cell antigens, but we believe this approach can be applied to many other data types, such as microorganism antigens and antibodies and clinical findings that are sometimes reported as collections of postcoordinated terms and sometimes as a single, precoordinated term. This approach has potential for use with other repositories or networks of repositories with heterogeneous data.

Biomedical Implications

We were surprised at the incidence of intra-patient blood type variation among patients with multiple sets of test results (2%). Human blood antigens do not normally change during a patient's lifetime, except in unusual circumstances such as transplantation,[9] leukemia[10, 11] and, very rarely, viral infection[12]. It is possible – in fact probable – that some of this variation was due to laboratory error. The correlation (r=.72) between numbers of tests performed and likelihood is consistent with an independent influence such as systematic error; however the slope of the correlation (0.04) indicates that this would only account for about 4% of the variance. The data collected in this study are insufficient for determin-

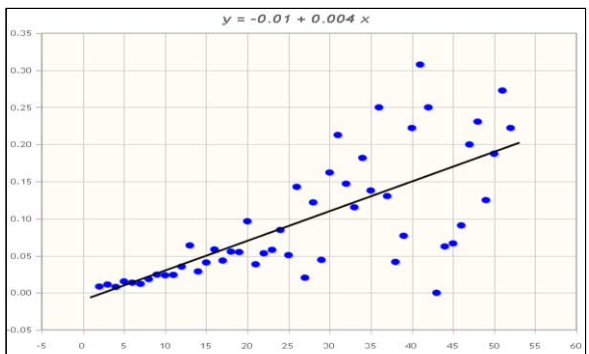

Figure 4: Pearson's correlation between number of tests performed and incidence of at least one discrepant result between the tests. (http://www.mathportal. org/ calculators /statistics-calculator/correlation-and-regression-calculator.php)

Table 2: Antigen patterns found in test results, classified as Complete (corresponding to an actual real phenotype found in nature), Incomplete (lacking sufficient information to determine the phenotype) or Aberrant (not corresponding to an actual phenotype)

AaBbr	(aberrant)	3
ABbRr	(aberrant)	2

ing what is likely to be a multifactorial cause for the variations. Discovering them will require a future study in which the entire patient records are accessed.

Conclusions

The reduction of heterogeneous laboratory results to their atomic phenotypic characteristics was an effective approach for normalizing patient test results from a longitudinal repository with 40 years of data from disparate sources systems. The normalization makes some patient characteristics explicit (e.g., by inferring Type O from the absence of A and B) as well as highlighting data that are discrepant. The approach seems extensible to other domains and repositories. The incidental finding of intra-patient blood type variation reminds us that the re-use of data constantly holds challenges and surprises, and that every question we seek to resolve seems to produce more new questions than answers.

Abstract

Recruitment of patients in clinical trials is nowadays preoccupying, as the inclusion rate is particularly low. The main identified factors are the multiplicity of open clinical trials, the high number and complexity of eligibility criteria, and the additional workload that a systematic search of the clinical trials a patient could be enrolled in for a physician. The principal objective of the ASTEC project is to automate the prescreening phase during multidisciplinary meetings (MDM). This paper presents the evaluation of a computerized recruitment support systems (CRSS) based on semantic web approach. The evaluation of the system was based on data collected retrospectively from a 6 month period of MDM in Urology and on 4 clinical trials of prostate cancer. The classification performance of the ASTEC system had a precision of 21%, recall of 93%, and an error rate equal to 37%. Missing data was the main issue encountered. The system was designed to be both scalable to other clinical domains and usable during MDM process.

Keywords:

Clinical research, Decision support system, Semantic interoperability, automatic reasoning.

Introduction

Clinical trials (CTs) are the gold standard for testing therapies or new diagnosis techniques that would improve clinical care. CTs often rely on adequate sample sizes, but often remain incomplete or are cancelled due to missed recruitment targets within a certain timeframe and financial cost. The recruitment process faces many barriers that have already been well identified in the literature. The automation of the patient screening process by computerized recruitment support systems (CRSS) should address some of the recruitment barriers. In a review paper, we analysed the advantages and drawbacks of each CCRS described in the literature[1]. Based on this analysis, we developed a system based on the 3 following principles:

1. Electronic health records (EHRs) and eligibility criteria (EC) are usually written by humans for humans. Consequently, their formalization for an automatic screening system can prove to be challenging. An CRSS should rather process structured and coded data. Free text formulation of patient data and eligibility criteria results in too many ambiguities. Despite the efficiency of NLP methods, coded and structured data with a formal semantic remain the best situation to successfully develop and apply automatic reasoning methods.
2. To be scalable, a CRSS should be connected to any kind of clinical EHR source. Indeed, data from the same patient might be scattered in different hospital information systems. To address this issue, an CRSS should adopt a service-oriented architecture and use semantic interoperability standards to communicate with the different data sources.
3. Similarly to any decision support system, CRSS should provide useful information about the eligibility status of patients strategically at the right time and place, such as when physicians decide on treatment plans. For instance in oncology, this decision could be taken during MultiDisciplinary Meetings (MDM).

ASTEC (Automatic Selection of clinical Trials based on Eligibility Criteria) is a French national research project that aims to develop an CRSS designed on the 3 principles mentioned above. This system has been tested by the Centre Eugene Marquis (CEM), a Regional Comprehensive Cancer Centre located at Rennes (Brittany,France). In this paper, we present the evaluation of the system.

Background

Multidisciplinary meeting and the recruitment process in clinical trials: MDM are an integrated team approach to health care in which medical and allied healthcare professionals consider all relevant treatment options and develop collaboratively an individual treatment plan for each patient. That is, MDM is about all relevant health professionals discussing options and making joint decisions about treatment and supportive care plans, taking into account the personal preferences of the patient. In France, multidisciplinary decisions are mandatory for all oncology patients.

Decision support systems for recruitment: For over 25 years, many attempts have been made to develop methods and tools supporting the recruitment process. More recently, projects with new technologies recent are arising, such as the Biomedical Translational Research Information System (BTRIS) developed at NIH to consolidate clinical research data [2]. It is intended to simplify data access to and analysis of data from active clinical trials and to facilitate reuse of existing data to answer new questions. The EHR4CR [3] project supports the feasibility, exploration, design and execution of clinical studies and long-term surveillance of patient populations by providing services supported by an european infrastructure connected to hospital Clinical Data Warehouses. TRANSFoRm project has similar objectives but focused on primary care patient data. STRIDE [4] is a platform supporting clinical and translational research consisting of a clinical data warehouse, an application development framework for building research data management applications and a biospecimen data management system. The ObTiMA system relies on OWL and SWRL to perform semantic mediation between heterogeneous data sources [5]. MATE [6] is an interactive computer system to facilitate explicit, evidence-based decision-making in MDM for

breast cancer care. MATE [7] provides prognostication and risk assessment and also flags up patients eligible for recruiting into ongoing research trials. Trinzeck et al have designed and implemented a generic architecture for Patient Recruitment System compatible with most of the currently available German Hospital Information System environnements.

Formal representation of eligibility criteria: The question of the formal representation of eligibility criteria is still an open issue. Several works have been developed or reused formalism for eligibility criteria representation such as CDISC's ASPIRE, Arden Syntax, SAGE, or GELLO or ERGO.

Interoperability and communication: To determine the eligibility status of patient, CRSS has to match clinical data coming from one or several EHR sources to the Clinical trial criteria. This supposes a semantic interoperability and a communication layer between the clinical data sources and the CRSS. To address this issue, the current trend is to combine interoperability standards coming from clinical or research domains (e.g HL7/CDISC), such as the Bridge model.

Methods

Use case addressed by the system: The different steps (S_x) of the MDM process and the system functionalities used all along this process (fig. 1) are : **S1.** A clinical research associate or a principal investigator enter the eligibility criteria of all open clinical trial into the system. This step consist of translating the free text criteria into a computable representation with a graphic user interface. **S2.** Mr. Dupont, a patient having a prostate cancer, consults with Dr. Durant, a urologist. **S3.** Dr Durant schedules a MDM to decide the best therapeutic strategy for his patient. Dr. Durant fills up a MDM form provided by a regional EHR. This MDM report contains the most important medical information about Mr. Dupont, that the MD Team will use during the meeting to take the decision. **S4.** Before the meeting, all the MDM reports are sent through a web service to the system. The system analyses, for each MDM report, all the criteria of all open clinical Trials. **S6.** As output, the system provides an eligibility report for each patient, containing all proposed and rejected clinical trials with the reasoning of the system decision. **S7.** During the meeting, both MDM report and eligibility report are displayed to the multidisciplinary team. The case of Mr. Durant is discussed and a decision is taken by the team. The decision is added to the MDM report. **S8 :** Either, the therapeutic decision is a standard treatment. The MDM report with the decision is then sent to Dr. Durant who informs Mr. Dupont. The patient then either accepts or rejects the proposal. **S9 :** Or according the conclusion of the eligibility criteria report provided by the system, the multidisciplinary team can propose to Mr. Durant to be enrolled into a clinical trial. **S10 :** In this case, a Clinical Research Associate (CRA) is warned after the MDM by a notification. The CRA is in charge to verify details the eligibility of Mr. Durant to. Eventually, Mr. Dupont is contacted, to sign the CT consent. Most of the time, specific exams are scheduled (**S11**) to determine whether the patient is eligible or not. Mr. Dupont is finally included (**S12**).

System Architecture

Patient data source and communication components:

The system was tested with the oncology EHR of the regional oncology network of Brittany. The EHR communicates to the system through secured webs services. A semantic interoperability framework was defined based on the HL7/CDAr2 Level 3 standards and more specifically on HL7 Care Provision/R-MIM Care Record (DSTU) and HL7v3 Standard Transport Specification, Web services Profile, Simple Object Access Protocol version 1.2 (SOAP 1.2). HL7 R-MIM was constrained and only useful classes for the project were implemented. From this refinement, we have produced a set of HL7 templates to formalise and encode the set of data elements of the MDM reports. To encode both the patient data and the CT criteria, the National Cancer Terminology Thesaurus (NCIT) was chosen as reference ontology/terminology. For each data elements of the MDM report, entities and related value were manually mapped to NCIT concepts. In case of missing concepts, we have enriched the ontology by selecting codes and labels from other reference terminologies (e.g. SNOMED CT, LOINC, etc). The communication between the patient data source and the system was performed by a securitized web service. At the message reception, a virtual Medical Record (vMR) was populated by the system with the transmitted patient data (vMR is a generic HL7 data model dedicated to decision support systems).

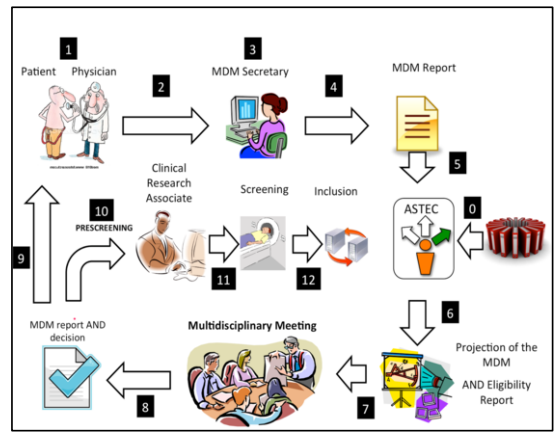

Figure 1 – MultiDisciplinary Meeting workflow

Eligibility and patient data representation: EC refer to complex conditions that a patient needs to fulfill to be included or excluded from a given clinical trial. All clinical trials can be seen as a concatenation of a set of inclusion criteria and a set of exclusion criteria. Patients need to meet the inclusion criteria and avoid the exclusion criteria in order for them to be considered in the clinical trial. Patient data as well as eligibility criteria were formalized relying on OWL models. Namely, patients are defined as a set of *entities*, to which several properties can be associated. Every *property* has a unique *value* that represents its state.

Formalization and processing of the eligible criteria: EC are written by physicians so the terminology used can be subject to interpretation and involve several simple predicates. Thus, a specific criterion can be complex and depend on several *entities.* Complex criteria such as the GETUG 14 eligibility criterion "Cancer in intermediate prognostic group", were decomposed into a set of *atomic criterion*, i.e. a simple predicate on a unique OWL triplet (e, p, v) and a logic AND/OR relationship. As example, Fig. 2 illustrates how this criterion can be broken down to simple predicates (right side of the graph, i.e., leaves of the graph) and a set of Boolean operations.

A patient is included in a CT if his root criteria score is equal to 1. Only patients that met all inclusion criteria and met none of the exclusion criteria received a score of 1.

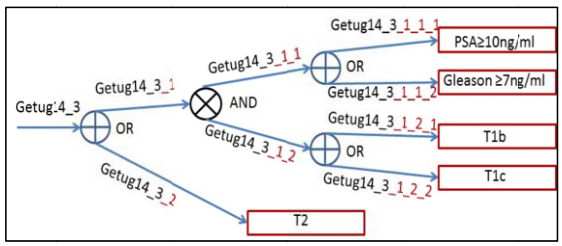

Figure 2-…

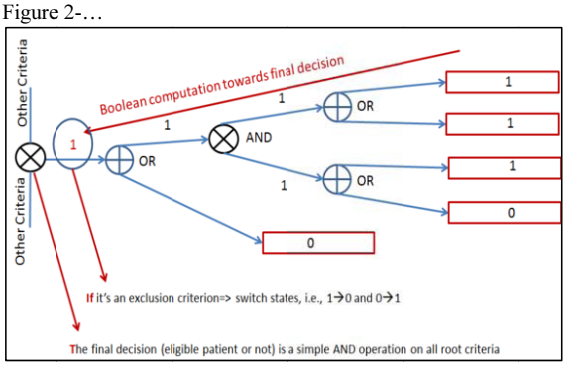

Figure 2- Criterion representation

Inference method: The inference method used in the system has been explained in details in our previous paper [8]. The core of the system is a simple ontology that glues together the components: it imports NCIT ontology and the ontologies that define SWRL built-ins and the classes they could require. This glue ontology defines the classes that are used to represent patient data and the EC in CTs. EC expressed in SWRL are inferred with patient data by an inference engine (JESS). The information granularity is most of the time different between patient data and the EC. This issue is addressed by Jess - subsumption reasoning capability.

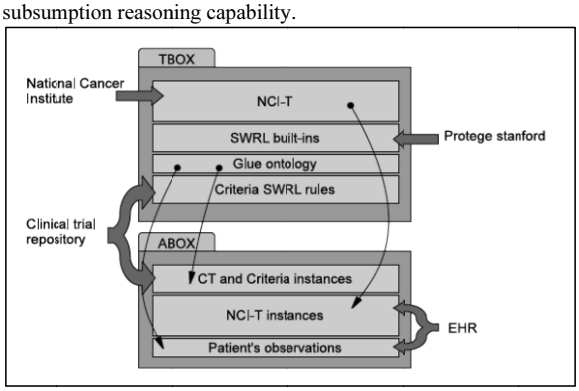

Figure 3 – System design

Figure 3 shows the general architecture: TBox contains the glue ontology that imports NCIT and the SWRL ontologies. The SWRL rules are definitions, and therefore are part of the TBox. The ABox contains the instances of NCIT classes, which are linked by observations, and the instances of the EC.

The eligibility report: A clinical trial has a list of arguments in favour and one against enrolment of the patient. The list in favour is filled by inclusion criteria, while the list against by exclusion criteria. Once the criteria rules are run, the instances of the criteria will have the property *supported_by* either filled with one or more observations, or empty. Inclusion criteria with the property filled are supported, and they in turn support the clinical trial. Exclusion criteria with the *supported_by* property filled are arguments against the enrolling of the patient to the clinical trial. At this point, rules specific to CTs are run to aggregate the results of the criteria. All inclusion criteria of a CT need to be verified: there must be, for each CT, a rule stating that the conjunction of all inclusion criteria must have at least one supporting argument. It is also possible to trace the exclusionary criteria to an observation that fits it. However, extracting the CTs that are supported without arguments against it requires to reason with the closed world assumption: according to the open world assumption, the empty list of arguments against enrolment is considered ignorance, and cannot be used to infer that the there are no arguments against enrolment. The last step needs to be performed outside the ontology. An external program obtains the list of all clinical trials and selects those that are both supported and have no arguments against.

Evaluation of the system

Clinical trials for the evaluation of ASTEC

To evaluate our proposed system, we performed retroactive chart review of all patients in every MDMs from October 2008 to march 2009. Only a selection of CTs recruiting at the CEM during the study period was chosen for the ASTEC evaluation. The study focused on prostate cancer, which is the most common cancer in urology and the main topic of discussions at the urology MDM and of many clinical trials. All criteria of the selected CTs were considered for the study, but required some interpretations to be coded in the system. Some high level criteria were rather vague (e.g. "life expectancy >=10"). Moreover such an item is not present explicitly in the multidisciplinary reports (and probably rarely in most of EHRs). In this case, the Clinical Research Assistant (CRA) in charge of the system setting in accordance with the principal investigator, encoded a set of sub-criteria, that could be match with the information present in the MDM report (to continue with life expectancy ≥ 10, it was encoded in ASTEC as no hepatic failure AND no renal failure … AND Age < 75). Eventually, the aggregating algorithm described above, was used to recompose the initial eligibility criteria and determine the final status of eligibility according to the availability of the real data of the MDM reports.

Automatic screening evaluation and Statistical analysis:

We compared screening performed by the ASTEC system with screening performed by two kinds of human decisions:

- The "MDM Decisions", i.e. the real-time decisions taken during MDM, which are finally the real screening decisions;
- The "Reviewer Decisions", i.e. the decisions taken after review by the CRA and the Principal Investigator (PI) of each study. For that, the overall MD reports were reviewed, manually and independently from the MDM decisions, to propose eligible patients to the RCT. Standard performance metrics are used to assess information retrieval: true and false positives, true and false negatives, recall, precision, f1-measure and overall error rate.

$$precision = \frac{tp}{tp + fp} \quad recall = \frac{tp}{tp + fn}$$

$$f1 - measure = 2.\frac{precision.recall}{precision + recall}$$

Results

During the study period, 23 Multidisciplinary meetings took place with about 285 medical reports. Four ongoing CTs (GETUG 14, 15, 16, 17) concerning prostate cancer were recruiting at the CEM during the study period. Only results from the GETUG 14 are presented, which was the CT with the most eligible patients.

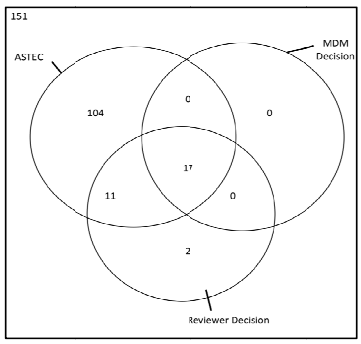

Figure 4 - Venn diagram of the ASTEC decisions, the Reviewer decisions and the MDM decisions

We considered the screening reviewer decisions as gold standard, while the MDM decisions reflected the screening performed in real world by physicians.

As shown in Figure 4, the 3 screening methods all excluded 151 patients. The MDM decisions selected 17 patients eligible to GETUG 14, while the ASTEC system selected 132 patients and the reviewer decisions selected 30 patients eligible to GETUG 14. Finally, the automatic patient screening by the ASTEC system collected 11 additional patients from the selection of the MDM team, and only 2 patients eligible to GETUG 14 were missed.

Table 1–. Performance metrics of the ASTEC system

	MDM Decisions (1)	**Reviewer Decisions (2)**
n total	285	285
n selected patients	17	30
ASTEC classification results with (1) or (2) as reference		
True positives	17	28
False positives	115	104
True negatives	153	151
False negatives	0	2
Precision	13%	21%
Recall	100%	93%
Error Rate	40%	37%
F1-measure	23%	34%

The ASTEC system had a 21% precision rate and 93% recall rate, and an error rate equal to 37% (**Error! Reference source not found.**).

Error! Reference source not found. presents if each GETUG 14 eligible criterion was verified, not verified, or unknown (when data is missing) for all the screened patients. For instance, only the histological confirmation of the prostate cancer was collected in all the MDM reports.

Table 2– Status of the GETUG 14 eligible criteria

Criteria	**Verified**	**Not verified**	**Unknown**
Histologically confirmed prostate cancer	285 (100%)	0	0
Intermediate-risk cancer	57 (20%)	41 (14%)	187 (66%)
No lymph node invasion	20 (7%)	4 (1%)	261 (92%)
No metastatic disease	14 (5%)	5 (2%)	266 (93%)
PSA < 30 ng/mL	261 (92%)	10 (4%)	14 (5%)
No history of invasive cancer	1 (0.4%)	0	284 (99.6%)
Life expectancy ≥ 10 years	89 (31%)	34 (12%)	162 (57%)
No prior pelvic radiotherapy	27 (9.5%)	2 (0.7%)	256 (89.8%)
No radical prostatectomy (and TURP < 3 months)	34 (11.9%)	5 (1.8%)	246 (86.3%)
No prior hormonal therapy and castration	31 (10.9%)	0	254 (89.1%)
Other exclusion criteria (x5)	171 (12%)	379 (26.6%)	875 (61.4%)

Discussion

Semantic interoperability

We developed an interoperability framework using HL7 standards and the ASTEC ontology (based on the NCIT) to encode the data elements. This approach ensures through a service oriented architecture, an effective and secure communication between the oncology EHR and the CRSS. As far as we know, this is the first CRSS project using this kind of interoperability approach. Despite the fact we tested our system on a single commercial EHR, this architecture will help to connect the system to any kind of data sources using the same communication framework.

Reasoning on structured and coded data

A new contribution of ASTEC is that it demonstrates how it is possible to represent eligibility criteria of clinical trials using SWRL on top of a large domain ontology. Some of the criteria were directly translated into SWRL. Others require more thought, especially these which involve temporal reasoning.

In our project, time of processing is not a stringent requirement: the matching of the patients to the available clinical trials is done offline, before the MDM. The slowest step in the overall procedure is loading NCIT ontology. On a dual core machine, with 8Gb of memory, the process takes over 100 seconds and 2Gb of memory. Importing data into the ontology is nearly instantaneous: we load one patient at the time, and only the clinical trials currently active in the hospital are loaded. The next bottleneck is the conversion of the ontology and of the SWRL rules into Jess, which takes on average 10 seconds. The actual running of the engine takes less than a third of a second. Compared to X[1], we use a much smaller ontology (SNOMED CT is over a million classes, while NCIT is only 75000). Loading the background ontology is performed once.

Integration of ASTEC into the business process of MDM

We have designed ASTEC to be seamlessly integrated into the workflow of MDM. However, in this paper, since we have used a retrospective dataset, we don't provide here any evidence of the user acceptance. This is the object of a current study. Regardless, we can give some arguments in favor. As the data processing occurs before the MDM, the eligibility report is available immediately when the case is discussed by the medical MD Team. The system requires very few interactions from the users. During the MDM, the discussions of the experts are extremely short and efficient, so we don't believe that in case of error or misclassification by ASTEC, the users will have the time to modify and rerun the system on line. ASTEC is not intrusive in the decision process, and it behaves as a reminder system, giving for each patient, a short and clear argumentation in favor or against its selection into a CT.

Evaluation of the performance

The results shows that most of the patients eligible to GETUG 14 were selected by the ASTEC system (28/30 patients). Despite numerous false positives (104 patients), the ASTEC system allowed to rightly exclude 151 patients automatically. The 2 patients missed by the ASTEC system, was also missed by the MDM team.

However, we recognise some limitations. Despite considering 4 different CTs at the beginning of the study, only the results for GETUG 14 are presented here. Indeed, 0, 6 and 1 patients were eligible to GETUG 15, 16 and 17 respectively, while 30 eligible patients were eligible for GETUG 14. This led us to solely discuss ASTEC results on a single clinical trial.

Moreover, GETUG is focused on prostate cancer which is one specific domain in oncology.

The question of the scalability of our system to a broader medical domain is still open. But we can assume that the system will be robust at least for cancer domain. Firstly, because we used quite generic interoperability and reasoning methods. Secondly, because the system is based on a recognized and comprehensive terminology in this domain. And finally, and because the process of MDM is quite similar for all cancers.

Dealing with low data quality and missing data

It is worth noting that decomposing patients' conditions into a set of entities is of course challenging as many entities can be only considered at the physician's discretion. We showed in a preliminary study [9] that a CDSS as the ASTEC system must deal with a high level of missing data and unknown information for the majority of the eligibility criteria. Indeed, we demonstrate the existence of implicit information (i.e either data not mentioned into MDM reports, or other eligibility criteria than those mentioned by the protocol) used by physicians to perform the screening task. For instance, when a given condition is not present (e.g., heart condition or failure), it is usually omitted and not explicitly set as such into medical record. A physician can overcome this lack of information, but it is hardly the case when it comes to automatic systems. Moreover, we found in the preliminary study a low rate of data quality from the oncology EHR. Initially, we had assumed that multidisciplinary reports were forensic documents, containing mandatory, explicit and comprehensive information. Indeed, the critical decision of the multidisciplinary team is supposed to rely on this set of information. Actually, it turned out that multidisciplinary reports were just a short summary of the main information. They did not cover all the aspects of the patient condition, such as psychological or psychiatric conditions. We also noted that some of very important data which were supposed to be coded by the clinician in the dedicated structured fields of the MDM form, were present but in the free text fields of the reports. So, these data were unusable by the ASTEC system. For instance, in some multidisciplinary reports, TNM staging was not filled out in the dedicated field of the report and was mentioned in the free text but in an implicit way (e.g. "malign tumor of the both sides of the prostate without extension" which implicitly, stands for a T2 stage). It was unlikely for ASTEC, the multidisiplinary team or the reviewer to deduct at a glance the cancer stage and account for this information during decision making.

Such factors explain the main reasons for discrepancies between the system decision and the human decisions, especially based on false positive screened patients by the system. It is nevertheless considered as a decent approximation, one that can enable an efficient pre-selection and help physicians focus on a subset of promising patients.

To address the issue of missing data, we have developed and tested in a related work [8], an OWL model of clinical trial eligibility criteria compatible with partially-known information. In this work, we proposed an OWL design pattern for modeling the eligibility criteria based on the open world assumption. Our approach successfully distinguished clinical trials for which the patient is eligible, clinical trials for which we know that the patient is not eligible and clinical trials for which the patient may be eligible provided that further pieces of information (which we can identify) can be obtained. The OWL study was evaluated on the same clinical trial and on the same set of patients. The results were similar to the ones reported here, with 149 patients potentially eligible patients (132 in the present study). The difference of performance lies in a simpler data extraction process for the OWL model, which does not affect reasoning. Once the data are extracted from the patient's records, the determination of the patient's eligibility requires a reasoning framework capable of handling both (i) the difference of precision between the data and the criteria, and (ii) the pervasive incompleteness of data. Together, these two studies demonstrate the feasibility of such a task.

Conclusion

Clinical trials are required for the evaluation of medical treatments. Their weakness lies in the difficulty of recruiting enough patients in order to make them statistically meaningful. In this paper we have presented an approach based on OWL and SWRL that addresses the problem of recruitment of patients. The evaluation showed that it is possible to represent the great majority of criteria, and that the system detected most of the patients eligible to the trial and eliminate most of the False negative. The false positives were essentially due to missing data coming from the EHR.

Acknowledgments

The French National Agency of Research (ANR) under the TecSan program 2008 funded the ASTEC project (ASTEC n°ANR-08-003). The authors would like to especially thank Sahar Bayat, Elisabeth Le Prisé, Jean-François Laurent, Nicolas Garcelon, Renaud De Crovoisier for their valuable help.

Abstract

Randomized controlled trials generate high-quality medical evidence. However, the use of unjustified inclusion/exclusion criteria may compromise the external validity of a study. We have introduced a method to assess the population representativeness of related clinical trials using electronic health record (EHR) data. As EHR data may not perfectly represent the real-world patient population, in this work, we further validated the method and its results using the National Health and Nutrition Examination Survey (NHANES) data. We visualized and quantified the differences in the distributions of age, HbA1c, and BMI among the target population of Type 2 diabetes trials, diabetics in NHANES databases, and a convenience sample of patients enrolled in selected Type 2 diabetes trials. The results are consistent with the previous study.

Keywords:

Clinical Trial; Patient Selection; Selection Bias.

Introduction

Randomized controlled trials are the gold standard for producing high-quality medical evidence. However, they may suffer from delayed enrollment and lack of population representativeness, resulting in compromised generalizability to the real-world patients to whom the results or findings of a trial are usually applied. To assess the external validity of a trial, researchers often compared the study population of its enrolled patients and the patient population with certain medical conditions, e.g., breast cancer [1] or major depression [2]. Our previous work showed that many clinical trials, especially those on the same medical condition, use similar or identical eligibility criteria [3]. Therefore, we hypothesize that the generalizability issue might be at not only the individual trial level but also the community level of the entire clinical trial enterprise.

As a step to advance the field for generalizability assessment, we previously proposed a method to compare patient populations in electronic health records (EHRs) with aggregated clinical trial target populations that characterize the patients who can be recruited in a set of trials according to their inclusion and exclusion criteria [4]. This method also introduced *Generalizability Index for Study Traits (GIST)* for quantifying the population representativeness of clinical trials to the general patient population. This approach is advantageous over existing methods [1, 2] in that generalizability assessment can be performed proactively during design. Using this method, we found that Type 2 diabetes studies are more generalizable with respect to age than they are with respect to HbA1c. However, one of the limitations of the study is the potential bias in EHR data towards certain population subgroups [5].

The available public datasets offer great opportunity to further validate the method and the results generated from EHR data. The National Health and Nutrition Examination Survey (NHANES) is a continuous cross-sectional health survey conducted by the National Center for Health Statistics of CDC [6]. It evaluates a stratified multistage probability sample of the non-institutionalized population of the United States. The survey samples are first interviewed at home, followed by a physical and laboratory test in a mobile examination center. Its rigorous quality control standards ensure national representativeness and high-quality data collection. NHANES data have facilitated various translational bioinformatics research. Chen *et al.*, for example, have built a predictive aging model of adolescent development [7]. Bays *et al.* have analyzed connections between body mass index and metabolic diseases [8]. These promising results have propelled our use of NHANES data to support our population-based study. In this paper, we assess the collective population representativeness of multiple related Type 2 diabetes mellitus (T2DM) trials through pair-wise comparison between the patient population derived from the NHANES data, the target population derived from clinical trial summaries, and a convenience sample of study population derived from the results of selected trials in ClinicalTrials.gov. We hypothesize that NHANES data can be used to assess the population representativeness of trials and to validate the results of our previous study using EHR data [4].

Methods

Figure 1 shows the workflow of this study. We first identified frequently used quantitative eligibility features (i.e., with a permissible value range) in T2DM trials between 2003 and 2012.

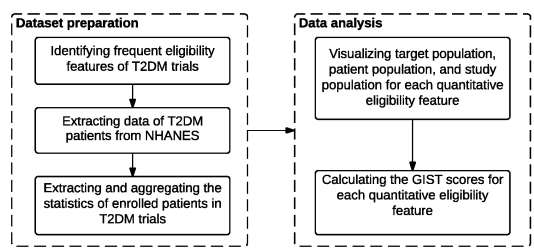

Figure 1– The workflow of the study

In the NHANES data of continuous survey years 2003 to 2012, we identified sample subjects with T2DM and extracted interview and laboratory test results relevant to this work. We

also extracted results of selected T2DM clinical trials between 2003 and 2012 from ClinicalTrials.gov and used these data to profile a convenience sample of the study population. We visualized and analyzed the differences among the T2DM patient population, the target populations of T2DM trials, and a convenience sample of study populations of enrolled patients in T2DM trials, all of which were profiled by one eligibility feature at a time. Then we calculated the GIST scores [4] for each eligibility feature.

Dataset Preparation

Processing clinical trial summaries

We have built and published a database COMPACT [9], which stores parsed eligibility criteria and trial descriptors of 162,586 clinical study summaries in ClinicalTrials.gov downloaded on March 18, 2014. All the trials were indexed by medical conditions using the API provided by ClinicalTrials.gov. From COMPACT, we retrieved 2,731 interventional studies on T2DM with a start date between 01/2003 and 12/2012. Age, HbA1c, and body mass index (BMI) were identified as three most frequently used quantitative eligibility features that appear in 2,702 (99.0%), 1,463 (53.6%), and 1,274 (46.6%) of the trials, respectively. We formed one trial set for each of the three features and included them for analyzing the distribution of trials over age, HbA1c, and BMI, respectively.

Processing NHANES data

We extracted relevant interview data and laboratory measurements for each NHANES sample during 2003 – 2012. The data elements included *SEQN* (the unique identifier of a sample), *gender*, *age*, *race/ethnicity*, *BMI*, *Glycohemoglobin (HbA1c) values*, *two-year sample weights for the interview and mobile examination portion of the study*, *two year cycle*, and interview questions "*Were you told to have diabetes by a doctor or a health professional*", "*Age when first you were told to have diabetes*", and "*Are you taking insulin?*" The laboratory methodology to measure Glycohemoglobin value of NHANES sample subjects can be found at [10].

In NHANES, we identified 3,304 diabetic sample subjects who were told to have diabetes by a doctor or a health professional and had an HbA1c measurement [11]. Since NHANES participants were not asked to report the type of diabetes (type 1 or type 2) they were diagnosed with, we employed a method used by Dodd *et al.* [11] to further exclude 222 samples with Type 1 diabetes who were (1) first diagnosed with diabetes before age 30; and (2) taking insulin. The rationale is that as one grows older, his/her lifestyle (e.g., dietary habits) will play a more important factor in developing T2DM; thus, if a person is diagnosed with diabetes at a young age and takes only insulin, it is likely that s/he is with Type 1 diabetes.

Out of the 3,082 T2DM samples, 2,695 had no missing values for age, HbA1c, and BMI. Because the number of samples with missing data (3,082 - 2,695) exceeded 10% of the total number of T2DM samples, we used two categorical variables gender and race/ethnicity that every sample of NHANES has to assess the representativeness of these 2,695 samples for all 3,082 T2DM samples. With respect to gender and race/ethnicity, we used the chi-square test to test the statistically significant differences between any pair of the following three sets of samples: (1) all 3,082 samples, (2) 2,695 samples with age, HbA1c and BMI values, and (3) 387 samples with missing values. No statistically significant pair-wise difference was found between any pair of samples (all *p-values* > 0.05). Further, we used the two-sample *t*-test to test the pair-wise differences for HbA1c, age, BMI. No statistically significant difference was found (all *p-values* > 0.05). Therefore, we concluded that the 2,695 samples that had complete age, HbA1c, and age values is a representative sample of all the T2DM samples in NHANES and we used this sample as the patient cohort of this study.

To account for complex survey design (e.g., oversampling), non-response, and post-stratification, NHANES assigned each sample subject a sample weight, which represents the number of people in the U.S. national population that a specific sample can represent. When a sample is weighted, it is representative of the U.S. civilian non-institutionalized Census population [12]. NHANES publishes survey data once every two years. In this study, we combined data of five two-year cycles from 2003 to 2012. Following the analytical guideline of NHANES [13], we used WTMEC2YR as the sample weight and calculated the ten-year sample weight WTMEC10YR (1/5 * WTMEC2YR). After taking the ten-year sample weight into account, these 2,695 samples can thus represent 15,575,484 T2DM patients in the U.S. national population. More importantly, the distribution of patients with sample weight can represent the real distribution of the U.S. national population. In this paper, all the subsequent analyses were performed after taking sample weights into account. Table 1 shows the baseline characteristics of the T2DM patient cohort of the study.

Table 1– Baseline characteristics of patient cohort

Characteristics	Number
Sample, n	2,695
Population, n	15,575,484
Age (mean ± SD)	60.6 ± 13.3
Gender, male%	48.2
Race/Ethnicity	
Mexican American, %	8.5
Other Hispanic, %	5.5
Non-Hispanic White, %	61.8
Non-Hispanic Black, %	16.0
Other races, %	8.2
HbA1c, % (mean ± SD)	7.2 ± 1.7
BMI, kg/m^2 (mean ± SD)	32.9 ± 7.6

Processing clinical trial results

To profile the study populations, we parsed the baseline characteristics of enrolled patients for the T2DM studies that published results in ClinicalTrials.gov. Out of 2,731 T2DM trials between 2003 and 2012, only 531 reported their baseline characteristics of enrolled participants in ClinicalTrials.gov. The numbers of trials that reported mean and standard deviation (SD) of age, HbA1c, and BMI of their enrolled participants are 389, 137, and 108, respectively. Since only a small portion of trials reported results in ClinicalTrials.gov, the study population included in this analysis represents merely a convenience sample of the study population. For each study, we extracted participant counts, mean and SD for age, HbA1c, and BMI. We aggregated the mean and SD for each feature using the following formulas (adapted from [14]), where T is the number of studies,

$$\boldsymbol{Weighted\_mean} = \frac{\sum_{i=1}^{T}(mean_i * number\_participants_i)}{\sum_{i=1}^{T} number\_participants_i} \quad (1)$$

$$\boldsymbol{Weighted\_SD} = \sqrt{\frac{\sum_{i=1}^{T}(SD_i^2 * (number\_participants_i - 1))}{\sum_{i=1}^{T}(number\_participants_i - 1)}} \quad (2)$$

Visualizing populations

Effective visualization of target populations, patient population, and study population over a quantitative trait allows interested viewers to easily discern the differences among them. To profile the target populations of T2DM

studies represented by a quantitative eligibility feature, we plotted the distribution of trials over a quantitative feature (i.e., age, HbA1c, and BMI). This distribution shows the number of trials that recruit patients with a certain value, which can reveal systematically excluded or overly included value ranges. The patient population of T2DM was presented by the distributions of several patients' features. The study population was similarly plotted using Gaussian distributions with weighted means and SDs of several features.

For each feature, we plotted the distributions of patient population, target population, and study population in the same figure. We employed 2nd degree polynomial local weighted regression fitting with a span of 20% to smooth the curves [15].

Quantitative metric of population representativess

To quantify the population representativeness of studies for a single quantitative feature, such as age, HbA1c, and BMI, we calculated the GIST scores [4]. GIST is the sum across all consecutive non-overlapping value intervals of the percentage of studies that recruit patients in that interval, multiplied by the percentage of patients observed in that interval:

$$GIST = \sum_{i=1}^{N} \frac{\sum_{j=1}^{T} I([i_{low}, i_{high}] \subset w_j)}{T} * \frac{\sum_{k=1}^{P} I(i_{low} \le y_k < i_{high})}{P} \quad (3)$$

where N is the number of distinct value intervals of the quantitative feature, T is the number of trials, P is the number of patients, w_i is the inclusion value interval of the quantitative feature for the j^{th} study, such that indicator I can be defined as j^{th} study interval subsumes the i^{th} interval low and high boundary values, and y_k is the observed value of the quantitative feature for the k^{th} patient such that an indicator I can be defined when k^{th} patient has a value of the quantitative feature falls within the i^{th} interval.

The GIST score ranges between 0 and 1 and characterizes the proportion of patients that would be potentially eligible across trials, with 1 being perfectly generalizable and 0 being completely not generalizable. Note that the formula for calculating the GIST score can also be applied to categorical variables, whereby the values are integers.

Results

Visualization of populations

Figure 2 shows the juxtaposition of the distributions of T2DM patients (blue solid curve), T2DM trials (green dot-and-dashed curve), and study samples enrolled in T2DM trials (red dashed curve) over age values. The x-axis represents the age values. The left y-axis represents the percentage of patients of a certain age. The right y-axis represents the percentage of trials that recruit patients of a certain age. Note that both target population (green dot-and-dashed curve) and study population (red dashed curve) use the same value ticks on the right y-axis. From the visualization, we can observe that T2DM trials recruit patients with broad age range (between 18 – 80), whereas most real-world patients are older. Comparing the target population (green dot-and-dashed curve) and study population (red dashed curve), we can see that even though T2DM studies tend to recruit patients of broad age range, most enrolled patients were between 40 to 70 years old.

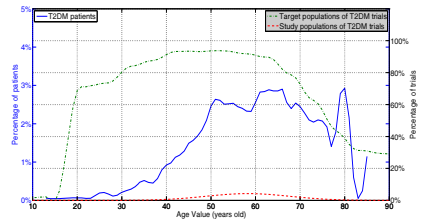

Figure 2– Target population, patient population, and study population of T2DM trials on age values

Figure 3 visualizes the comparison of these three populations over HbA1c values. Between years 2003 and 2012, targeted HbA1c values in T2DM trials are consistently higher than that of the patient population, indicating that T2DM trials tend to recruit sicker diabetic patients. This observation is consistent with the results of our previous study [4]. There is also a noticeable shift between the study population (red dashed curve) and the patient population (blue solid curve), indicating that on average patients enrolled in T2DM trials had a higher HbA1c value than the general T2DM patient population. The curves for study patients and target patients aligned well with similar curve shapes.

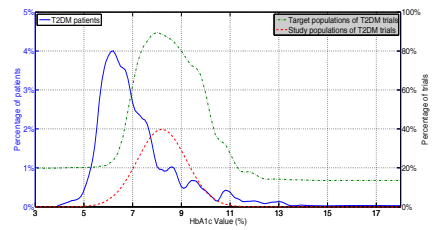

Figure 3– Target population, patient population, and study population of T2DM trials on HbA1c values

Figure 4 is the visualization for BMI. We can see that three curves aligned better than those for age and HbA1c, indicating that T2DM studies may have a better population representativeness with respect to BMI. The concentration of BMI values is accordance with real-world T2DM patients.

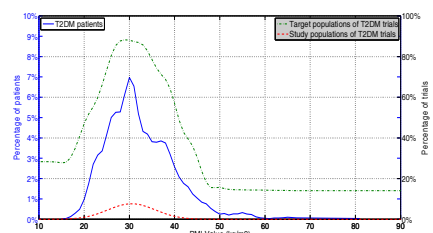

Figure 4– Target population, patient population, and study population of T2DM trials on BMI valuesComparison: study population vs. patient population

Table 2 presents the comparison between the study population (i.e., patients who were enrolled in T2DM trials) and the general patient population. One-sample *t*-test was performed to test the statistical significance of the differences between these two populations for each feature, whose mean value of the general patients was used as hypothetical mean. As shown in the table, statistically significant differences between the study population and the general patient population were observed for all three features. On average, the patients enrolled in T2DM trials are younger, with lower BMI and

higher HbA1c than the general patient population ($p < 0.0001$).

Table 2– Comparison between the convenience sample of the study population and the patient population

Feature (*mean* ± *SD*)	Study population	Patient population	Difference, mean (95% CI)	*P value*
N	198,050	15,575,484	--	--
Age	58.3 ± 9.4	60.6 ± 13.3	– 2.3 (– 2.34 to – 2.26)	< 0.0001
N	62,931	15,575,484	--	--
HbA1c	8.2 ± 1.0	7.2 ± 1.7	1.0 (0.99 to 1.01)	< 0.0001
N	70,678	15,575,484	--	--
BMI	30.5 ± 5.2	32.9 ± 7.6	– 2.4 (– 2.44 to – 2.36)	< 0.0001

GIST scores

The GIST scores were computed for age, HbA1c, and BMI for each phase using fixed-width value intervals of width 1.0, 0.5, and 1.0, respectively (Table 3). Note that large value intervals may exclude some trials; thus, we used these small interval widths to ensure that all the trials were included. To calculate the GIST score correctly, one could also use all the threshold values of a feature in all the trials to divide its value spectrum into bins of varying widths. The overall GIST scores show that T2DM trials have the best population representativeness with regard to age, followed by BMI and then HbA1c. Comparing the results across trials in different phases, we observed that the GIST of age increases from Phase I to Phase III, whereas the GIST of HbA1c decreases from Phase I to Phase III, which confirms our previous study using EHR data [4].

We have provided the interim data and results of this work as supplementary material, which can be accessed at http://is.gd/tbwzj9.

Table 3– GIST scores of age, HbA1c, and BMI for each phase

GIST	Variable		
Phase	Age	HbA1c	BMI
I	0.60 (N=368)	0.55 (N=141)	0.64 (N=204)
II	0.77 (N=517)	0.45 (N=244)	0.71 (N=194)
III	0.87 (N=766)	0.38 (N=438)	0.77 (N=356)
IV	0.80 (N=484)	0.42 (N=306)	0.69 (N=194)
All	0.77 (N=2702)	0.44 (N=1463)	0.69 (N=1274)

Discussion

In this study, we used both visualization and quantitative metric GIST to assess the population representativeness of T2DM trials to the general T2DM patient population. One interesting observation is that even though the curves of BMI (Figure 2) aligned better than those of age (Figure 4) in the visualization, the GIST score of BMI (0.69) is lower than age (0.77), showing that visualization may not be sufficient for comparing population representativeness between variables. Conversely, the GIST score may not be as intuitive as visualization for discerning systematic included or excluded value ranges.

Clinical trials may serve varying purposes. Not all clinical trials need to generalize to a broad patient population. Many trials require a "clean" and specific cohort to ensure internal validity, which is usually achieved by minimizing confounding variables with tightened eligibility criteria. Therefore, the purpose of this study is not to demonstrate the systematic bias in T2DM trials, but to uncover collective design patterns via aggregate analysis of multiple trials. We identified and visualized the significant differences among the aggregated study populations, target populations in trials that investigate the same medical condition, and patient populations that are supposed to benefit from these trials. Our method intends to quantify the differences among these three populations so that they can differentiate them for research in any disease domain and make informed decisions for future trial designs.

NHANES data vs. EHR data

Using NHANES data, we generated results that are consistent with our previous study using EHR data [4]. We further validated the effectiveness of the method for assessing the population representativeness of clinical trials. With the large amount of patient data existing in both EHRs and public databases, it is important to understand their respective strengths and weaknesses for different kinds of analyses. NHANES may be more efficient than EHRs for population-based studies. Firstly, EHRs only contain the data of patients who have paid visits to a hospital, whereas NHANES samples are not limited to patients in hospitals and can represent the U.S. national patient population. Secondly, NHANES data are well structured and readily analyzable, whereas the multi-dimensional data quality problem and largely unstructured data elements of EHRs pose significant impediments for their secondary use. Conversely, EHR data usually contain multiple readings for a variable for a patient, allowing longitudinal analysis of disease progression. Most variables in NHANES have only one reading for each sample. Meanwhile, NHANES may not provide sufficient data for assessing the population representativeness of trials on other medical conditions.

Other works for improving generalizability of trials

To improve the generalizability of clinical trials, Arterburn *et al.* proposed a population-based shared decision-making recruitment approach, which achieved a relatively high ratio of outreach-to-randomized subjects [16]. However, the selection biases with this approach may still remain. Frangakis *et al.* discussed various strategies to calibrate the treatment effects from clinical trials to target populations, including calibration of pre-treatment exclusion criteria and post-treatment measures [17]. However, pre-treatment calibration can only generalize categorical and dichotomous variables but not continuous variables such as age, HbA1c, and BMI. Post-treatment calibration can only generalize components of randomized controlled trials that are not causal effects of treatment [18]. Therefore, these methods may not fully resolve the generalizability issue. We hope that this line of research can help trial designers better balance the tradeoffs between internal validity and external validity during the design phase of a new trial, thereby improving its population representatives.

Limitations and future work

Quite a few limitations are noteworthy when interpreting this study. NHANES uses self-reported medical condition. We borrowed a method from Dodd *et al.* [11] to distinguish between Type 2 and Type 1 diabetes patients, which, in conjunction with the self-reported data, may have led to some misclassification of samples.

Even though the Food and Drug Administration Admendments Act (FDAAA) mandates the reporting of basic summary results on registered or approved product to be submitted to ClinicalTrials.gov, only about 20% of T2DM trials between 2003 and 2012 have submitted results to

ClinicalTrials.gov. Fewer than half of NIH-funded trials published their results in scientific journals within 30 months of trial completion [19]. Since trials with positive results tend to report them, the convenience sample of study populations we used in this work may not be a random sample of the enrolled patients in all the T2DM trials. Moreover, the study population plotted in Gaussian distribution may differ from the histogram of the actual patients. Recently, the US Department of Health and Human Services proposed a new regulation to require public sharing of summary data from clinical trials of the Food and Drug Administration (FDA) regulated drugs and devices regardless of their approval status for marketing [20]. As more and more studies publish their results in ClinicalTrials.gov, a uniform reporting mechanism would significantly help aggregate analysis such as the one we performed in this study. Another frequent concern is that clinical trials retrieved by ClinicalTrials.gov's API may have condition-indexing errors, though we checked a random sample of 100 T2DM trials and found that the accuracy of indexing is acceptable for this condition and this study. The accuracy of our natural language processing tool for parsing complex free-text eligibility criteria needs further improvements.

Different eligibility features may have inherent correlations. For example, impaired fasting glucose is positively correlated with age [21]. In the future, we plan to use multiple features simultaneously to assess the population representativeness of trials.

Conclusions

In this study, we identified and visualized statistically significant differences among the T2DM patient population, the target population of T2DM trials, and a convenience sample of the study population extracted from the results of selected T2DM trials in ClinicalTrials.gov. The consistent results with our previous study [4] have demonstrated the feasibility of using NHANES data to assess the population representativeness of clinical trials. We have further validated the results of our previous study using EHR data [4].

Acknowledgments

We thank Dr. Praveen Chandar for the insightful discussion on this work. This study is sponsored by the National Library of Medicine Grant R01LM009886 (PI: Weng) and the National Center for Advancing Translational Science Award UL1 TR000040 (PI: Ginsberg).

Abstract

The vision of creating accessible, reliable clinical evidence by accessing the clincial experience of hundreds of millions of patients across the globe is a reality. Observational Health Data Sciences and Informatics (OHDSI) has built on learnings from the Observational Medical Outcomes Partnership to turn methods research and insights into a suite of applications and exploration tools that move the field closer to the ultimate goal of generating evidence about all aspects of healthcare to serve the needs of patients, clinicians and all other decision-makers around the world.

Keywords:

Health Services Research; Databases; Observation.

Introduction

Observational Health Data Sciences and Informatics (OHDSI, pronounced "Odyssey") [1] is an international collaborative whose goal is to create and apply open-source data analytic solutions to a large network of health databases to improve human health and wellbeing. The OHDSI team comprises academics, industry scientists, health care providers, and regulators whose formal mission is to transform medical decision making by creating reliable scientific evidence about disease natural history, healthcare delivery, and the effects of medical interventions through large-scale analysis of observational health databases for population-level estimation and patient-level predictions [2]. Over 90 participants from around the world have joined the collaborative with a vision to access a network of one billion patients to generate evidence about all aspects of healthcare, where patients, clinicians and all other decision-makers around the world use OHDSI tools and evidence every day [3].

Methods

OHDSI grew out of the Observational Medical Outcomes Partnership (OMOP) [4], which was a public-private partnership established in the US to inform the appropriate use of observational healthcare databases for studying the effects of medical products. The five-year project developed new methods in observational research and established an observational research laboratory. At the conclusion of this five-year project, the OMOP research investigators initiated the OHDSI effort. The research laboratory moved to the Reagan-Udall Foundation for the FDA under the Innovation in Medical Evidence Development and Surveillance (IMEDS)

Table 1. Tables in the OMOP Common Data Model V5.0

Model Domain	Table Names
Standardized Clinical Data Tables	PERSON, OBSERVATION_PERIOD, SPECIMEN, DEATH, VISIT_OCCURRENCE, PROCEDURE_OCCURRENCE, DRUG_EXPOSURE, DEVICE_EXPOSURE, CONDITION_OCCURRENCE, MEASUREMENT, NOTE, OBSERVATION, FACT_RELATIONSHIP
Standardized Health System Data Tables	LOCATION, CARE_SITE, PROVIDER

Standardized Derived Elements	COHORT, COHORT_ATTRIBUTE, DRUG_ERA, DOSE_ERA, CONDITION_ERA

Program [5].

A centerpiece of the OMOP project was the development of the OMOP Common Data Model (CDM) [4] which represents healthcare data from diverse sources in a consistent and standardized way (see Table 1). This CDM is a "strong" information model, in which the encoding and relationships among concepts are explicitly and formally specified. The OHDSI team has adopted and continued maintenance of this model and its associated vocabulary services. OHDSI's overall approach is to create an open network of observational data holders, and require that they translate their data to the OMOP CDM. Each element in the participant's database must be mapped to the approved CDM vocabulary and placed in the data schema. In return, this approach creates a unique opportunity of implementing a number of existing data exploration and evidence generation tools and participating in world-wide studies because any given query can be executed at any site without modification. This enables multicenter, global analyses to be executed rapidly and efficiently using applications or programs developed at a single site.

Data are retained at the participant's site, simplifying patient and business privacy issues. The team previously found that simply merging the databases is likely to give poor answers because of heterogeneity [6]. Instead, analyses are carried out locally and the results transmitted to the coordinating center, where they can be studied on a population level and aggregated as appropriate.

OHDSI operates at several levels: infrastructure, data, methods, applications, and experiments. These levels serve both to support and inform the work of each other to ensure that the infrastructure and products support the mission. Rather than just creating a data network, OHDSI directly integrates researchers who use the network and data scientists who create the algorithms with the use cases for the data network.

The group's guiding principles are that the effort be:

1. Evidence-based, such that OHDSI's scientific research and development are driven by objective, empirical evidence to ensure accuracy and reliability;
2. Practical, going beyond methodological research, but developing applied solutions and generating clinical evidence;
3. Comprehensive, aiming to generate reliable scientific evidence for all interventions and all outcomes;
4. Transparent, such that all work products within OHDSI are Open Source and publicly available, including source code, analysis results, and other evidence generated in all our activities;
5. Inclusive, encouraging active participation from all stakeholders – patients, providers, payers, government, industry, academia – in all phases of research and development; and finally
6. Secure, protecting patient privacy and respecting data

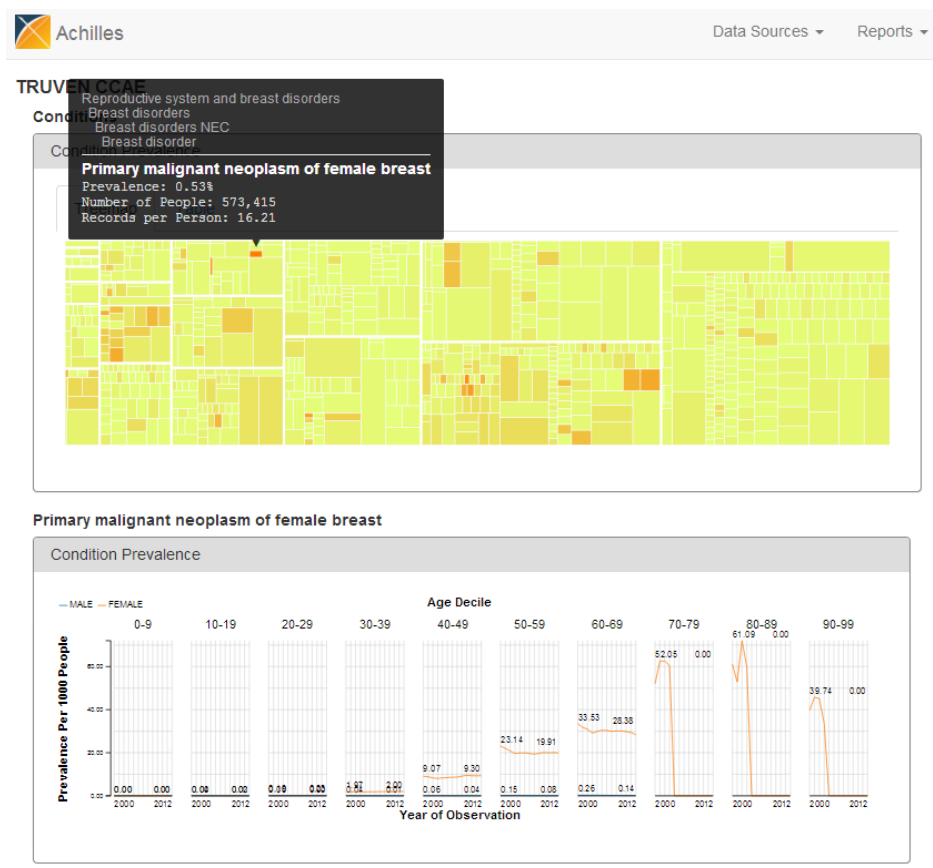

Figure 1. ACHILLES. A tree map (top half) summarizes the content of the database, where the rectangle size indicates prevalence and color indicates average number of records per patient. The bottom half reports prevalence by year, age, and sex.

holder interests at all times.

To achieve the principle of inclusivity, OHDSI is an open collaborative. Anyone who can give time, data, or funding is welcome, and participation in the operation of OHDSI is expected. Currently, participants come from around the world, including the United States, United Kingdom, Netherlands, Sweden, Italy, Korea, Taiwan, Hong Kong, and Australia.

Software Tools

OHDSI is building a suite of tools to faciliate data exploration and evidence generation. The first of these, ACHILLES (Automated Characterization of Health Information at Large-scale Longitudinal Exploration System), is a browser-based visualization tool for reviewing a clinical database based on pre-extracted summary statistics from datasets in OMOP CDM format. ACHILLES enables characterization, quality assessment, and visualization of observational data; and provides users with an interactive, exploratory framework to assess patient demographics and the prevalence of all conditions, drugs, procedures, and observations stored in the dataset. The ACHILLES application and source code is available in the public domain [6] and a demonstration is hosted on the OHDSI Web site [7].

ACHILLES has two main components. The first component is implemented as an R package and runs securely within an organization's local environment without disclosing any patient identifiable information. The R package generates summary statistics that describe the quality and content of the patient-level observational health database and provides features to perform a simple review or bulk export of the summary statistics in JSON data files. The second component of ACHILLES is implemented as an HTML5 / JavaScript website with a series of interactive reports that allow exploration and visualization of generated summary statistics. Summary statistics from multiple databases can be made available from a single installation of the ACHILLES website.

Data owners have used ACHILLES to assess the quality of their database, looking for gaps that may signify upload errors. Other investigators have used ACHILLES to do an initial assessment of whether the database is likely to hold a sufficient number of cases of interest to be worth investigating further. Figure 1 shows a typical visualization for a researcher interested in primary malignant neoplasm of the female breast. As shown, ACHILLES displays the prevalence of the condition, the depth of data on those patients, the age distribution, the sex distribution (less relevant here), and the time of observation. Other current ACHILLES views show the temporal characteristics of the data (e.g., prevalence by month), quality reports, and treemaps of subsets of data where each box's size and color represent different database metrics. Its data quality reports help the data owner curate the database and allow outsiders to review supported aspects of data quality.

Additional OHDSI tools are in development. HERMES (Health Entity Relationship and Metadata Exploration System) is a web-based vocabulary browsing tool with the ability to search for a term and explore related concepts. PLATO (Patient-Level Assessment of Treatment Outcomes) provides predictive models that assess probability of a patient experiencing any outcome following initiation of any intervention, given his or her personal medical history. For example, a patient could enter his gender, age, primary diagnosis, and medication to check the prevalence of side effects to the medication. HERACLES (Health Enterprise Resource and Care Learning Exploration System) helps the user to build and explore cohorts to assess a specific clinical population across a wide-variety of clinical dimensions, including specialized analytics for performing clinical quality metrics. And HOMER (Health Outcomes and Medical Effectiveness Research) enables risk identification and comparative effectiveness studies, with real-time exploration of the effects of medical products. HOMER supports exploratory analyses for a wide variety of dimensions that serve as evidence for or against causality, such as the

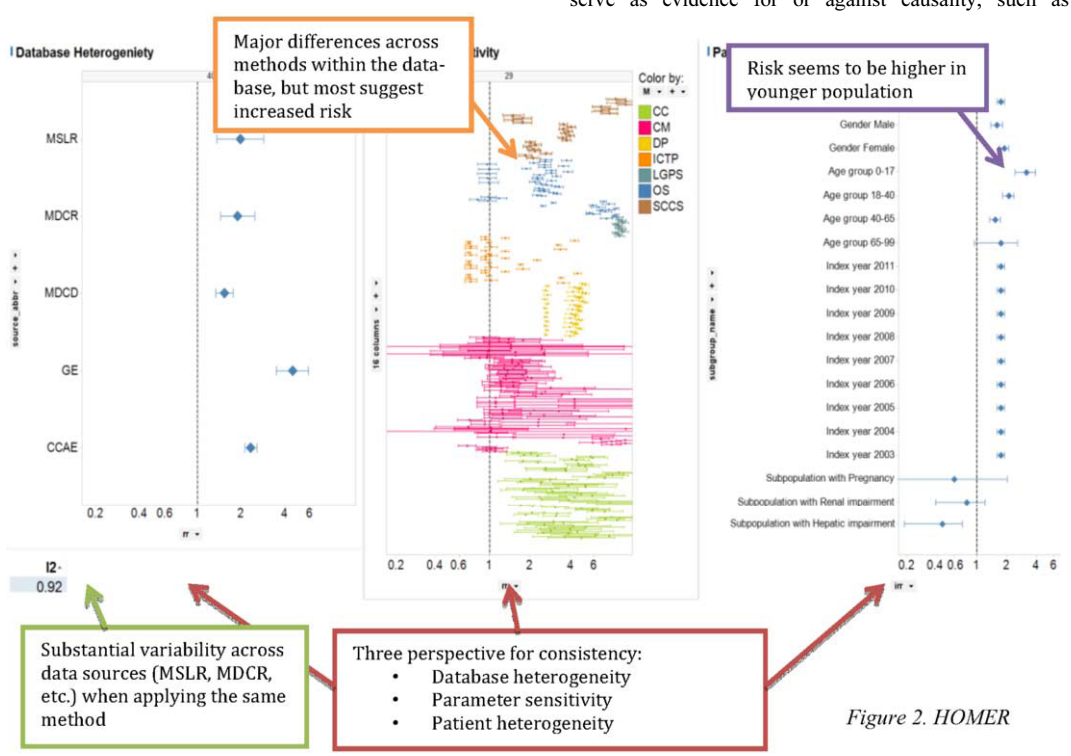

Figure 2. HOMER

consistency of findings. Consistency can be assessed across source datasets, analysis methods, or patient subpopulations. Figure 2 shows a prototype screen from HOMER, in which the relationship between a drug and adverse effect are explored across multiple dimensions.

In addition to creating user-friendly software, OHDSI also engages in the development of advanced analytic methods, including making Bayesian regression feasible over large data sets, handling sparse coding, and performing hierarchical association mining. Finally, OHDSI has been a leader in application of empircal calibration techniques to healthcare datasets to account for the biases inherent in these data sources as another contribution to the transparency and integrity of observational data research.

Research Network

The goal of the Research Network is to lower barrier to performing large-scale collaborative research using observational data and to generate high-quality evidence through peer review across study design, execution, and data analysis. Data owners make data available in return for algorithms and tools and the ability to post queries to the network. OHDSI has developed a process for the development and execution of research studies across the data network. This process includes proposal by a collaborator, review by the community, and promotion to active project. Initial proposals typically comprise a basic protocol including objective, rationale, target population, and initial source code. Once posted to the OHDSI Research Forum [8], the proposed project will be reviewed by other collaborators to determine interest level as well as to generate suggestions for modification to the design, target phenotypes, or analytic methods. Projects that generate interest from multiple sites and produce a complete protocol and cross-tested code are promoted to an Active Project. All community members are invited to run the analysis on their local dataset and return the results (de-identified, aggregate) centrally. Analyses across several sites rely on CDM standardization of various data domains to common terminologies, such as SNOMED for diagnoses, RxNorm for drug ingredients and LOINC for laboratory results. OHDSI's choice of standard terminologies does not limit who may participate because mappings and tools are supplied to translate from other terminologies. After a defined period, result submission is closed and the data are analyzed and presented back to the community. Based on these findings, publications and follow-up studies may result.

OMOP previously demonstrated that databases from different sources can give vastly different answers [9]. A blind aggregation of the results may increase variance due to heterogeneity instead of decreasing it due to sample size. Therefore, depending on the research question and the participating sites, the collected results may simply be reported without aggregation, summarized, or, if sufficient homogeneity can be demonstrated, aggregated.

Results

OHDSI held its first annual meeting at Columbia University Medical Center in New York City on 16 and 17 of October 2014. Fifty-eight participants reviewed the vision and goals giving rise to the creation of OHDSI and formed working groups to address the common data model, vocabulary, knowledge bases, estimation methods, phenotype generation, clinical characterization, and cohort definition. The outcomes of the meeting included the following:

1. Confirmation of the commitment of data custodians to participate in federated research studies;
2. Decision to open the database to queries from external researchers under a formal process; and
3. Work progress on each of the working group areas.

In preparation for the meeting, the OHDSI team surveyed current users of the OMOP data model. They found that 58 existing OMOP databases have collectively converted 682 million patient records to the OMOP CDM. This large number includes both patients and sources that are duplicated across databases and also includes databases that are not currently participating in the OHDSI Research Forum. Nevertheless, the total count demonstrates the feasibility of imposing a strong information model and executing a CDM conversion on a number of records that would represent a significant fraction of the world's population. In other words, the OHDSI vision is, in fact, feasible today. Furthermore, we estimate that the actual number of patients currently available in the OHDSI Research Forum is over 200 million.

OHDSI has just begun to distribute research queries. The first published OHDSI study used databases maintained by one site to carry out a medication-wide association study, assessing whether drugs with similar function or structure cause similar side effects [10].

Discussion and Conclusion

We envision a future where observational studies will inform clinical practice—by providing practice-based evidence—using the unprecedented amount of available patient data and the use of computerized systems to process the data [11]. Feinstein et al. initiated the idea of using data on 678 lung cancer patients as an electronic 'library of clinical experience' to obtain a personalized prognosis [12]. We believe that it now should be possible to provide not only prognosis information but also provide estimates on the comparative effectiveness as well as patient level assesment of treatment options.

We are not alone in this endeavor. For example, PCORnet [13] is designed to improve the national infrastructure for conducting clinical outcomes research. The network will enable a national capacity to conduct comparative effectiveness research efficiently and to learn from the health care experiences of millions of Americans.

OHDSI is implementing such a collaboration internationally by building on the OMOP experience for observational research. The existence of multiple very large databases that use the OMOP Common Data Model demonstrates that a worldwide conversion of clinical data from all patients is in fact feasible. Previous success in algorithm development, software distribution, and evidence generation points to potential success in the overall evidence-generating OHDSI project.

Identifying Repetitive Institutional Review Board Stipulations by Natural Language Processing and Network Analysis

Fabrício S. P. Kury, MD, James J. Cimino, MD

National Library of Medicine, US National Institutes of Health, Bethesda, Maryland, USA

Abstract

The corrections ("stipulations") to a proposed research study protocol produced by an institutional review board (IRB) can often be repetitive across many studies; however, there is no standard set of stipulations that could be used, for example, by researchers wishing to anticipate and correct problems in their research proposals prior to submitting to an IRB. The objective of the research was to *computationally identify the most repetitive types of stipulations generated in the course of IRB deliberations. The text of each stipulation was normalized using the natural language processing techniques. An undirected weighted network was constructed in which each stipulation was represented by a node, and each link, if present, had weight corresponding to the TF-IDF Cosine Similarity of the stipulations. Network analysis software was then used to identify clusters in the network representing similar stipulations. The final results were correlated with additional data to produce further insights about the IRB workflow. From a corpus of 18,582 stipulations we identified 31 types of repetitive stipulations. Those types accounted for 3,870 stipulations (20.8% of the corpus) produced for 697 (88.7%) of all protocols in 392 (also 88.7%) of all the CNS IRB meetings with stipulations entered in our data source. A notable peroportion of the corrections produced by the IRB can be considered highly repetitive. Our shareable method relied on a minimal manual analysis and provides an intuitive exploration with theoretically unbounded granularity. Finer granularity allowed for the insight that is anticipated to prevent the need for identifying the IRB panel expertise or any human supervision.*

Keywords:

Cluster Analysis; Natural Language Processing; Ethics Committees.

Background

For a majority of research proposal submissions the corrections to the text proposed by an Institutional Review Board (IRB), called "stipulations", are often stereotypical [1, 2]. Though these stipulations recur in a large number of protocols they can be categorized into a fewer common types. These repetitive problems can often be stylistic and editorial rather than regulatory [2], indicating that common problems, though undesirable, might be have an easy resolution. Automating the detection of stipulation-producing conditions in research proposals could streamline the review process. It could even be used to help researchers to correct the issues before submiting their proposals to the IRB. The existing work on identifying repetitive IRB stipulations was based on manual review [1] and thus burdensome to reproduce, limited in its breadth (total number of protocols and stipulations analysed), and low on granularity (how specific the results were). In this study we present a semi-automated and reproducible method for identifying repetitive stipulations, which allows intuitive exploration of its results, relies on minimal manual work, and does not use commercial software.

Introduction

This study sought to develop a method that identifies the most frequently occuring IRB stipulation types and is easily reproducible at other institutions using open access software. We used an approach to design a method for text clustering suitable to the stipulations' corpus.

A wealth of algorithms exist for text clustering [3]. However, they are either available as programming libraries for use in larger applications or as features of specialized commercial software that are rarely optimized for the characteristics inherent to very small texts – as are the individual IRB stipulations (which are often single sentences). Moreover, each algorithm has different tradeoffs and configurable parameters [3] that require advanced expertise. The available metrics for assessing the quality of the generated clusters is also an advanced topic. Effective visualization of the results is a task disconnected from the clustering itself.

The modeling of our text clustering task as a network cluster represented a way around the referred hindrances. The network analysis community is mature and provids a wealth of free software [4] with graphical user interfaces.Likewise, network clustering is a well-developed field of research with an array of free, and sometimes peer-reviewed, algorithms for use within the various network analysis suites. If a network could be built to truthfully represent the similarities of stipulations, its node clusters would represent the text clusters in graphical and user-friendly manner.

Method

Our methodology has five consecutive parts: A) Raw data retrieval and parsing; B) normalization of the text of the stipulation; C) construction of a network based on their similarities; D) identification of clusters in the network; and E) summarization the clusters for easier reporting. Parts A, B and C were performed by one Java program written for this study. Parts D and E were done manually using Cytoscape [7], a free network analysis software.

Raw data access and parsing

The raw data source for this study was the Combined Neurosciences (CNS) IRB database maintained by the NIH's Protocol Tracking and Monitoring System (PTMS), which was launched in 2005 but contains data dating back to 1999. As of December 15th, 2014, the PTMS database contained 786 protocols for the CNS that had been reviewed in 442 meetings of the three CNS IRB panels and with stipulations entered in the system.

In PTMS, all stipulations produced for a given protocol in a meeting are stored as a continuous narrative text. The structured text of the stipulations (each stipulation is written on a new line), enabled the use of regular expressions to parse and separate them individually. The proportion of incorrectly parsed stipulations was auite low because of their dissimilarity to all others, those would tend to not interfere with the rest of the results. The availability of separated stipulations was therefore assumed for this study.

Normalization of the stipulation text

To mitigate the inherent variability of the natural language, each stipulation was normalized into a set of non-repeating terms ("a bag of terms"). The normalization process focused on preserving the conceptual content of the stipulation subject while systematizing the ways in which the content could be verbalized by removing minor details. The repeating terms in small text strings of varying structures were not likely to represent different core concepts and therefore were considered only once.

The normalization part made principal use of the freely available Stanford Core NLP (SCNLP) library for Java [5]. In a six-step process, the normalization 1) removed personal names and dates identified by SCNLP's Named Entity Recognizer; 2) converted terms to their preferred synonyms, using a list of 9654 mappings from a previous unpublished work of our group (Table 1); 3) converted words to their lemmas as per the SCNLP's 'lemmatizer'; 4) removed 475 stop words that likely have a grammatical function; 5) applied the Porter Stemmer [6] to all terms; and 6) used the "\W" regular expression in Java to remove punctuation, tabs, special characters, etc. Table 2 provides examples of stipulations, their normalized versions, and calculated similarities.

Construction of an undirected weighted network based on the similarities among the stipulations

A network node, with a unique ID, was created for each stipulation . The nodes were numbered cardinally (1, 2, 3,…) wothout regard to the order of their creation. Each node also contained a "Stipulation property", with the original unmodified stipulation text that it represents, to allow its reading from the network analysis software. The TF-IDF Cosine Similarity algorithm [3] was then used to calculate the similarity (a number from 0 to 1) between each normalized stipulation to each one of the others. An undirected link (or "edge") was created between two similar nodes with a weight property that is a mathematical inverse of the calculated similarity ($weight = \frac{1}{similarity}$). Links with similarity lower than a predefined minimum similarity threshold (MST) were not created. Though the network clustering algorithm used in part C takes the link weight into consideration when identifying the clusters, links with similarity lower than a predefined minimum similarity threshold (MST) were not created to expedite the processing. After iterative testing the MST was set at 0.15, which, while imperceptible to human reader, significantly reduced the total number of links in the network.

Table 1 – Examples of preferred synonym mappings

Term	Preferred synonym
GUIDELINE	RULE
GUIDELINES	RULE
HEADACHE	CEPHALALGIA
VII	7
VIII	8
TOOTHS	TEETH
TOOTH	TEETH
MALIGNANCY	NEOPLASM
NEOPLASTIC	NEOPLASM
MALIGNANT	NEOPLASM

Identication of clusters in the network

The similarity-interlinked stipulation network is produced as a GraphML file by the Java program, which is then loaded into the free Cytoscape [7] software for the final task of identifying the clusters. In Cytoscape we opted to use the free plugin ClusterONE, which provides the official implementation of a peer-reviewed algorithm [8] to identify overlapping clusters in weighted networks.

We configured ClusterONE parameters so as to deem a stipulation repetitive if it appeared in more than 10% of all the 782 protocols, making our minimum cluster size to be 79. We left all other parameters at the predefined levels. We would only accept clusters with a p-value ≤ 0.05, as calculated by the Mann-Whitney U test provided by ClusterONE. As preconfigured in ClusterONE, the clusters were allowed to overlap each other.

Summarization of the clusters

As the task of manually reviewing the entire content of each cluster would be prohibitive, undermining the reason of using computational methods in first place, the summarization of each cluster also had to be carried out computationally. From the network analysis perspective this is a simple task. Since the links are weighted according to the corresponding stipulation similarity, it follows that the nodes with the highest weighted closeness centrality (WCC, Figure 2) correspond to the stipulations with closest similarity to all other stipulations in the cluster. Therefore, each cluster identified in part D was cloned as a separate network; we then used the free Cytoscape plugin CytoNCA [9] to calculate WCCs. If two clusters happened to share the same highest WCC node, they were merged using the union merge command in Cytoscape, which recognized identical nodes by their identical ID numbers preventing their duplication. From each of the final clusters, the node with the highest WCC was reported in Table 3.

[1] Numbers are approximate and Groups can overlap each other. [2] As measured by ClusterONE [8]; [3] Value of the biggest cluster before merging. 4: Names are fictitious.

Results

We parsed 18,582 stipulations from 786 protocols and 442 IRB meetings (examples in Table 2). A network with 124,219 links was generated for the minimum TF-IDF Cosine Similarity seting of 0.15. When seen in its entirety the network was cluttered and opeque, with no visual clusters. In the first execution, ClusterONE identified 36 clusters larger than 79 nodes, 29 of them with a p-value below 0.001, six below 0.05, and one above 0.05 (0.083) which was discarded. Four cluster pairs were found to share their node with highest WCC and were therefore merged (clusters 3, 14, 23 and 28 in Table 3). The *cluster quality*, as measured by ClusterONE (with the stronger connections being inside the cluster), ranged from 0.347 to 0.872. Altogether, the 31 final clusters (after merging 4 of them) contained 3,870 stipulations (20.8% of the corpus) produced for 697 (88.7%) of all protocols in 392 (also 88.7%) of all the CNS IRB meetings with stipulations entered in the PTMS.

Discussion

Modeling the problem as a network permitted instant visual assessment and exploration of the results. The visualization of the clusters in link (edge)-weighted layouts, which position each node according to its links and their weights, provides intuitive insight about the collective characteristics of the stipulatons and the existance of the cluster subgroups. Without a visual resource it is cumbersome to assess the variation among the stipulations.

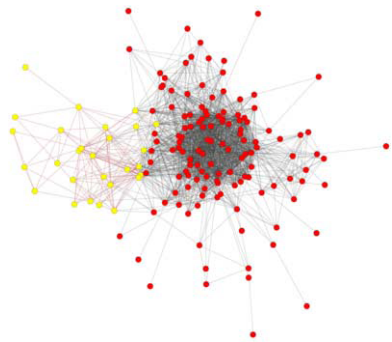
Defining 79 repetitions (over 10% of all protocols) to deem a stipulation stereotyped was a conservative approach. Reducing that parameter to 40 resulted in 96 initial clusters with p-value ≤ 0.05 (out of a total 105), however, the smaller clusters pose unnecessary separate representations of the same core term as understood by a human reader. This minimum cluster size parameter, as well as the others provided by ClusterONE, can be used for deeper investigation: for example, to subdevide an initial large cluster into smaller ones using lower minimum cluster sizes (Figure 3).

Limitations

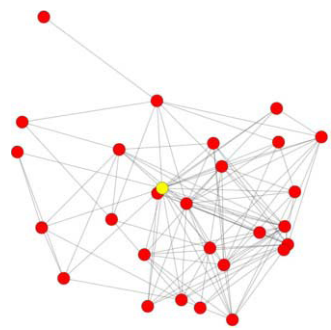
The text in Table 3 may be taken as a representation of the stipulation types, however, there may be other variations. For example, Group 5 contained stipulations stating the exact opposite of the one cited in the Table, and Group 15 included the same stipulation for other specific cohorts such as HIV-positive persons, cognitively impaired persons, persons who cannot give consent, and so on. Figure 3 provides an example of exploring the internal variability of a group. The granularity of the final results is theoretically indefinite with visual navigation, however, the realization of the presence of sub-clusters is not as easy due to their proximity. Nevertheless, the proximity of similar stipulations facilitates identification of sub-clusters by trial-and-error.

The boundaries of the clusters and sub-clusters are often not precise (compareGroups 16 with 19, and 22 with 29 in Table 3). The cluster-size, therefore, is an approximation. These imperfections were not investigated in this study beyond the cluster quality measurements provided by our chosen plugin ClusterONE.

The network analysis is only as meaningful as the links between the nodes that represent the conceptual similarities between the stipulations. While the TF-IDF Cosine Similarity algorithm provides different weights for the words according to the frequency of their occurrance the stipulation text



Group 5 with sub-cluster (in yellow) as identified by running ClusterONE again with minimum cluster size of 25.



Node with highest WCC in sub-cluster (in yellow): "Specify the risk category for minor participants."

Figure 3 – Sub-clustering Group 5.

variability was essentially lexical. More elaborate methods for quantifying the semantic similarity between pieces of text do exist [10], however, their computational efficiency is not practical to cross-compare thousands of text strings (in this study, the production of the GraphML file took the Java program about 45 minutes on a dual-core 3.33 GHz/8 GB of RAM desktop computer). Finally, the use of a preferred synonym dictionary for reducing the lexical variablity – an extremely fast implementation approach available at our laboratory – can introduce a layer of semantic matching between the words; but a more robust and appropriate method would be to use a lexical database, such as WordNet, to get a normalized common denominator calculating the word-level similarity [11].

Clinical research implications

The high incidence of stereotyped stipulations in a majority of the protocols indicates insufficiency of the review process before submition to an IRB, and the repetition types suggest that their management does not require IRB-level expertise. Our method relies on a minimal manual effort and is expected to be reusable at other institutions. Our group will be glad to share our written Java program upon request.

Clinical research informatics implications

Several of the most recurring stipulation stereotypes can be computationally identified from the research protocol text. For example, Groups 7 and 17 in Table 3 could be resolved using spellcheck. Group 13, which demands the use of standard language, could be resolved by algorithms that identify the missing expressions. Group 28 could be addressed by a software that gauges the level of vocabulary and raises an alert

if it exceeds a predefined. Others (8, 9, 11, 14, 19, 27, 29) could be addressed by more elaborate protocol authoring tools involving structured data entry of the elements causing the stipulations.

Conclusion

We have successfully identified the most repetitive IRB stipulation types at lexical level with a hybrid approach that consists of computational algorithm using a free network analysis s/w and some manual effort. Our method allows indefinite breadth of investigation and granularity (detailing) amenable to a lay user thorough intuitive visual exploration. The knowledge, and subsequent resolution of, the most common problems can help authors to avoid delays in their protocol approvals. The IRBs can improve their own efficiency by developing strategies to identify the repetitive problems in protocols before initiating a review meeting. We believe that some of the most repetitive problems we have identified warrant further interest on the usefulness of computational analysis of the research protocols.

Abstract

CAPriCORN, the Chicago Area Patient Centered Outcomes Research Network, is one of the eleven PCORI-funded Clinical Data Research Networks. A collaboration of six academic medical centers, a Chicago public hospital, two VA hospitals and a network of federally qualified health centers, CAPriCORN addresses the needs of a diverse community and overlapping populations. To capture complete medical records without compromising patient privacy and confidentiality, the network created policies and mechanisms for patient consultation, central IRB approval, de-identification, de-duplication, and integration of patient data by study cohort, randomization and sampling, re-identification for consent by providers and patients, and communication with patients to elicit patient-reported outcomes through validated instruments. The paper describes these policies and mechanisms and discusses two case studies to prove the feasibility and effectiveness of the network.

Keywords:

Patient-Centered Outcomes Research; Comparative Effectiveness Research; Electronic Health Records; Data Collection; Data Linkage; Aggregation; Data Sets; Deidentification;Re-identification; Consent.

Introduction

PCOR, CER and PCORnet

The Patient-Centered Outcomes Research Institute (PCORI) was established following the US Patient Protection and Affordable Care Act in 2010. PCORI's mission is to advance and support Patient-Centered Outcomes Research (PCOR), which "helps people and their caregivers communicate and make informed healthcare decisions, allowing their voices to be heard in assessing the value of healthcare options." [1]

In particular, PCOR:

- Encompasses comparative effectiveness research (CER) on interventions to inform decision making.
- Addresses individuals' (especially patients' and care-givers') preferences and autonomy.
- Studies a diversity of settings and populations.
- Seeks to balance stakeholders' concerns, including burden to individuals and availability of resources.

One principal action of PCORI is to support 11 Clinical Data Research Networks (CDRN) and 18 Patient-Powered Research Networks (PPRN). Both kinds of research networks are seen as infrastructure-building projects, with specific structural, process and outcome goals to prove the feasibility and usefulness of the networks. CDRNs focus on major academic medical centers: apart from demonstration of viable infrastructures, CDRNs demonstrate their value by conducting research in a number of specific conditions. Each network nominates the conditions on which it will work. However, longer term sustainability for the infrastructure can only be achieved through success in early studies, and proving to the research community that the network represents a valuable resource that is worth both exploiting and supporting through further funded studies and grant proposals. PPRNs focus on specific conditions that are of concern to patients, care providers, and patient advocacy organizations. Many networks have formed around existing formal or informal networks of support and advocacy groups.

Overarching the CDRNs and PPRNs, PCORI established a supra-network, PCORnet, that acts as a collaboration venue, clearing house, and policy-development body. Best conceived of as a network of networks, PCORnet ensures that the infrastructures created by the different CDRNs and PPRNs will remain interoperable and responsive both to researchers' needs and to the expectations of patients, care providers and advocates.

CAPriCORN

One of the CDRNs, CAPriCORN, represents an alliance of Chicago institutions collaborating in recognition of the need for pre-competitive comparative effectiveness research (CER) in their highly diverse community—diverse both in the type of

institutions involved and, importantly, in the populations they serve. CAPriCORN is not typical of CDRNs, although it shares many characteristics. Some of its unique features provide a model for collaboration in environments where, for example, patient populations at different institutions overlap, where nevertheless a full picture of each patient's health record is necessary for meaningful research results.

Data for sharing within CAPriCORN—and in the wider community at a later stage—will be in a HIPAA-compliant, de-identified format. Two working groups (WG), Informatics WG and Ethics and Regulatory WG, devised a federated data architecture, a data model with appropriate standards, and a designed data flow engineered to ensure that no protected health information (PHI) is released other than under strictly controlled conditions and, at the same time, maintaining the research value of the data that is released. De-identified data will be released on a study-by-study basis. A statistically benchmarked process is used to generate a pseudonymous identity for each patient in such a way that distributed patients' records across different providers in the network can be matched and integrated. The records are not brought together into a single central database, but are instead put in a virtual repository – by allowing distributed queries across the different systems through the validated mechanism of PopMedNet [4, 5]. Consent will be sought when access to PHI, or directly to the patient for patient-reported outcomes, is necessary.

Methods

Population

CAPriCORN comprises a network of six academic medical centers (University of Chicago, University of Illinois, Chicago, Loyola University, NorthShore University HealthSystem, Northwestern University and Rush University Health), the Alliance of Chicago's Federally Qualified Health Centers, a major public hospital, Cook County Hospital, and two Veterans Affairs hospitals, VA Edward Hines and VA Jesse Brown. Geographically, these institutions serve the greater Chicago metropolitan area and are available to a total population of approximately 9.5 million. (In addition to these "data-providing" institutions, 22 other organizations contribute research, patient advocacy, and infrastructure services to CAPriCORN. Their role is described below.)

CAPriCORN institutions together held 2,860,000 covered lives in electronic health records. A preliminary analysis of seven of the ten institutions indicated 6,923,111 patients, of whom 1,465,285 were registered with a primary care provider; however, after de-duplication, the numbers were 5,741,268 and 1,242,380 unique patients respectively. Thus some 20.6% of patients are associated with more than one institution, and even among the primary populations, there are 18% of patients with more than one PCP registration. This appears to be symptomatic of deprivation in the inner city, where economic necessity requires individuals to move opportunistically from provider to provider.

The racial breakdown of the primary population is 47.5% Caucasian, 27.9% African American and 14.9 Hispanic, with just over 9% in other categories. Of this population, 59.3% are female, 40.7% male. The mean age is 50 with a standard deviation of 17.9.

De-identification and De-duplication

While fragmented care may be suboptimal, research on comparative effectiveness of treatments requires as accurate and as complete a record of each patient's health status and episodes of illness as can be reconstructed, if meaningful and valid results are to be achieved. With multiple records for up to 20% of patients, de-duplication is strongly indicated. The means of achieving this lie in a method of de-identification.

In the US, there is currently little prospect of a single unique patient identification code. Where health information exchanges have been instituted, it is necessary to implement an "enterprise master patient index" (EMPI), but even these are rare because of a number of concerns, principally privacy and security, and economics and sustainability. Nevertheless, prior experience was sufficiently encouraging to suggest that a specific design and implementation in the Chicago area would be worthwhile. This prior knowledge and experience provided a fundamental cornerstone for the CAPriCORN network.

The de-identification algorithm comes from Kho *et al* [2, 3]. The algorithm uses a set of strictly personal identifiers, i.e., nothing that may be institution-specific, to generate up to 17 different combination strings and uses a statistically selected subset of these to construct a "hash-ID." The hashing algorithm is not reversible, but its high specificity allows patients who have multiple records to be discovered, albeit anonymously.

Organizational Design

CAPriCORN is led by a Principal Investigator at the Chicago Community Trust, an organization focused on civic leadership and philanthropy. A Steering Committee is the decision-making body, whose composition was designed around the natural concerns of a network to conduct and facilitate patient-centered outcomes and comparative effectiveness research across a number of healthcare institutions. The Steering Committee also reflects the underlying architectural design of the infrastructure and the projected governance and regulatory framework of that infrastructure.

Clinical Data Research Networks are intended to be open to external collaboration, explicitly designed to be open to patient concerns, and subject to all the normal ethical and regulatory processes that apply to human subjects and social science research. These are, respectively, reflected in the network's External Researcher Committee, Patient and Clinician Advisory Committee, and Chicago Area Institutional Review Board (CHAIRb). All these committees define processes and workflows for patient and carer consultation, the triage of internal and external research proposals, the handling of data requests, the release of data, and the consenting process prior to any re-identification of and contact with patients.

Critical to the infrastructural design are two "honest broker" roles in the network. Other than in very specific, precisely defined circumstances involving only consented patients, these organizations hold no protected personal health information (PHI) but handle the "de-identifiers", principally the hash-IDs for de-duplication, and subsequent to the definition of specific condition cohorts, a second level of pseudonymization, the cluster-IDs, which are randomly generated "per study, per hash-ID" thus avoiding any unintended crosstalk between independent studies.

The principles, explicit and implicit, that guided this design are:

- All studies, including those submitted as "proof of principle" for the network, along with new and external proposals, will be subject to triage by the Patient and Clinician Advisory and External Researcher committees, then subject to review by CHAIRb, with the ultimate decision resting with the Steering Committee.

- All PHI will be held at institutions, benefiting from all the protections (firewalls, authorizations, etc.) that each applies to its own patient data.
- The data collected will be strictly non-PHI and minimal with respect to any cohort identification needs (all that is needed, but no more).
- Identifiers will be hashed into pseudonymous "hash-IDs" for the purpose of de-duplication. Honest Broker 1 (HB1) will provide institutions with a unique "hash seed" that each will use to de-identify its own patients through hashing.
- The second honest broker, HB2, will use the hash-IDs provided by institutions to identify "duplication" and determine the set of institutions to which each patient corresponds. HB2 then generates a random identifier, the cluster-ID, for each unique patient in the given cohort. At this point, if considered necessary, the institutions themselves may be pseudonymized. (No PHI will flow to HB2.)
- Patients' records may only be linked through the hash-ID. Cohort identification for specific studies and non-PHI data requests from sites for constructing aggregate records may be conducted only by means of a distributed query mechanism (currently, PopMedNet [4, 5]) which allows inspection and vetting of queries prior to execution and results from queries to be examined prior to release.
- All studies that require access to PHI must identify a co-investigator at each site.
- Provider consent to approach patients to consent for particular studies will be requested, and subsequent patient consent will be sought, according to institutional rules and norms.
- Randomization of patients for consent will be done anonymously both in respect to patients and institutions.

As noted above, these principles are visible in the organizational structure of the network, but they are also evident in the architectural design of the infrastructure.

Network Architecture

The architecture and processes represented by the various flows in this diagram are detailed in Figure 1.

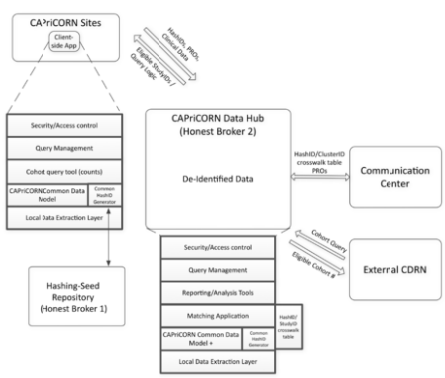

Figure 1 – A schematic diagram of the network displaying the two "honest broker" roles, the institutional repositories and the central "data hub" which hosts the matching and distributed query services.

CAPriCORN developed a data model and data standards, together with "extract-transform-load" processes for its institutional data marts. The data model is effectively based on a star schema with the concept *Encounter* at its center, so that data can be understood at a transactional level. A data dictionary was adopted showing domains and variables within them (apart from patient demographics, radiating out from encounters are diagnoses, medications, procedures, vital signs, laboratory results, and some additional local variables). Standards and terminologies indicate values in each category. The degree of privacy restriction for each variable (within-institution, within-CAPriCORN, within-PCORnet) is also indicated.

Each institution established a data mart (or other local database) which, notwithstanding the differences in platforms, precisely matches the CAPriCORN data model. Thus, although local adaptations of SQL queries will be necessary, the essential logic of queries submitted to the "data hub", i.e., the distributed query service, will remain unaltered, as required by PCORnet for its greater vision of seamless patient-centered, comparative effectiveness research.

A Communication Center is also being established to facilitate the process of re-identification of patients for provider consent to approach patients and for patient consent to participate in survey research (patient-reported outcomes, or PROs) and intervention studies. Each institution's processes are respected, and no pre-consent PHI flows through the center.

Process Description

1. HB1 hosts a stand-alone, generic hashing-seed generator application; it generates a SEED and passes it automatically to all participating institutions.
2. Each INSTITUTION uses the SEED and a set identifiers to generate a set of multiple *hashes* for each patient on record:

   [SSN, FirstName, LastName, DoB, Gender] ⊗ SEED
   → { hashes }

   from which a unique hash-ID is generated and cross-linked to the patient's MRN for internal identification.

This is per patient; […] signifies a vector of personal data.

Hash-IDs can be used within each INSTITUTION locally, if desired.

3. For each STUDY, every INSTITUTION runs the appropriate phenotyping algorithm to select its subpopulation of all unique patients who satisfy the cohort criteria. The hash-IDs along with all the hashes are returned to HB2.
4. For each study, HB2 collects all hashed data and de-duplicates, storing the result in a vector as follows:

   { (institutionID=1) : hash-ID$_1$ }
   $\Diamond_{\text{hash-ID}}$ … $\Diamond_{\text{hash-ID}}$
   { (institutionID=10) : hash-ID$_{10}$ }
   → hash-ID : institutionVector

where $\Diamond_{\text{hash-ID}}$ represent the join on hash-ID. The patient's hash-ID and institutionVector now appear thus:

	Institutions									
Disease D	AL	CC	UC	UI	LU	NS	NU	RU	VH	VJ

hash-ID										
xyz123	0	0	0	1	0	0	0	1	0	0

The patient whose hash-ID is "xyz123" was identified as having disease D and having partial records at UI and RU. We note that

(i) the hash-ID is in reality a more complex object (cf. [2]);

(ii) this may not be the complete record for this patient.

5. The five collections { hash-ID }, one for each study, are returned to all the institutions for cohort verification.

This is necessary, because, for example, a patient with an anemia record at one hospital (RU) may turn out to have a record at another hospital (UI) that does not mention anemia. Nevertheless, a complete record for that patient must include the partial records from both institutions.

6. Each institution checks the lists against its reference hash-ID list and so completes each patient's record if necessary.

For the sake of illustration, suppose now that we have found the patient above has also been seen at yet another hospital (CC) for an unrelated condition. The vector now becomes:

Disease D	AL	CC	UC	UI	LU	NS	NU	RU	VH	VJ

hash-ID										
xyz123	0	1	0	1	0	0	0	1	0	0

We can now confidently compile a complete record of the patient.

7. At this point, HB2, as an honest broker, must do two more de-identification steps:

   a. disguise the institutions

   b. replace hash-IDs with non-derived ids for the patients; these are the cluster-IDs.

For the first step, HB2 randomly assigns pseudonyms to the institutions, say:

AL	CC	UC	UI	LU	NS	NU	RU	VH	VJ
ff	*dd*	*aa*	*jj*	*bb*	*ii*	*cc*	*ee*	*hh*	*gg*

and these are then indexed as:

aa	*bb*	*cc*	*dd*	*ee*	*ff*	*gg*	*hh*	*ii*	*jj*
UC	LU	NU	CC	RU	AL	VJ	VH	NS	UI

The example patient now appears as:

Disease D	*aa*	*bb*	*cc*	*dd*	*ee*	*ff*	*gg*	*hh*	*ii*	*jj*

hash-ID										
xyz123	0	0	0	1	1	0	0	0	0	1

   c. The hash-IDs for each study cohort can now be replaced with unique cluster-IDs.

Our example patient now appears as:

Disease D	*aa*	*bb*	*cc*	*dd*	*ee*	*ff*	*gg*	*hh*	*ii*	*jj*

cluster-ID										
D-900093	0	0	0	1	1	0	0	0	0	1

Now, only possession of the table converting hash-IDs to cluster-IDs can enable anyone to re-identify the patient.

Distributed Queries

With cohort cluster-IDs collected, HB2 routes data requests through the distributed query service to the institutional data marts (IDMs). Locally, each institution will determine if the proposed query against its IDM is acceptable, allow the query to execute, and even then scrutinize the results before releasing them. Both in sending the requests and as results are received, HB2 can match cluster-IDs to hash-IDs, so that even a clinician researcher working on a project in their own specialty may be able to view expanded records of their own patients without recognizing them as their own. This provides a very high standard of de-identification.

Re-identification

Once particular studies based on entire cohorts are launched, re-identification of subsets of patients will most likely be necessary. Having received approval both from the Steering Committee (with advice from PCAC and ERC) and permission to proceed from CHAIRb, a researcher may request the Communication Center to randomly select a possibly weighted sample from across institutional or other populations for re-identification. The researcher will also be able to submit, through HB2, a data request for controls. Subject to CHAIRb's approval, institutional processes can be employed to gain provider consent and from there patient consent to participate in a study. Given the cluster-IDs of the patients in the study group, the Communication Center can alert institutions to the hash-IDs of patients to be approached for re-identification. In some cases, the Communication Center will also provide institutions with the means to collect patient-reported outcomes.

In the case of patients attending multiple institutions, which institution (or more precisely, which provider) should consent the patient for an identified study may be complex. A variety of algorithmic approaches is possible, including some that may work well but are computationally expensive. This may take the form of querying the system for the number of encounters at each institution in the last year (complex, but likely to reflect the patient's expectation) or it may suffice to look where the patient is registered for primary care (inexpensive, but may be irrelevant). The present ruling of CHAIRb only constrains the approach to be through a provider who is actually involved in the patient's care.

Results

Approximately at the halfway point in the project, achievements across a number of fronts include:

- Establishment of a sound governance structure, including a common central IRB, with data use and business associate agreements in place.
- Establishment and launch of a Patient and Clinician Advisory Committee with a clear role in the review, triage, and approval of new research proposals and a comprehensive manual for its operations.
- Approved design for the technological infrastructure, including a data model designed for ease of distributed query as well as with model evolution in mind.
- Approved processes and workflows now increasingly described and approved in protocols.

- Preliminary tests of the de-identification process and the distributed query machinery.
- Preliminary phenotyping in all five study cohorts proposed at project submission (see below). Preparatory phenotyping for a number of other studies, including incidental findings in osteoporosis, the national aspirin trial, bariatric surgery, antibiotics and childhood weight, bisphosphonates, and others.
- The de-identification and de-duplication processes in CAPriCORN are increasingly being reviewed as a model to be replicated across other CDRNs.

The internal organization of the network lends itself well to establishing CAPriCORN as a corporate entity; this would no doubt present new challenges, but is under consideration.

Discussion

The data model deployed at institutions to construct a data mart. Based on model variables, five phenotyping algorithms were devised and tested at multiple sites to identify overweight and obese patients (as required of all CDRNs); ambulatory patients suffering from asthma and in-patients with anemia (the two common disease cohorts); and patients with recurrent *Clostridium difficile* infection (RCDI) and sickle-cell disease sufferers (the two rare conditions).

In preparation for all these studies (and other anticipated future studies, including the PCORnet-inspired Aspirin trial and various collaborations with other CDRNs and PPRNs) the central IRB, CHAIRb, reviewed a Master Protocol which serves as a prefix to all specific study protocols.

Extract-Transform-Load (ETL) processes were undertaken against a number of different proprietory EHR systems. Some of these were shared publicly (e.g., through an EHR vendor's community sharing portal, thus conforming with requirements of commercial confidentiality). ETL logic was shared among all data-contributing sites to ensure compatibility.

The CAPriCORN data model is a superset of the PCORnet common data model against which external requests will be formulated. This model produces a straightforward mapping of data and requests from PCORnet to CAPriCORN. Additional data models influence the central PCORnet design, such as (Mini-)Sentinel, OMOP, i2b2 and others, and studied with a view to establishing correspondences should collaboration make a translation between CAPriCORN and another data model desirable.

Among the proposed cohort studies, the case of RCDI provides a convenient example of a hard test-case for the infrastructure. The study has not yet been completed, but based on data stored according to the data model and addressing queries to pre-existing institutional data warehouses rather than the institutional data marts, accurate cohort counts have been achieved.

Index cases of *Clostridium difficile* (CDiff) infection were identified, either by the presence of a diagnosis code or by laboratory test results. The first difficulty arises in recognizing resolved CDiff infection: how to differentiate between refractory and recurrent infection. If there is no encounter with CDiff code, laboratory test or relevant medication within eighteen days of date of diagnosis or of positive test result, the infection is assumed to have cleared. Any further infection in 18 to 56 days post index date is recorded as recurrence. Infections later than 56 days are considered new rather than recurrent.

One of the key challenges to CAPriCORN's distributed architecture will be the identification of recurrence across institutions. This challenge has not yet been attempted, but will be among the first studies that the system will address. The cohort is anticipated to be relatively small and the patient cases moving from one institution to another, while at risk of recurrence of CDiff, should be fewer still, so that discovery of such cases will represent success with truly rare events.

Conclusion

Along with ten other CDRNs, CAPriCORN is at the halfway point of its "Phase I" life span and is ready to test its systems with real use cases. The infrastructure was designed to allow for evolution in the data model and increasing complexity of queries in the future. Five submitted cohort studies are currently being processed through stages of the CAPriCORN workflow, and a number of new study proposals are being prepared.

Sustainability of the architecture will be demonstrated through a number of additional research studies that had not been considered at the proposal stage. These studies provide a valuable challenge to CAPriCORN's proposal triage, patient-centeredness, and external researcher engagement workflows.

Acknowledgements

The authors are principal informaticians on the CAPriCORN project. Acknowledgement is due to the overall project PI, Terry Mazany of the Chicago Community Trust for his leadership, and to site PIs: other than those listed as co-authors, Fred Rachman of the Alliance, Raj Shah at Rush, and Brian Schmitt at VA Hines; also Jerry Krishnan who was the original site PI at UIC. Doriane Miller and Madeleine Shalowitz direct the PCAC and have provided great clarity on patient engagement. Jonathan Tobin (NYC CDRN) has been a great supporter with ideas and proposals in the External Researcher Committee. Last but not least, John Collins and Shelly Sital at the Illinois Medical District Commission have provided a consistently high standard of project support.

Abstract

This paper presents CA²JU, a hardware/software tool that aims to help individuals with severe speech or language problems in their communication in order to promote their social and digital inclusion. CA²JU is composed of two applications: CA²JU Accelerated, which makes typing faster by suggesting potential words to the user; and CA²JU Illustrated, which automatically converts a sentence of words into a sequence of pictographic symbols, allowing a user familiar with the symbols to verify whether the written sentence is correct. We have implemented, evaluated in a controlled scenario, and deployed CA²JU in a real environment with children with cerebral palsy. In the controlled settings, the results confirm CA²JU Accelerated speed up typing by reducing the number of clicks made by users, and CA²JU Illustrated obtained high accuracy by suggesting the correct pictograms from sentences. In the real scenario, the two use cases show that the children improved their communication and linguistic abilities.

Keywords:

Natural Language Processing; AAC; Web Interface.

Introduction

Communication is a key attribute for a human being. It is fundamental for expressing necessities and desires, enabling access to information, and socialization. Because of that, when a person lacks the power of communication, it is frustrating for her and for people around her. As a consequence, many assistive technologies have been proposed to deal with these limitations such as, for instance, Augmentative and Alternative Communication (AAC) [1],[2],[3]. According to the American Speech and Hearing Association [4]: AAC is a research and educational area of clinical practice for Speech Therapists who aim to "compensate and facilitate, temporarily or permanently for the impairment and disability patterns of individuals with severe expressive and/or language comprehension disorders". AAC allows communicative interactions of individuals with speech impairment, helping them in the process of language building and school interaction, which are fundamental for learning.

Natural language processing can have an important role in AAC [5]. For instance, it can reduce the input necessary to produce a text, increasing the communication speed; it can add semantics to written text to improve its comprehension etc. For instance, [1] described an English language word prediction tool that has a virtual keyboard. Mihalcea and Leong [6] proposed a system for the construction of pictorial representations by sentences. Finally, Nakamura and Zeng [7] described a text-pictogram conversion system to assist the creation of illustrated education for patients. Unfortunately, these and other initiatives focused primarily on the English language, lack proper integration between the software and the needed hardware, and do not provide an updated and intuitive Web interface which actually aids both the patient and therapist to use the software.

This paper presents the assistive tool called CA²JU, a hardware/software solution that aims to improve the communication in Brazilian Portuguese of children with cerebral palsy. The hardware is the interface of the system with the users. It allows the children with disabilities to provide the input to the software. The software is composed of two applications: CA²JU Accelerated and CA²JU Illustrated. CA²JU Accelerated predicts the next words to be typed by the user. It uses a NLP technique known as language modeling to perform this task. We implemented two different approaches for this task: N-gram and HMM. CA²JU Illustrated allows users to select pictograms to create sentences by converting sequences of pictograms into written sentences. To perform this task, it uses different NLP techniques such as Stemming and Name Entity Recognition to clean and add semantics to the sentences.

We evaluated CA²JU in a controlled setting and the results show that: (1) CA²JU Accelerated considerably reduced the number of clicks needed to be performed by the users to write sentences, where HMM showed a superior performance over N-gram; and (2) CA²JU Illustrated demonstrated a high accuracy of suggesting the correct sequence of pictograms from known sentences. We also report two use cases showing the experience of children with cerebral palsy using CA²JU. The child who used CA²JU Accelerated presented a great improvement in her communication and linguistic abilities. Initially, the child produced meaningless texts but, after many sessions using the application, she was able to write sentences with some semantic structure. The other child, who used CA²JU Illustrated, could communicate more effectively and improved his linguistic knowledge after starting to use the application.

The remainder of this paper is organized as follows. In Section 3, we explain CA²JU in detail, showing its input devices, architecture and the techniques used to perform its tasks. In Sections 3 and 4, we present the experimental evaluation of the deployment of CA²JU Accelerated and CA²JU Illustrated, respectively. We conclude Section 5 with our final remarks.

The Tool CA²JU

As we mentioned before, CA²JU is composed of two applications: CA²JU Accelerated and CA²JU Illustrated. In this section, we describe them in more detail.

CA²JU Accelerated

CA²JU Accelerated aims to speed up text input in Brazilian Portuguese of children with cerebral palsy. It does so by using word prediction to suggest to users the next word to input [8]. Figure 1 presents the user interface of CA²JU Accelerated. It contains a virtual keyboard used to input text, and a list of suggested words for the sentence currently being typed.

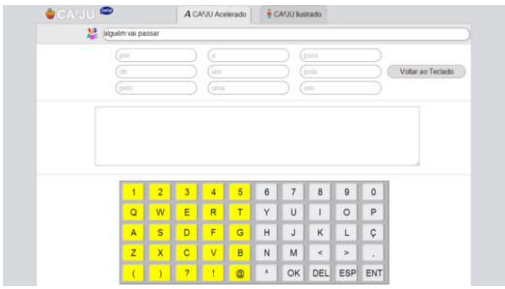

Figure 1 - Interface of CA²JU Accelerated

Language models are probabilistic models commonly used for word prediction. In this paper, we implemented two types of language models: N-gram and Hidden Markov Models (HMM).

Word prediction using N-gram

The joint probability of a given sentence *S* composed by $W_1 \ldots W_n$ words can be calculated using the chain rule:

$$P(W1, W2 \ldots Wn) = P(W1)P(W2 \mid W1) \ldots P(Wn \mid W1 \ldots Wn\text{-}1) \quad (1)$$

Since it is not computationally feasible to keep the whole previous context for all words, we limit the previous context of a word *W* to a fixed number of N-1 words. As a result:

$$P(W_n \mid W_1 \ldots W_{n-1}) \approx P(W_n \mid W_{n-N+1} \ldots W_{n-1}) \quad (2)$$

This is known as the N-gram model [9]. The assumption is that knowing the fixed previous context of *W* is enough to predict the probability of *W* (Markov assumption). For bigrams (N=2), for instance, the context is the immediately preceding word. Using bigrams, the joint probability presented in equation 1 becomes:

$$P(X_1, X_2 \ldots X_n) \approx P(X_1)P(X_2 \mid X_1) \ldots P(X_n \mid X_{n-1}) \quad (3)$$

To calculate the N-gram conditional probability, we use Maximum Likelihood Estimation (MLE). For bigrams, we have:

$$P(W_n \mid W_{n-1}) = C(W_{n-1}, W_n) / C(W_{n-1}) \quad (4)$$

where $C(W_{n-1}, W_n)$ is the number of times the words W_{n-1} and W_n appear together in the corpus, and $C(W_{n-1})$ the frequency of W_{n-1} in the corpus.

Word prediction using HMM

Another way to perform word prediction is using Hidden Markov Models [10]. In this work we have implemented the first order HMM, in which the current state depends only on the previous state and not on all previous states, so we can compare with the word prediction algorithm using N-GRAM, and then decide which algorithm to use. Hidden Markov Models is a temporal probabilistic model, where the state of the process is characterized by a single discrete random variable. In our case, the possible values of the variable representing the state are the parts of speech of the Portuguese language. The model is composed of a set of state variables:

$$X_t = \{X_1, X_2, \ldots, X_N\} \quad (5)$$

A set of evidence variables:

$$E_t = \{E_1, E_2, \ldots, E_K\} \quad (6)$$

A T_{ij} matrix of state transition probability i to state j:

$$T = [P(X_j \mid X_i) * P(X_i)] = \begin{bmatrix} T_{11} & T_{12} & \ldots & T_{1j} \\ T_{21} & T_{22} & \ldots & T_{2j} \\ \vdots & \ldots & \ldots & \ldots \\ T_{i1} & \ldots & \ldots & Ti_j \end{bmatrix} \quad (7)$$

A S_{ik} matrix of state transition probability X_i for E_k evidence variable:

$$S = [P(E_k \mid X_i) * P(X_i)] = \begin{bmatrix} S_{11} & S_{12} & \ldots & S_{1k} \\ S_{21} & S_{22} & \ldots & S_{2k} \\ \vdots & \ldots & \ldots & \ldots \\ S_{i1} & \ldots & \ldots & S_{ik} \end{bmatrix} \quad (8)$$

An array of evidence A_{1K} output variable probability belonging to the state X_i, X_i for each state:

$$A_{1k} = [P(E_1)\ P(E_2)\ \ldots\ P(E_k)] \quad (9)$$

To perform word prediction, we classify the input word according to its grammatical class, Part of Speech Tagging [9], then consult the matrix presented in equation (8) regarding the part of speech resulting, and then get the possible variables of evidence that we have.

CA²JU Illustrated

CA²JU Illustrated allows users to convert a sentence, written in Brazilian Portuguese, into an ordered pictogram representing the meaning of the sentence. Its goal is to help children with cerebral palsy in reading and writing learning, since it allows the child familiar with pictograms to verify whether the written sentence is correct by looking at its corresponding pictogram sequence. In addition, the application provides information about the words such as their part-of-speech tag, synonyms and the entity they belong to (e.g. if it is a place, an organization or a person), which can help them learn these concepts. Figure 2 presents the user interface of CA²JU Illustrated.

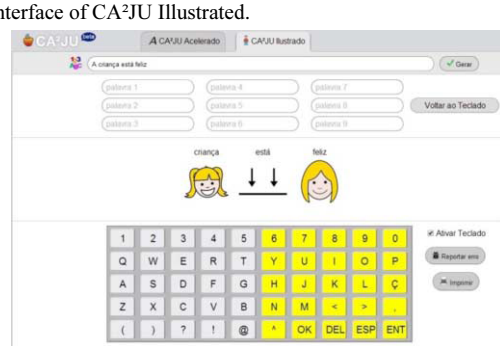

Figure 2 - CA²JU Illustrated's interface

Given a written sentence *S*, CA²JU Illustrated, first applies the RSLP Stemmer algorithm [11] in the words of *S*, so that suffixes of each word are removed. Next, it performs stopword removal, whose goal is to keep only the meaningful words in *S*. Since our original stopword removal, using a list of words, removed meaningful words, we used a Naïve Bayes classifier to identify important parts of the sentences: subject, verb and object (SVO), as well as greeting expressions, which we want to keep in the sentences.

The resulting sentences, with SVO information, are used to map to pictograms. The algorithm searches for the maximum sequence of words in each SVO portion in the sentence that

maps to a pictogram in a given mapping dataset. If no pictogram is found, it does a similar process looking at the root words, identified by the RSLP Stemmer algorithm, instead of the actual words. If still no pictogram is found, a not-found pictogram is presented.

Last, CA²JU Illustrated runs a Name Entity Recognizer (NER) [9] to identify entities such as place, organization and person. From the tagged entities, CA²JU Illustrated is now able to add entity information to their respective pictograms. For the NER detection, we used a logistic regression model, also known as maxent [12]. Maxent performs a linear combination of predictor variables (features) to perform the classification. More specifically, it calculates the probability of that an instance x is member of a class c in the following way:

$$p(c \mid x) = \frac{\exp(W_c x)}{\sum_{c' \in C} \exp(W_c x)} \quad (10)$$

Where W_c is the weight matrix of the features associated to the class c, and C is the set of classes. The instance x is classified in the class with the highest probability.

During training, the algorithm finds the model, represented by W, with the largest entropy from all models that fits the training data. To train the classifier for our task, we used the corpus of the Golden Collection of HAREM [13], which contains 225,000 words.

Buccal Input Device and Virtual Keyboard

The input module is composed of a hardware system for detecting the opening and closing of the mouth, signal conditioning, and the filtering and communication with the computer. The central element of the detector is the module composed of a magnet and a transducer that detects the magnetic field generated by the magnet into electrical signals.

The virtual keyword works in the following way. Initially, its cursor keeps switching between the left half of the virtual keyboard and the right half (see Figure 1). After receiving an input from the buccal device, the cursor vertically keeps changing from line to line on the chosen half. After a second input in the buccal device, the cursor keeps changing horizontally, going over each letter on the chosen line. Finally, the user can select a desired letter by moving the buccal device when the cursor is on the letter.

Figure 3 – Buccal Input Device

Experimental Evaluation of CA²JU Accelerated

It is difficult to assess word predictor softwares because many factors that have influence in the writing time are related to not only the software but also the user (user familiarity and level of disability) and the user environment.

Data Description

We used a generic corpus and personalized corpora for each user in Portuguese for this evaluation. The generic corpus used was Bosque Sintático [14], which has 14,844 words taken from generic news articles. The personalized corpora were obtained from social media conversations, e-mail messages, scientific works, blog posts of 8 users without disabilities. Table 1 presents information about these data.

Table 1 – Information about the personalized corpora

User	Number of words
1	15476
2	2795
3	16793
4	6084
5	33353
6	17426
7	13514
8	113211

Metrics and Test Set

To evaluate the different word prediction strategies, we use the writing speed of the users. For that, we use a metric called Keystroke (KSR) which is defined as follows:

$$\text{Ksr} = (1\text{-KP/KA})*100 \quad (11)$$

KP is the number of inputs on the sensor needed to write the sentence using word prediction, and *KA* is the number of inputs without word prediction. We also used the *HR* metric, which calculates how many times the user selected a word from the suggested list. These metrics were used to calculate how the approaches' perform over one sentence per user (see Table 2).

GRAM and HMM Results

Table 2 presents the results for the N-Gram model and Table 3 the results for the HMM model.

Table 2 - Generic=G, Personalized=P

User	Sentence Size	Ksr in G	HR in G	Ksr in P	HR in P
U1	92	28.26%	3	39.13%	6
U2	66	18.56%	4	48.49%	7
U3	90	29,17%	7	68,06%	15
U4	89	14,61%	3	32,58%	12
U5	104	32,77%	11	33,04%	12
U6	129	14,73%	8	48,84%	14
U7	99	43%	7	51.60%	11
U8	114	15.79%	5	71.28%	18

Table 3 - Generic=G, Personalized =P

Name	Sentence Size	Ksr in G	HR in G	Ksr in P	HR in P
U1	92	34.17%	4	52.28%	10
U2	66	23.29%	4	66.66%	7
U3	90	33.43%	7	70.62%	15
U4	89	19.91%	4	46.34%	15
U5	104	37.58%	12	64.56%	16
U6	129	16,14%	8	54,91%	13
U7	99	48.38%	9	71.75%	14
U8	114	27.81%	8	71.92%	18

The results show that both word prediction models, N-gram and HMM, reduce the number of clicks for all users. In addition, the personalized corpora using HMM outperformed

N-gram in all cases. Another interesting result is that the size of the corpus not necessarily implies the reduction of clicks. For instance, user 5 has a worse result than user 7 but the corpus of user 5 (33353 words) is much bigger than user 7 (13514 words).

Use case of a teenager with cerebral palsy

We now show a successful use case of CA²JU Illustrated with a user with severe quadriplegic mixed cerebral palsy who we in this section call user M. After 74 sessions performed by the Speech and Hearing Department at Federal University of Sergipe, user M presented a great improvement in her writing abilities as we describe next.

In each session, the speech and language therapist worked with user M using CA²JU Illustrated along with linguistic activities. Before using CA²JU Illustrated, user M could not write due to her motor conditions. The first words produced by user M were meaningless, as one can read from the therapist report: "[...] we tested the virtual keyboard and user M wrote disconnected letters and then we asked whether she was writing something or just playing with the keyboard. User M smiled, looking excited and delighted with the possibility of handling the computer by herself "(12 ° Excerpt care; 13.08.12).

After understanding the operation of the system, user M wrote a single word when she wanted to convey some information and as she got more familiar with the system, she started to be able to tell stories using disconnected words, which were understandable for those who were mediating the story creation. Here is what the therapist reported from a story written by user M that she could understand: "[...] The story was that on holiday somebody had traveled to Los Angeles to play football. He had gone with his girlfriend who was a cheerleader. His team whose name was "ESFLAISSDL" had won "ERREST". It was interesting to note that she deleted letters a few times while writing these strange names to convince us that they actually existed "(Excerpt from 32 ° session; 19.11.12).

After a few more sessions, M. felt the need to better structure her writing in order to allow a more effective communication, not only with people close to her, but also to any other person. This is the therapist's repost regarding that: "[…] we realized a progress, a change in the writing of user M, since in previous sessions, user M had never worried about placing the pronoun + verb + noun to build a complete sentence" (Excerpt the 48th session; 11.04.13).

Experimental Evaluation of CA²JU Illustrated

Testing Scenarios

We evaluated CA²JU Illustrated with 10 users without disabilities as follows. First, the users were trained with respect to the pictograms by showing them some pictograms in sentences and their respective meanings. We then converted 10 sentences into sequences of pictograms, hiding the word associated with each pictogram. These sequences of pictograms were presented to the users, asking them to write associated sentences. Finally, we measured the similarity between the correct sentences and the written sentences by the users using the metric presented in Section 4.3.

Dataset and Metrics

The pictogram dataset used in the experiments contains 13,013 colored pictograms from CATEDU [15].

The metric used was the Levenshtein distance [16], which calculates the similarity between two sentences based on the number of character operations (i.e. insertions, deletions or substitutions) needed to change one word into the other. The Levenshtein distance is calculated by the following formula:

$$lev_{a,b}(|a|,|b|) = \begin{cases} \max(|a|,|b|) & , \min(|a|,|b|) = 0 \\ \min \begin{cases} lev_{a,b}(i-1,j)+1 \\ lev_{a,b}(i,j-1)+1 \\ lev_{a,b}(i-1,j-1)+1_{(a_i \neq b_j)} \end{cases} & , otherwise \end{cases} \quad (12)$$

Results

Tables 4 and 5 show the results for the 10 users and the 10 sentences.

Table 4 –Results from sentence 1 to 5

Users	Sent.1	Sent.2	Sent.3	Sent.4	Sent.5
User1	84.31	66.67%	100.0%	75.00%	62.22%
User2	56,00	100,0%	95,65%	83,33%	100,0%
User3	67,92	83,33%	35,00%	71,21%	100,0%
User4	30,00	100,0%	20,00%	20,41%	83,78%
User5	50,00	45,83%	73,91%	46,29%	54,34%
User6	40,00	62,50%	95,65%	65,71%	59,45%
User7	60,00	100,0%	61,76%	86,53%	89,18%
User8	72,00	100,0%	95,65%	42,26%	100,0%
User9	16,00	100,0%	41,66%	56,34%	100,0%
User10	34,00	100,0%	50,00%	25,49%	100,0%
Avg.	42,68	85,83	66,93	57,26	84,90

Table 5 - Results from sentence 6 to 10

Users	Sent.6	Sent.7	Sent.8	Sent.9	Sent.10
User1	81,48	58.82%	76.47%	62.90%	75.00%
User2	95,45	61,76%	82,97%	62,29%	75,00%
User3	98,18	58,82%	75,00%	64,70%	75,00%
User4	89,74	17,65%	72,09%	61,01%	100,0%
User5	41,66	23,52%	64,28%	57,62%	20,00%
User6	80,55	17,64%	54,76%	57,62%	40,00%
User7	94,44	52,94%	100,0%	59,32%	75,00%
User8	98,18	61,76%	95,23%	34,92%	75,00%
User9	62,04	61,76%	88,09%	66,10%	35,48%
User10	75,00	20,58%	100,0%	50,00%	100,0%
Avg.	81,67	43,53	80,89	57,65	67,05

The numbers show that the similarity between the sentences created by the users was fairly similar to the correct ones. For instance, only 2 out 10 users had an average similarity lower than 0.5. These results confirm that CA²JU Illustrated is really able to present the meaning of sentences in sequences of pictograms. Another observation is that for certain sentences the similarity among users varies a lot. This can indicate the users might have different interpretations of the pictograms, and they might need to be disambiguated in some way.

Use case of a teenager with cerebral palsy

User G is a 12-year-old male teenager, diagnosed with severe quadriplegic mixed cerebral palsy. He does not speak, neither studies at a special school. He has weekly speech and language therapy sessions where one of the goals is to teach him how to use CA²JU Illustrated. During the sessions where we used the software, user G understood well its functionalities. He interacted with CA²JU Illustrated by kicking a sensor device (see Figure 4). Using this input device, user G is able to select pictograms to form sentences.

Figure 4 – User G using the device.

The use of CA²JU Illustrated has positively contributed to his communication, improving his linguistic structure. We plan to allow him to use CA²JU Illustrated in other environments such as his home and school.

Conclusion

We presented in this paper CA²JU, our AAC tool composed of CA²JU Accelerated, which helps users with disabilities to type text by suggesting the next word, and CA²JU Illustrated, which helps users to compose sentences by using pictograms.

We evaluated both applications in controlled scenarios, as well as in real ones, with children with cerebral palsy. For CA²JU Accelerated, the results showed word prediction reduced the number of clicks needed to create a text, and its use by a teenager with disabilities helped improve his linguistic skills and communication. The results of CA²JU Illustrated confirm that it creates meaningful sequences of pictograms and also helped a teenager with cerebral palsy to improve his communication.

Generation of Natural-Language Textual Summaries from Longitudinal Clinical Records

Ayelet Goldstein[a], Yuval Shahar[a]

[a] Medical Informatics Research Center, Department of Information Systems Engineering, Ben Gurion University of the Negev, Beer Sheva, Israel

Abstract

Physicians are required to interpret, abstract and present in free-text large amounts of clinical data in their daily tasks. This is especially true for chronic-disease domains, but holds also in other clinical domains. We have recently developed a prototype system, CliniText, which, given a time-oriented clinical database, and appropriate formal abstraction and summarization knowledge, combines the computational mechanisms of knowledge-based temporal data abstraction, textual summarization, abduction, and natural-language generation techniques, to generate an intelligent textual summary of longitudinal clinical data. We demonstrate our methodology, and the feasibility of providing a free-text summary of longitudinal electronic patient records, by generating summaries in two very different domains – Diabetes Management and Cardiothoracic surgery. In particular, we explain the process of generating a discharge summary of a patient who had undergone a Coronary Artery Bypass Graft operation, and a brief summary of the treatment of a diabetes patient for five years.

Keywords:

Summarization; Natural Language Generation; Temporal Abstraction; Knowledge Representation.

Introduction

Increasingly, large amounts of clinical data accumulate during the process of managing patients, in particular, chronic patients. To make diagnostic and therapeutic decisions regarding an individual patient, physicians increasingly need support to assist them in quickly comprehending the longitudinal clinical course of that patient, preferably a free-text summary of the quality that would be produced by a knowledgeable clinician. A high level of summarization, however, requires more than just enumerating the diagnoses made, the procedures performed, the medications administered, and the results of the laboratory tests taken. An intelligent analysis requires also an explicit representation and application to the data of relevant clinical knowledge.

Visualization is an effective approach to facilitate analysis and presentation of high volume data, specifically when dealing with huge amounts of data [2]. However, other findings showed that graphical representation is not always more effective than other methods, and in the medical domain, clinical decision-making was not necessarily improved by the use of a graphical display. For example, studies have shown that a graphical representation is not always more effective than other methods [3], and that in the case of large and dense graphs, common when high level complex decision making is required, graphical representation has marked disadvantages [4]. Other studies have demonstrated that graph interpretation requires complex cognitive processes [5, 6] and that errors can be made even when interpreting simple graphs [7, 8]. More recent work [9] compared the interpretation of business process descriptions presented in a graphical notation and in an alternative textual notation. Their work has demonstrated an increased understanding of the process when the textual model was read by many different users, while the graphical representation showed an increased understanding only in trained readers. A study in the medical domain [10] has shown that when dealing with large volumes of complex clinical data, a textual presentation might even be advantageous over a graphical one, for the purpose of certain clinical tasks.

The *Natural Language Generation* (NLG) task deals with the generation of natural language from a machine-language form input [13]. Although the NLG task has been implemented in different domains [14], in most of the implemented systems the data are relatively well-defined, not requiring advanced data analysis techniques. Furthermore, in the case of the summary of small data sets, only brief summaries are produced, which significantly reduces the complexity of many NLG tasks. In the medical domain, existing NLG systems are far from optimal [14]. A more recent NLG system [15], which focuses on decision support, also performs temporal data abstraction; however, the abstraction process is relatively simple, and does not consider different contexts when determining the importance of an event. In addition, it considers only short and pre-defined periods of data. Dealing with different periods of time, especially longer periods, as is common in chronic-disease patients, requires additional temporal-information handling techniques.

Our objective is to provide an intelligent verbal (free-text) summary of electronic patient records. These records include time-stamped data that have accumulated during an extended time period, such as during hospitalization, or over years of medical care. Such summaries might help care providers in their daily tasks, and support several decision-making processes.

In a preliminary study [1], we had proposed an architecture that supports a process of transforming longitudinal data into an intelligent, concise, text-based summary. In the current study, we have implemented the proposed architecture as a prototype system, the **CliniText** system. In this paper, we describe the inner workings of the CliniText system, using detailed examples of how each module contributes to the process of automatically transforming time-based data into a free-text summary. To be concrete, we will focus on the conversion of a typical case in the electronic cardiothoracic surgery MIMIC-II public database, into a free-text discharge summary, and on the generation of a summary of the management of a diabetes patient, given his five year electronic record in a collaborating health maintenance organization (HMO).

The input to the CliniText system includes longitudinal patient data and domain-specific knowledge. The output of the system

is a condensed textual summary of the patient's data. We opted to use only numeric or structured input data, because that is the input type usable by the temporal-abstraction method that we use to interpret the data. Including textual segments would require methods such as natural language processing, to first analyze and understand the text. Furthermore, the accuracy of such methods is far from 100%, but the requirement for highly accurate output is of major importance in the medical domain.

Methods

Our input data arrives from a time-oriented clinical database. The required medical knowledge is specified through a graphical knowledge specification tool called Gesher [16] using a Temporal Abstraction Knowledge (TAK) schema we developed. We define both *declarative* (e.g. What is mild-anemia in a pregnant women) and *procedural* (e.g. How to manage the patient, by administering two drugs in parallel) knowledge, necessary in the abstraction process. The knowledge is also exploited in other modules of the system.

We implemented the CliniText system using a framework composed of several modules, each performing a specific task. The architecture of the system, composed of six main modules, is displayed in Figure 1.

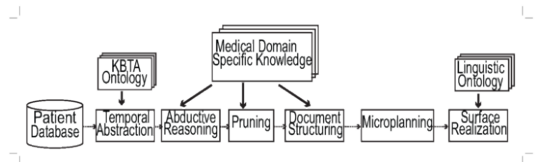

Figure 1. The architecture of the Clinitext System. Knowledge is used by the temporal abstraction module to abstract the data. Additional knowledge is used in further modules to perform abduction, pruning and document structuring of the data.. Dashed horizontal arrows = control/data flow; Bold vertical arrows = knowledge flow

The flow of the data between the components defines the workflow of the process; longitudinal raw data coming from the time-oriented database is abstracted by the *Temporal Abstraction* module, adding abstract data to the original raw data. Additional data is inferred through abduction in the *Abductive Reasoning* module. Raw, abstract and abducted data are then pruned in the *Pruning* module, responsible for selecting the important and domain-relevant data, leaving only the information that will appear in the final text. The *Document Structuring* module structures these data, determining the order they should appear in the final text. The *Microplanning* component groups and prepares the structured data to the expected format by the *Surface Realization* module, which finally realizes the data into the final text.

We shall now describe each component and its role in the process, using two example patient records: one who had undergone a coronary artery bypass graft operation, and one who had been followed for five years due to diabetes.

Temporal Abstraction (TA)

The TA step is responsible for the performance of the abstraction of time-oriented data. In the implementation of this module, we used a variation of the IDAN temporal-abstraction mediator [17], which implements Shahar's *Knowledge-Based Temporal-Abstraction* (KBTA) method [11]. Our input to the TA module, is time-stamped raw concepts (e.g., red blood-cell [RBC] values).

Abductive Reasoning

Not all important concepts, such as events or actions performed, can always be found in the input data. However, in some cases, these events can be inferred by a process of *abduction* from the existing data, with a high probability, albeit not necessarily with complete certainty. For example, knowing that a Swan-Ganz catheter (SG) is used to measure the pulmonary artery systolic/diastolic pressure (PAP) concept, even though the event of inserting a SG (SG-in) does not appear in the database we can hypothesize that the event SG-in occurred through an instance of the PAP concept in the database.

We can say that knowing that concept C_1 *enables* the existence of concept C_2, within a certain time, Δt, allows, given the existence of C_2 in the database, with a timestamp t_2, the abduction of C_1 with a timestamp between t_2-Δt and t_2, as shown in Figure 3. In general, of course, the abduction process involves uncertainty. Formally, assuming for simplicity only one enabled or associated item per concept, we compute ahead of time, for every *i*, $P(C_i[t_2-\Delta t_i] \mid C_2[t_2])$: The probability of each concept C_i, given the concept C_2, t_2 (timestamp of C_2), $Prior_i$ (a-priori probability of each related concept C_i), $P(C_2[t_0+\Delta t_i] \mid C_i[t_0])$ (the probability of C_2, given C_i) and Δt_i (the [past] interval of time during which C_i can hold, given C_2. For simplification, we consider only a uniform probability measure). The computation is then a simple temporal-extension of Bayesian diagnostic problem solving [18].

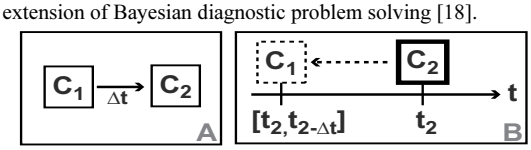

Figure 2. An abduction example. A: The knowledge: concept C1 is followed by concept C2 within a period of Δt. B: The abduction process: Concept C2 at t2 allows the abduction of concept C1 with a timestamp between t2 and t2-Δt

From a knowledge representation point of view, the abduction knowledge typically links declarative data items (e.g., measurements) in the patient's record, to procedural data that enabled the data's existence, although other combinations are possible. An example of linking two instances of procedural data is the abduction from the event "syringe-insertion," of the event "skin-sterilization" 5 to 10 seconds before; an example of abducting a declarative datum from a procedural one is that administration of antibiotics in certain contexts suggests the existence or the suspicion of infection. The relationship between the concepts can be either causal (A causes B) or associative (A typically occurs before B).

To perform abduction, we need to explicitly represent abduction knowledge in the KB. For example, we need to specify beforehand in the procedural knowledge for each event (e.g. SG-in) what are the declarative concepts (e.g. PAP) that it enables or is associated with, and what is the probability/strength of this relation (e.g., are there other events that could also generate this declarative concept?). For example, the event SG-in (whose prior probability is quite low) enables PAP with P(PAP|SG-in) = 0.95. Furthermore, in the ICU, it is the *only* method used to measure PAP. Thus, regardless of the low prior probability and the association strength, in the ICU context, P(SG-in|PAP) = 1.

In our case, we enable the inference of the existence of a procedural action (e.g. SG-in) by the existence of a declarative concept (e.g. PAP). Since we deal with the medical domain, we abduct only concepts that have a probability that is close to certainty, to avoid as much as possible the generation of

incorrect summaries. We denote events abducted from declarative concepts as *inferred interventions*.

Table 1 shows several interventions, inferred through abduction, for a cardiothoracic surgery record.

Table 1. Declarative concepts used to generate "inferred interventions". An intervention can have modifiers (e.g. "inserted" or "removed"), according to the value of the raw concept from which it was deducted (e.g., certain PAP values indicate non-measurement)

Raw concept(s)	Inferred inter-ventions	# instances
[PAP S/D]	SG catheter	1
[CVP], [A.BP]	Arterial Line	3
[Airway Size], [ETTMark]	Artificially breathing	1

Pruning

After enriching our original data with abstractions and inferred interventions, we need to select what information is important and what should be removed to avoid overloading the user.

We prune the data by using general heuristics and several "independent" parameters (e.g., text length, detail level, profiles, time-period, etc). We use *pruning-heuristics*, which define which data should be pruned, and *maintaining heuristics*, defining which data instances should be maintained (and which override the pruning-heuristics).

The current maintaining heuristics include: (1) data instances that must be described; these are determined according to the domain, although certain events appear in every domain, such as death of the patient; and (2) maintaining extreme raw data values. In this case, even though they have an abstract value, we might want to maintain the raw data also.

Document Structuring

After considering which data will appear in the final text, we define how these data will be presented. In the *Document Structuring* (DS) module it is decided how much information will be expressed in each phrase, in which order the facts will appear, how they will be organized into paragraphs, etc. The structure of the final text varies according to the output format expected as well as the domain.

We use two approaches for the DS: a *top-bottom* approach, which defines the main structure of the final text (e.g. division of paragraphs), and a *bottom-up* approach, which groups and combines events until all the events are linked together, by using appropriate discourse relations.

The output of the DS module resembles a tree. We prepare ahead of time, for each domain, a "stub" of the tree which includes the main textual segments in that domain, in a top-bottom approach. We build up from the pruned data a set of intermediate nodes that we try to link to the most appropriate node in the pre-prepared stub, in a bottom-up fashion. We call the leaves of the tree Document-Messages and the inner-nodes of the tree Document-Blocks. The tree has some parts that are more structured, part of the "stub" pre-defined, and others that are more flexible, with their structure affected and defined by the patient's data. An example of the trees used in both, the cardiac and diabetes, domains can be seen in Figure 3.

Document-blocks can be rigid or flexible. For example, in the cardiac domain, the Document-blocks: "*Admission Details*", "*Operation Admission*", "I*CUOutDischarge*", and "*Discharge Details*" have a rigid structure, which was mostly defined previously, while the blocks "*Operation Procedure Routine*" and "*Operation Recovery*" are more flexible and their context will be determined and modeled based on the patient's actual instances of data associated with them. *Document-Messages* can be generic, such as in the case of Drug-Message, Intervention-Message, or Data-Message, or specific, such as Admission-Message, PrevDiseases-Message, and ICUAdmission-Message.

Structured-blocks will be populated with the specific Document-Messages associated with it. In the cardiac domain for example, the structured section "Admission Details" will be populated with Document-Messages: Admission-Message and PrevDiseases-Message. Each specific Document-Message has specific data associated with it. Less-structured blocks may contain further Document-Blocks as well as generic Document-Messages. The creation of further Document-Blocks is affected by contexts that the data may generate. For example, the less-structured Document-block OperationRoutine will have further Document-Block children generated by the contexts associated with a specific operation event. Note that in general, the TA process applied by the KBTA method in the first step already generates (in addition to the temporal abstractions) all domain-specific contexts as well.

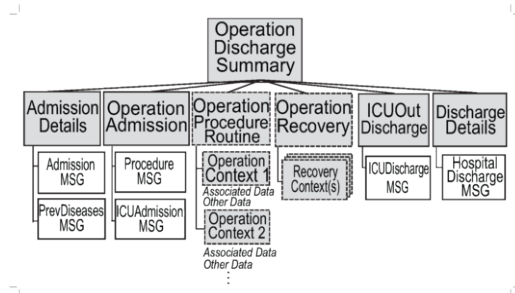

Figure 3. The document structuring tree in the case of the cardiothoracic surgery domain. The Document Structuring module structures the final text into a tree. The tree defines how the data will be presented – the order, the paragraphs division and also the relation between events. (Gray rectangles are Document-Block objects, white rectangles are Document-Message objects. Document-Blocks can contain one or more Document-Messages or Document-Blocks.) Dashed-lined blocks represent flexible segments whose structure is defined by the data. Non-dashed blocks represent rigid segments of the text, whose structure was pre-defined

The structure of the Document Structure tree establishes the structure of an operation discharge summary for any given patient that has gone through an operation. To produce a Discharge Summary specific for a given patient, we need to populate the tree with the patient's data. After populating the tree, by traversing the tree in a Depth First Search, we generate the order of the events in the final text.

Microplanning

In the *Microplanning* step, we (1) define the words and syntax structures that are used by the final text generator, (2) perform aggregation of the data, and (3) generate referring expressions.

In the aggregation process, we define how much information will be expressed in each sentence. In the aggregation process, the semantic order has preference over the chronological order that was kept until now. Taking into consideration semantic considerations, we group together messages according to their type (drug, intervention or data message types).

In the case of drug messages, for example, we group together different (drugs) with the same value. For example, instead of:

"drug X was started, drug Y was started and drug Z was stopped" we will have: “drug X and Y were started and drug Z was stopped". Note that messages are grouped only if they occur within the same context, although not necessarily during the same time.

The exact format of the Microplanning output depends on the expected format of the step following it, Surface Realization.

Surface Realization

Surface Realization is the module responsible for generating the final text. Consequently, this step is language dependent, and observes the grammar rules of the language chosen. We opted to implement the Surface realization module using the existent Java module “SimpleNLG” [19].

The realization of the text is done per section. Sections were defined within the tree structure, during the DS step. When the tree is flattened, the sections are kept and the flattened list of messages is divided into these sections. Each section is realized separately and in the same order it appears in the flattened list. One section might have sub-sections (generated by contexts). For example, the OperationRoutine section has two contexts: “Early-postCABG day” and “Late-postCABG day”. Each context (or sub-section) is also realized separately.

Each section has a relationType (defined in the DS step) defining how messages within the section are related. For example the "sequence" relation defines that they should be realized one after the other, while the “causal” relation defines a cause-effect relationship between the messages.

Preliminary Evaluation

In the cardiothoracic surgery domain, we used data from the Multiparameter Intelligent Monitoring in Intensive Care II database (MIMIC-II) [20]. There are two types of data in the MIMIC-II database: clinical data (numeric and textual) and bedside monitor waveforms. We used only the first type, and mainly numeric data. Textual data were used only to compare our generated text to the original discharge summary. We focused on data of patients in the cardiac domain, more specifically on patients that went through a CABG procedure.

Our current evaluation was purely technical, judging the feasibility of the overall process, and comparing the generated text to the MIMIC texts, without involving any users yet.

The diabetes dataset, provided as part of collaboration with an Israeli health-maintenance organization, contains data that were collected each month from 2002 to 2007. The dataset contains six measurements, including hemoglobin A1c, blood glucose level, and cholesterol values, and the medications the patients purchased, including oral hypoglycemic medications, cholesterol reducing statins, and beta blockers, with a mean of 39.5 records per patient. In this dataset, there was no corresponding human text to compare our summary to; nevertheless, the generated text allows one to judge the general quality of the text (readability, soundness, etc.).

Results

Table 2 compares the generated text summary for the cardiothoracic example record with the original human-generated discharge summary found in the public database we used. Part of the original summary could not be reproduced, since there was no data in the database that would support it. Presumably, such parts were written using some external data source, or perhaps textual progress notes.

Table 2. A comparison between the human- and CliniText-generated text, in the cardiothoracic surgery domain. Striked-through text between brackets [text] indicates text parts that cannot be generated, i.e., without supporting electronic data. Bold text on the right (left) column indicates data that were not explicitly mentioned in the other column, although they could have been

The human discharge summary	**The CliniText discharge summary**
(1) “On **3285-5-17**, the patient was brought to the Operating Room for a redo coronary artery bypass grafting [~~times two and aortic valve replacement.~~] (2) The patient [~~tolerated the procedure well and~~] was transported intubated to the PACU **in stable condition** on a Levophed drip, Milrinone drip, and a Propofol drip. The patient had atrial wires and a chest tube. (3) On postoperative day #1, the patient was continued on his Levophed drip and Milrinone drip over night. The patient was extubated over night and was on a nasal cannula of 4 Lungs: **oxygen saturation 95% on room air**. The patient's **vital signs were otherwise stable**. (4) The patient had a post-operative hematocrit of 26.8; otherwise laboratory values were all within normal limits. [~~The patient was encouraged to be out of bed.~~] Drips were weaned. [~~The patient was started on his Plavix.~~] (5) On postoperative day #2, the patient was off all drips, [~~was started on Aspirin 325 per day and Captopril 6.25 t.i.d.~~] […] (6) The patient was transferred to the floor .	*(1) “On the 15/05/2005 Mr.97, a married, 82 years old patient, was admitted to the hospital. The patient's previous history includes peripheral_vascular disease(s). (2) On the 17/05/2005 the patient went through a "CABG" operation and was admitted to the ICU. (3) In the first hours following the CABG procedure, propofol, levophed and milrinone were started.* ***Swan-ganz catheter, arterial line, chest tube, atrial wires and vent wires were inserted,*** *artificially breathing was started,* ***heart rhythm was Paced.*** *The patient's hematocrit,* ***arterial bp and spo2 were Low,*** *temperature was Afebrile and his urine source was through an external catheter. (4) Later on, propofol was stopped. O2 delivery device was Nasal Cannula, heart rhythm was Normal sinus* ***and blood transfusion was given.*** *The patient's O2 Flow State* ***was 3*** *then 4 ; hematocrit* ***and urine output*** *were Low. (5) On post-oper day #1, the patient's* ***Arterial BP State remained Low*** *and Hematocrit State remained Low ;* ***o2 flow was 2****. Levophed and milrinone were stopped. […] (6) The patient was discharged from ICU on 21/05/2005. The patient was discharged from hospital on 23/05/2005.”*

Below we bring the text generated from the longitudinal example record in the diabetes domain (this particular database did not include human-generated text for comparison):

“Mr.1111 is a male diabetes patient in the age group: 75-84. He was monitored and treated in our clinic between Aug-2002 to Jan-2004. His Creatinine_State and Albumin-State level were normal from Jun-2002 to Jan-2004. To decrease the bloodPressure the patient received calcium channel blockers, beta blocking agents, ace inhibitors and thiazides. Due to infection, the patient received sulfonamides. To decrease the glucose the patient received metformin. Glucose decreased from Jun-2002 to Jan-2004 from grade_3 to grade_2...”.

Judging by examples we have gone through, the overall process is quite feasible and shows definite promise, but we have learned from our current preliminary experiments that much additional domain knowledge needs to be added.

Discussion

In the cardiothoracic surgery domain, it can be noted that in the CliniText summary text, there are data items that do not appear in the original text. If some of these data are redundant,

we could prune them by defining additional heuristics in the pruning step, for example.

Another interesting point to be observed is that in the original text the levels of abstraction varies as compared to the levels of abstraction that appear in the CliniText summary, in which we always strive to have a uniformly high level of abstraction (e.g. "hematocrit = 22.3" vs. "hematocrit state = Low"). Allowing the user to interactively navigate into the raw concepts that the abstraction was abstracted from can provide them with lower levels of abstraction when required. We are currently adding this capability.

Note that the original text, produced by humans, may contain wrong information. In our example (Table 2), it is stated in paragraph #6 that the patient was discharged from the ICU, and in paragraph #7 the error is corrected by saying that the patient was actually kept in the ICU due to bed availability. Such errors cannot occur in the CliniText summary, if the data are correct. On the other hand, when there are erroneous data, we cannot avoid generating an incorrect text. An additional layer of data validity checks could be added to the process to clean the data before the text starts to be generated.

One of the advantages of having a discharge summary text being produced automatically is that the output format is structured and does not depend on subjective factors (e.g. how tired is the physician writing it, or how many discharge summaries she already wrote). Furthermore, the information to be included or omitted has been defined by objective consistent criteria, resulting in an objective data-and-knowledge-based summary. Finally, adding several surface realization modules might enable the future generation of multi-lingual summaries of the same record.

The knowledge acquisition step when applying the system to a new medical domain is an essential step of the process. Although the representation of the knowledge in our knowledge-representation language allows reuse and easy update of the knowledge, and is supported by a previously-evaluated graphical medical knowledge-engineering tool [16], it still requires a collaboration between a medical expert, who provides the medical knowledge, and a knowledge engineer who converts the knowledge into knowledge instances.

The main purpose of building the described prototype was to demonstrate the feasibility of creating a system that can generate a complex knowledge-based textual summary of arbitrarily long time-oriented clinical data, in different domains. We showed that it is possible to produce a readable textual summary, and include the main events and data, using domain knowledge. We intend to evaluate the CliniText system regarding the quality of the generated text and functionality of the summary for relevant pre-defined tasks.

We described a new generalized architecture for generation of free text summaries of longitudinal clinical data. In our system, the input data are allowed to be (1) heterogeneous, which makes the NLG task significantly more complex, (2) of high density, which means that the summaries will not be brief, and (3) longitudinal, with unlimited duration. Unlike the approach we took, most existing approaches are not based on the use of complex knowledge specific to the application domain, and thus cannot automatically create meaningful domain-specific interpretations. Furthermore, these systems cannot decide what data or interpretations are potentially redundant by using a robust domain-specific knowledge base and a formal interpretation theory. Moreover, existing systems do not have the capability for interactive exploration of the resulting text summaries at various domain-specific, semantically meaningful levels of abstraction, a capability for which our system provides the infrastructure.

Conclusion

An architecture such as implemented in the CliniText system can be used to summarize longitudinal clinical data using rich domain knowledge. Further evaluation is needed to assess the quality and functionality of the generated text.

Abstract

Knowledge of the left ventricular ejection fraction is critical for the optimal care of patients with heart failure. When a document contains multiple ejection fraction assessments, accurate classification of their contextual use is necessary to filter out historical findings or recommendations and prioritize the assessments for selection of document level ejection fraction information. We present a natural language processing system that classifies the contextual use of both quantitative and qualitative left ventricular ejection fraction assessments in clinical narrative documents. We created support vector machine classifiers with a variety of features extracted from the target assessment, associated concepts, and document section information. The experimental results showed that our classifiers achieved good performance, reaching 95.6% F_1-measure for quantitative assessments and 94.2% F_1-measure for qualitative assessments in a five-fold cross- validation evaluation.

Introduction

Ejection fraction is a measure of the percentage of the blood in a heart ventricle that is expelled during contraction. Knowledge of the left ventricular ejection fraction (LVEF) is critical for the optimal care of patients with heart failure. Multiple life-prolonging treatments for patients with heart failure (HF) have been demonstrated in randomized trials that enrolled patients with an LVEF below 40%. The LVEF is needed to determine if patients will benefit from treatment and ensure that these treatments are prescribed to the appropriate patients.

The U.S. Veterans Healthcare Administration (VHA) Consortium for Healthcare Informatics Research (CHIR) Translational Use-Case Project for Ejection Fraction (TUCP-EF), and the Automated Data Acquisition for Heart Failure (ADAHF) research project aimed at the automated extraction of LVEF mentions, LVSF (left ventricular systolic function) mentions, and their associated quantitative and qualitative assessments, as described in the following examples:

- LVEF mentions (e.g., “left ventricular ejection fraction”, “VISUAL ESTIMATE OF LVEF”, “EF”)
- LVEF quantitative values (e.g., “~0.60-0.65”, “0.45”, “50%”)
- LVEF or LVSF qualitative assessments (e.g., “NORMAL”, “mildly decreased”, “SEVERE”)
- LVSF mentions (e.g., “Global left ventricular systolic function”, “systolic dysfunction”, “LVSF”)

When determining the current and most reliable LVEF assessment in a clinical note, identifying the contextual use of these assessments is important. For example, those that are mentioned as recommendations or historical values can be ignored or used for historical reference for longitudinal evaluation, and knowing whether an assessment was a summary, interpretation or a measurement can be used to prioritize the values used for document-level LVEF assessment. For this study, we focused on classification of the contextual use of LVEF quantitative and qualitative assessments into five different categories: summary, interpretation, technical measurement, recommendation, or past finding.

To our knowledge, this is the first attempt at LVEF assessment contextual use classification in HF, however several studies have focused on classification of similar specialized purpose, such as tumor status [1], lung cancer stages [2], and medication prescription status classification [3]. More for local context recognition and analysis, several Natural Language Processing (NLP) systems have been developed that focused on the negation or other assertions of medical concepts. For negation classification, rule-based systems like Negfinder [4] and NegEx [5] have been introduced. They used regular expressions with trigger terms to determine whether a medical term was negated. In BioNLP-2009 [6] and CoNLL-2010 [7-8] Shared Tasks, detecting negations (and their scope) in the natural language text was the focus. Kilicoglu and Bergler [9] compiled negation cues from the corpus and detected the negation using dependency-based heuristics. Morante et al. [10] implemented two stages of negation scope detection: sentence- level classification and phrase level with memory-based learning.

Assertion classification was the focus of the 2010 i2b2 NLP challenge [11]. The defined task consisted in choosing the status of medical problems by assigning one of the six categories: present, absent, hypothetical, possible, conditional, or not associated with the patient. Several studies then used this challenge data and showed that machine learning approaches [12-14] performed better than handcrafted rule-based systems.

In the following sections, we will describe the methods we used for context classification and present our experimental results with feature contribution analysis.

Materials and Methods

We approached the contextual use classification task as a supervised learning problem. The classifier is given a LVEF assessment as input and must assign one of the five context categories as output. We created Support Vector Machine (SVM) classifiers with a variety of lexical features extracted from the target assessment, associated concepts, and section titles.

The TUCP-EF corpus of clinical notes used for this task consists of echocardiography reports, radiology reports, and other note types in the VHA developed using the Text Integration Utility (TIU) software [15]. These clinical notes were manually annotated for LVEF and LVSF mentions and assessments along with the contextual use of these assessments. We defined each category of contextual use, as explained below:

Contextual Use of Assessments

Summary

Any assessment is appearing in the summary of important findings in the study. Summary is the short and concise briefing of the study, as the contrast to the usually detailed and lengthy interpretation. Examples:

- FINAL IMPRESSION: "Normal" LV function
- EF "55-65%".

Interpretation

Any assessment generated based on a clinician's synthesis of the echocardiography machine metrics and reading of the ultrasound images using expert clinical judgment. This assessment usually appears in the body of the echo report as detailed findings or impressions. Examples:

- Systolic function is "normal" with estimated ejection fraction "60%".
- LVEF appears "mildly reduced" ("35-40%").

Technical Measurement

Any metrics that appear to be taken directly from the echocardiography machine readings. This indicates that the assessment is calculated using various algorithms from the technician's measurement. Examples:

- Ejection fraction is calculated at "42%".
- LVEF (Teichholz): "33%"

Recommendation

Any assessment generated as part of decision support messages or reminders. This is not an assessment associated with the actual patient, but rather serves as a recommendation or instructional guidelines. Examples:

- Please contact primary care provider should patient's ejection fraction fall under "40%".
- If "severe" systolic dysfunction is observed in studies with limited visual, please repeat the study within - two days.

Past Finding

Any assessment from a previous echocardiography study. This reflects the patient's past LVEF assessments and is not the value estimated from the current study. Examples:

- No significant change from a previous study ("50-55%").
- Compared to the last echo,the systolic function has reduced from "normal" to mildly decreased.

Data Description

The TUCP-EF corpus includes 3,060 clinical notes from three different components of the VistA electronic health record files [15]: echocardiography laboratory reports (1140 reports, from 16 VHA medical centers sampled at random), the radiology package (720 reports, from 5 medical centers sampled at random), and TIU (1200 reports, from 17 sites sampled at random). Among these 3,060 reports, 1,465 reports contained at least one of our concepts of interest (i.e., LVEF or LVSF mentions or assessments) and were selected for this project. 2,185 quantitative assessments and 1,278 qualitative assessments were manually annotated. The distributions of contextual use categories are displayed in Table 1. No qualitative assessment was annotated as technical measurement, recommendation or past finding.

Table 1 – Distribution of contextual use categories

	Quantitative		Qualitative	
Contextual use	**Count**	**%**	**Count**	**%**
Summary	944	43.2	811	63.5
Interpretation	927	42.4	467	36.5
Tech. measurement	296	13.6	0	0.0
Recommendations	10	0.5	0	0.0
Past finding	8	0.4	0	0.0
All	2,185	100.0	1,278	100.0

Two of the contextual use categories (Summary and Interpretation) accounted for nearly 85% of the quantitative assessment instances in the data set, while the other three classes were relatively infrequent.

For qualitative assessments, a heart failure expert identified terms used to describe the left ventricular function and provided quantitative EF ranges to correspond to each term, as shown in Table 2. To enhance the consistency of assessments, we normalized and grouped each qualitative assessment into six ranges (<30%, 25-35%, 30-40%, 35%-45%, 40-50%, and >50%) and used a list of assessment terms for this purpose. This numerical range was assigned when the assessment contained one of the assessment terms.

Table 2 – Qualitative assessment ranges and terms

Range	Terms
<30%	Severe
25-35%	moderate to severe
30-40%	Moderate
35%-45%	mild to moderate
40-50%	Mild
>50%	normal, borderline low, lower limits of normal, hyperdynamic, preserved

We also normalized each quantitative value with the same ranges. To assess the consistency of assessments, we compared each pair of assessments in a document with the normalized ranges. 73 clinical notes (about 5% of the corpus) contained assessment pairs that did not agree with each other (i.e., their ranges were different), even when not considering the pairs with overlapping ranges (e.g., one assessment with 25-35% and the other with 30-40%.)

Contextual use classification is crucial to determine which assessment to use to determine the document-level LVEF, especially when multiple assessments have different ranges. When selecting the document-level LVEF, recommendations, and past findings were excluded, and the following order was used to prioritize the assessments:

summary (quantitative) > summary (qualitative) > interpretation (quantitative) > technical measurement (quantitative) > interpretation (qualitative)

In the next section, we describe how the feature vectors were extracted from clinical notes and which feature set was utilized for contextual use classification.

Methods

We built a NLP information extraction application with two pre-processing components and SVM classifiers, as depicted in Figure 1. Pre-processing includes a tokenizer and a section detector.

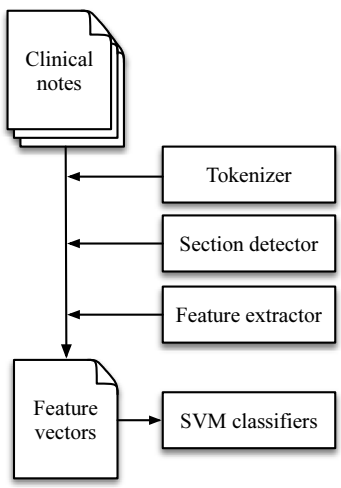

Figure 1 – Application architecture for feature extraction and classification of contextual use

The tokenizer is based on regular expressions and splits the text in groups of alphanumerical characters separated by white space characters. For clinical note section detection, we randomly selected 150 documents (about 10% of the corpus) and compiled the list of section headers related with the concepts of interest. A phrase was detected as a section header when it contained the following keywords: *impression*, *summary*, *findings*, *conclusion*, *assessment*, *interpretation*, *results*, and *note*.

Machine Learning Classification Features

Features extracted from pre-processors are listed below:

- Lexical: A bag-of-words representation of lexical features included the assessment term itself, uni-grams and bi-gams of five words preceding it, and five words following it.
- Concept position: We created two binary features to represent whether the occurrence of the assessment was the only one in the document, and whether any preceding assessment existed before the target assessment in the document. We also defined a feature representing the assessment location normalized by the document length.
- Related concept: We created features for mentions related to the target assessment. We captured the nearest LVEF or LVSF mentions. The mention term itself, uni-gram and bi-gams of five words preceding it, and five words following it were used for this set of features. We also computed the distance by counting the words between the target assessment and the nearest mention.
- Section: We detected the phrases containing the section header keywords listed above. Titles of the nearest section, the nearest previous section, and the nearest following section were used as section features.

Contextual Use Classification

We trained two multi-class SVM classifiers, one for quantitative assessments, and the other for qualitative assessments, both using the LIBLINEAR software [16]. The quantitative assessment classifier assigned one of the five contextual use categories: summary, interpretation, technical measurement, recommendations, and past finding. Due to the absence of annotations in all five categories, the qualitative assessment classifier only made a binary decision between summary and interpretation categories.

Experimental Results

Feature Contribution

For training and then testing our approach, we performed a five-fold cross validation with the TUCP-EF corpus to measure the contribution of each of the four subsets of features explained above. Table 3 shows the cross- validation results when cumulatively adding each set of features.

Like other previous contextual classification tasks (e.g., negation detection and assertion classification), using only lexical features provided a good baseline for quantitative assessments classification. However, the lexical features were less helpful for qualitative assessment classification. Surprisingly, using only section features allowed for an F_1-measure of 94% with qualitative assessments. It showed that global features such as section titles could be more beneficial than the local lexical features for qualitative assessments when there are not many distinguishable cue words in the context window surrounding the assessment mention.

Table 3 – Feature contribution: F_1-measure (%)

Features	Quantitative	Qualitative
1. Lexical	90.3	78.3
2. Concept position	57.2	77.2
3. Related concept	78.2	80.2
4. Section	80.9	94.0
1 + 2	91.9	85.9
1 + 2 + 3	91.6	86.9
All (1 + 2 + 3 + 4)	**95.6**	**94.2**

Using concept position features for qualitative assessments performed better than for quantitative assessment. Most summary assessments were mentioned later in the document than other assessments. The features extracted from the nearest LVEF or LVSF mentions were used to mitigate the

limited window size of lexical features. These related concept features helped more than lexical features for qualitative assessments and gave about 2% higher F_1-measures. Combining features, especially with section features, allowed for substantially better performance than with models trained with only individual sets of features. Using a chi-squared test to measure statistical significance, the performance of the full feature system (All, 1 + 2 + 3 + 4) was significantly better than the systems with other feature combinations ($p < 0.001$), but not significantly better than the system using only section for qualitative assessments ($p = 0.801$).

Classification Results

As seen in Table 4, the classification of summary, interpretation, and technical measurement quantitative assessments showed good performance with over 95% F_1-measures. The recommendation category benefitted the most from lexical features with 90% F_1-measure even with few instances (only ten examples). However, the classifier performed very poorly with past finding assessment. No past finding assessment was correctly classified with highly unbalanced class probabilities, indicating that there is ample room for improvement for this category.

Overall, our classifiers achieved good performance, reaching 95.6% F_1-measure for quantitative assessments and 94.2% F_1-measure for qualitative assessments in a five-fold cross-validation evaluation.

Table 4 – Classification results (%): recall (R), precision (P), and F_1-measure (F)

	Quantitative			Qualitative		
Contextual use	**R**	**P**	**F**	**R**	**P**	**F**
Summary	95.9	96.1	96.0	95.7	95.2	95.5
Interpretation	95.8	94.7	95.2	91.7	92.4	92.0
Tech. measurement	97.0	97.3	97.1			
Recommendations	90.0	90.0	90.0			
Past finding	0.0	0.0	0.0			
All	**95.6**	**95.6**	**95.6**	**94.2**	**94.2**	**94.2**

Table 5 displays counts of true positives (bolded), false positives, and false negatives of each category in a confusion matrix. Even though detecting sections played an important role in both quantitative and qualitative assessment classification, some summary assessments under the section titles that were not captured by our section detector were misclassified as interpretation assessments. Summary quantitative assessments were often misclassified as interpretation assessments with 39 false negatives and 32 false positives.

*Table 5 – Confusion matrix [True positives are **bolded**]*

	Classified as				
Contextual use	**Summ**	**Inte**	**Tech**	**Reco**	**Past**
Quantitative					
Summary	**905**	39	0	0	0
Interpretation	32	**888**	7	0	0
Tech. measurement	0	8	**287**	1	0
Recommendations	0	0	1	**9**	0
Past finding	5	3	0	0	**0**
Qualitative					
Summary	**776**	35			
Interpretation	39	**428**			

We observed that many technical measurement assessments were preceded by a colon mark (':') in the corpus. When there is no punctuation between a LVEF and a quantitative assessment, for example in “EF 57%”, the assessment was misclassified as an interpretation assessment. Several past finding assessments were misclassified as summary or interpretation assessments. Future improvement possibilities to reduce these errors include defining features capturing date expressions near the quantitative assessment for this past finding category.

Conclusion

This study demonstrated that the local context of quantitative and qualitative LVEF assessments could be successfully classified using multi-class SVM classifiers. We showed that our application performed well for both quantitative and qualitative assessments with various local and global features. We observed that lexical features and section information features contributed the most to this good performance.

Abstract

In this study we have developed a rule-based natural language processing (NLP) system to identify patients with family history of pancreatic cancer. The algorithm was developed in a Unstructured Information Management Architecture (UIMA) framework and consisted of section segmentation, relation discovery, and negation detection. The system was evaluated on data from two institutions. The family history identification precision was consistent across the institutions shifting from 88.9% on Indiana University (IU) dataset to 87.8% on Mayo Clinic dataset. Customizing the algorithm on the the Mayo Clinic data, increased its precision to 88.1%. The family member relation discovery achieved precision, recall, and F-measure of 75.3%, 91.6% and 82.6% respectively. Negation detection resulted in precision of 99.1%. The results show that rule-based NLP approaches for specific information extraction tasks are portable across institutions; however customization of the algorithm on the new dataset improves its performance.

Keywords:

Natural language processing, Unstructured Information Management Architecture, Family History, Pancreatic cancer.

Introduction

There has been a slow annual increase in the incidence of pancreatic cancer between 2000-2009 worldwide, in contrast to the decrease for most other major cancers. Pancreatic cancer is one of the deadliest cancers, with approximately 73% death rate among patients within the first year of their diagnosis [1]. It is estimated that 46,420 (23,530 men and 22,890 women) will be diagnosed with, and 39,590 (20,170 men and 19,420 women) will die of, cancer of the pancreas in 2014. Pancreatic cancer has several risk factors such as obesity, smoking, and alcohol intake, but its exact causes are not yet known. Screening the general population for early identification of pancreatic cancer is infeasible, and there is no reliable test for its early detection. Screening high-risk populations might be effective in reducing mortality. It is estimated that 10% of pancreatic cancers have a familial basis [2]. One first-degree relative (parents, siblings or children) with pancreatic cancer increases the risk 7-9 fold, and three or more first-degree relatives with pancreatic cancer increase the risk 17-32-fold [3]. Risk is also increased if a first-degree relative diagnosed with pancreatic cancer before age 50 [4].

Another group of patients that are at risk of having pancreatic cancer is patients with pancreatic cysts [5]. In our previous work, we developed natural language processing (NLP) techniques to identify patients with pancreatic cysts from clinical notes [6-8]. In this study, we are focusing on identifying patients with family history of pancreatic cancer using a rule-based algorithm.

Much of the information in clinical notes is in free text format, making it a challenge for secondary use of clinical data. Information extraction (IE) attempts to structure and encode the information buried in free text clinical notes. Statistical machine learning and rule-based approaches have been used in the development of IE techniques. Machine learning approaches require annotated training examples and lack portability. Rule-based approaches on the other hand perform very well when a task involves a specific subdomain or a limited number of named entities [9]. Although, rule-based approaches are cumbersome to implement, they have been widely used in clinical NLP. In this study, we have developed a rule-based method to identify patients with family history of pancreatic cancer and assessed the generalizability of our algorithm on a different institutions than it was originally developed.

Related Work

Family history identification consists of various steps, including section segmentation, relation discovery between family members and diagnosis, and negation detection. Automatic identification of section headers in clinical notes is an important preprocessing step in the family history extraction. Argumentative zoning is a closely related task that attempts to classify each sentence of a scientific article into one of seven sections of “background”, “other” (other researchers’ work), “own” (author’s work), “aim”, “textual” (textual organization of the paper), “contrast” (work weaknesses of others) and “basis” (authors’ work based on the work of others) [10]. Sequential tagging approaches such as Naïve Bayes (NB) and maximum entropy (MaxEnt) models have been used in solving this problem. MaxEnt model of Merity et al., achieved 96.88% F-Score [11]. Another closely related task is the classification of sentences, in abstracts of scientific articles, into separate sections such as introduction, methods, results, and conclusion. Machine learning algorithms such as SVM, Hidden Markov Models (HMM), and Conditional Random Fields (CRF) have achieved accuracies ranging from 90-94.3% [12-14].

In clinical domains, researchers have developed an algorithm called SecTag that uses a combination of NLP techniques, and rules-based and Naïve Bayesian scoring methods to identify section headers [15]. Section header terminology in this work was developed using the Quick Medical Reference (QMR) knowledge base, Logical Observation Identifiers Names and

Codes (LOINC), and various other resources with data models similar to UMLS [16]. Similar to argumentative zoning, sequential tagging algorithms have also been used in clinical section segmentation. Li et al. used HMM to label sections in clinical notes to one of 15 possible known section types achieving per section accuracy of 93% and per-note accuracy of 70% [17]. Tepper et al. used two methods: A one-step approach that segmented and classified sections in one step, and a two-step approach that used two different models for section segmentation and classification. In the one-step approach, they used the MaxEnt sequential tagging model to identify if a line was in the beginning, inside, or outside (BIO) of a section category. In the two-step approach, they used again MaxEnt sequential tagging to first label each line with BIO tags, and then used a separate classification algorithm to label each section with appropriate section categories. The two-step approach outperformed the one-step approach with precision, recall, F-measure of 90.0-97, 90.4-96.7, 89-96.8 (%) respectively, on three different datasets [18].

Once a family history section is identified and sentences within this section are parsed, the next step is to associate the diagnosis with the correct family members. Both rule-based and dependency parsers have been used to associate family members with diagnoses concepts. Goryachev et al. developed a rule-based algorithm using tokens such as “comma”, “and”, “dot”, “patient has”, “patient had” to assign diagnosis concepts to family members [19]. Their method achieved higher precision and recall in comparison to a dependency parser based algorithm used in another study [20].

Nearly half of the sentences related to family history were negated. Negation detection has been an inevitable step in processing clinical notes that has attracted much attention [21]. NegEx is one of the most commonly used negation algorithms in clinical NLP [22]. Several other negation identification algorithms (such as NegExpander [23], NegFinder [24], ChartIndex [25], DepNeg [26] and DEEPEN [7]) have also been developed using context-free grammar and dependency parsing to improve negation detection accuracy.

To our knowledge, none of the previous work in family history identification consider all of the steps involved in this task. Friedlin et al. reported sensitivity of 93% and positive predictive value of 97% in extraction of family history, but their method only considers family histories reported under the family history section and not those buried under various other sections in clinical notes [27]. It also doesn’t extract exact family members and classify family members as primary, secondary, and unknown relatives. Goryachev et al’s work does not examine the negation status of diagnoses found under the family history section [19]. Lewis et al. reported that only 2% of sentences with a family member term were negated compared to 17% of sentences reported under the family history section being negated. Although they stated their interest to identify negation in their future work, they have not analyzed negation in their latest work [20].

PancPro is a Bayesian modeling framework used to assess the pancreatic cancer risk of patients with family history of pancreatic cancer [28]. However, it does not use NLP techniques to extract family history information from clinical notes, so information was collected using a questionnaire.

Materials and Methods

Data Source

The study was approved by the Institutional Review Board (IRB) protocol of each institution separately. Below are the descriptions of each institution dataset.

Indiana University (IU)

Clinical notes of patients who visited Sidney and Lois Eskenazi Hospital in Indianapolis during March-December 2013 were used in this study. On average, 7,270 patients visited the hospital each month with a range of 80 to 95 thousand reports for all patients during that month. A detailed description of the dataset has been previously published [8]. The dataset was randomly divided into 60% for training and 40% for testing.

Mayo Clinic

We used Mayo cancer registry data to obtain a list of patients with pancreatic cancer. There were a total of 3,573 patients in the registry, out of which 2,923 had a family history section in their clinical notes. Clinical notes for those patients were extracted from the Mayo Clinic data repository, and text from the family history section of those notes form the second data set.

Methods

Clinical reports are organized into sections with headers such as “Physical Examination,” “Medication,” “Family History.” Usually a patient’s family history is reported under the family history section of the narrative reports. However, this is not always the case. It is sometimes mentioned in the patient’s history, diagnosis, or other sections. Based on this understanding, we divided family history identification into two parts: In the first part, the patient’s family history, which is reported under the family history section, was identified. In the second part, the family history section was removed from the clinical note and any mention of a family history in other sections was identified. The first part consisted of three sub-parts: 1) section header detection, 2) family members and diagnoses identification, and 3) relation discovery between family members and diagnoses.

Section header detection

A rule-based algorithm based on the SecTag terminology was developed to identify the clinical notes sections for the IU data set. While at Mayo, clinical notes are CDA 1.0 compliant, wherein sections have been codified. Although SecTag terminology is a large-scale effort to assemble an exhaustive list of terminologies used as section headers of clinical notes, due to lack of standard and universal convention there are still terms used in other institutions that are not found in the SecTag terminology list. For instance, section headers such as “Past Medical, Social, Family History” and “Social and Family History” were used in IU clinical notes, but were not available in the SeTag terminology. We added these terms to our dictionary list to identify family history sections.

Family member and diagnosis identification

After a family history section was identified, sentences reported under this section were detected using Ytex sentence detector [29]. A list of keywords indicating pancreatic cancer concepts and family members were collected using UMLS metathesaurus [30] and manual review of a random set of clinical notes. This dictionary was then used to identify family member and pancreatic cancer concepts within a sentence.

Relation Discovery

Associating family member with pancreatic cancer in a sentence with only one family member is trivial, e.g.:

> A. “Notable for a **father** with what sounds like cirrhosis, colorectal cancer, as well as **pancreatic cancer**, and alcohol abuse.”

However for sentences with more than one family member, this task is challenging (e.g. Sentence B):

B. "The only cancers in her **family** include a first **cousin** on her **mother's** side with breast cancer in her xxx, as well as a **paternal aunt** who had **pancreas cancer** in her xxx, and her **brother** who died of **pancreas cancer** at the age of xxx."

We developed a set of rules that divides the sentence into sub-sentences based on tokens such as ",", ";" or ", and" and associate family member and disease in each sub-sentence.

For example, in sentence "B", after dividing the sentence to three sub-sentences, we could link "paternal aunt" and "pancreas cancer" in the sub-sentence *"as well as a paternal aunt who had pancreas cancer in her xxx",* and the terms "brother" and "pancreas cancer" in the sub-sentence *"and her brother who died of pancreas cancer at the age of xxx"*

If the pancreatic cancer concept was found with no family members in sentences under the family history section, the general term "family history" was assigned to the concept.

In order to identify family history of pancreatic cancer mentioned other in sections of the report, the family history section was removed and the same algorithm was applied where at least one family member must be mentioned.

An NLP system using UIMA framework, shown in Figure 1, was developed to accommodate the above steps. First, two blocks in the UIMA pipeline are 'report separator' and 'metadata annotator' that extract each report's main body and its metadata information, such as report name, ID, date and patient medical record number. Reports' main bodies were then used as an input for the next block of code where family history sections were detected. After the family history section was extracted, the section was split into sentences and family member and diagnosis were identified. We used our previously developed negation algorithm called DEpEndency ParsEr Negation (DEEPEN) to find out the negation status of diagnosis concepts in a sentence [31]. DEEPEN improves the NegEx algorithm by double-checking the negation status of concepts using a nested chain of dependency relations between negation words and desired concepts within a sentence. Finally, all the extracted information (including patient medical number, report name, report date, the sentence containing the concept, the diagnosis concept, and related family members) was found in the sentence, and their negation status was stored in a database.

Figure 1- Analysis engines developed in the UIMA pipeline to identify patients with family history of pancreatic cancer.

Results

Table 1 shows the performance of the system on the IU training and testing sets. The system output consists of patient medical record number, sentence, diagnosis, family member and negation. The results were evaluated as correct or incorrect by two independent reviewers with inter annotator agreement of 95.9%. A result is correct if pancreatic cancer is associated with the correct family member and negation status of the diagnosis was identified accurately. Any errors in these finding were considered as an incorrect instance. We also considered hypothetical cases (i.e. a sister may have had pancreatic cancer.) as incorrect. If pancreatic cancer related to patient or a non-blood relative (e.g., wife or husband) was mentioned, it was considered as irrelevant.

Table 1- IU dataset evaluation.

Train	Correct	Incorrect	Irrelevant	Precision
Affirmed	22	7	2	75.9
Test Set	Correct	InCorrect	Irrelevant	
Affirmed	14	2	2	88.9
Negated	2	0	0	100%

We applied the same algorithm to the Mayo clinic dataset without any modifications (Table 2). Precision is defined as the number of correct instances over the total of correct and incorrect instances. As shown, the performance of the system has been consistent across the two institutions.

Table 2- Mayo dataset evaluation.

	Correct	InCorrect	Irrelevant	Precision
Affirmed	519	72	32	87.8
Negated	438	4	2	99.1

In order to ensure that we did not miss any patient with family history of pancreatic cancer, 100 reports were selected randomly and manually reviewed. Table 3 shows the result of our algorithm to incorporate missing patterns in these reports:

Table 3- Result of Mayo dataset evaluation after system customization.

	Correct	Incorrect	Irrelevant	Precision
Affirmed	550	74	34	88.1
Negated	443	4	2	99.1

Another batch of 100 reports were randomly selected from the Mayo dataset excluding the first 100 reports to manually review the family history of pancreatic cancer. There was no missing pattern in the second set of randomly selected reports.

In relation discovery evaluation, true positives were considered as instances where the pancreatic cancer concept was assigned to the correct family member in the sentence. False negatives were any family member relation that was missed by the system. A wrong family member assignment was considered a false positive.

There were total of 268 patients with a family history of pancreatic cancer out of 3,573 patients with pancreatic cancer in the Mayo Clinic's data set. Figure 2 shows the number of patients identified with first, second, or third degree relative.

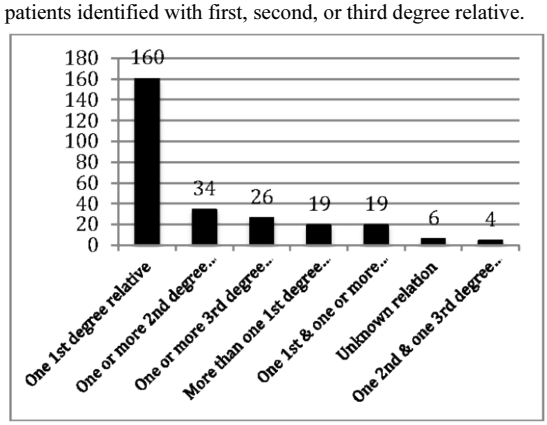

Figure 2- Number of identified patients with one or more 1st, 2nd, or 3rd degree relative.

Table 4- Results of family member identification.

	True Positive	False Positive	False Negative
Family member relation disocvery	579	190	53
	Precision	Recall	F-Measure
	75.3	91.6	82.6

Discussion

In this work, we have developed an NLP system in a UIMA framework with multiple analysis engines, including section segmentation, negation detection, and relation discovery to identify patients with a family history of pancreatic cancer from clinical notes.

We have developed our system on an IU dataset. The IU dataset consisted of any patient who visited the Eskenazi Hospital during 10 months for any reason. Due to low incidence of pancreatic cancer with a familial basis, we had a very low number of patients at IU compared to the Mayo Clinic dataset. Clinical notes at the Mayo Clinic are CDA 1.0 compliant; therefore, section detection developed at IU was not used for the Mayo Clinic dataset. We also did not consider the family history mentions in other sections of clinical notes, other than family history in Mayo Clinic dataset.

We can classify the errors in our system as follows:

1. Sentence Detector

Sentences "C" and "D" show two examples of instances where sentence detector fails to identify the correct boundary of a sentence and therefore the pancreatic cancer concept was improperly assigned to multiple family members.

C) "Father deceased xx-xx
colon polyp pancreatic cancer heart disease alcohol abuse depression
mother
mother alive
heart disease asthma stroke/tia high cholesterol arthritis depression
brothers
2 brothers alive 1 brother deceased
colon polyp asthma
sisters
2 sisters alive
osteoporosis
famhx updates (cvi)
high blood pressure – yes"

D) "His brother died of pancreatic cancer at the age of xx. A sister has a history of breast cancer."

2. Complicated Family Relations

Sentences "*E*", "*F*", and "*G*" show examples of family relation where multiple family member terms were used to show the relation. As we did not have these complicated instances of relationship in our dictionary set, our system related each family member term to the pancreatic cancer separately. For instance, in sentence "E" pancreatic cancer was related to mother, sister, and granddaughter. Sentence "*H*" shows an example where semantic inference is needed to infer that pancreatic cancer is related to the mother.

E) "Recently she found out about her mother's sister's granddaughter who was diagnosed with pancreatic cancer at the age of xx."

F) "He had an uncle that was actually a half-sibling to his mother that died of pancreatic cancer."

G) "He had one cousin on the patient's father's side of the family (the cousin was the son of the patient's father's brother) who had pancreas cancer at age xx."

H) "Her son (our patient) found her deceased about xx p.m. a postmortem examination showed cause of death was due to multiple blood clots and she was found to have a widespread pancreatic cancer."

3) System Failure

As mentioned in the relation discovery section, a set of rules was developed to divide the sentence into sub-sentences. When there are multiple family relation terms in a sentence such as sentence "I". Each family relation term was then associated with the pancreatic cancer concept within the sub-sentence. In sentence "I," "*pancreatic cancer*" is associated with "*paternal grandfather,*" but it failed to associate the "mother" and "father" with the pancreatic cancer concept in the sub-sentence *"his mother, father,"* because there is no pancreatic cancer concept in the sub-sentence.

I) "His mother, father, and paternal grandfather died from pancreatic cancer."

There were few instances where co-referencing was needed to extract the right family relation (see sentence "J"). Our current system does not handle co-referencing.

J) "She has one son living and one deceased. the one that is living has a recent diagnosis of pancreatic cancer, and three daughters."

Conclusions

Pancreatic cancer is referred to as silent killer due to its few sign and symptoms until it is in well-advanced cancer stages. Screening the general population for pancreatic cancer is not feasible because of its low incidence and the lack of effective screening tests. Pancreatic cyst and family history of pancreatic cancer represent two windows of opportunity for early detection of pancreatic cancer. We have developed a rule-based algorithm to identify patients with a family history of pancreatic cancer retrospectively from their clinical records. Development of clinical NLP system requires resources, such as domain experts to develop guidelines, nurse abstractors to create gold standards, and researchers/programmers to develop and analyse the system. Although rule-based methods highly depend on the natural language that they have been developed on, this study shows that as long as the rules are kept simple and generalizable, we can transfer an algorithm developed in one institution to other institutions.

Future steps involve refinement of the family relation discovery rules, especially regarding the sentence detection algorithm. A risk stratification method will also be developed based on the number and degree of family relations to assess patients' risk of having cancer and a surveillance strategy will be designed to follow up with patients according to their risk.

Abstract

Angiotensin Converting Enzyme Inhibitors (ACEI) and Angiotensin II Receptor Blockers (ARB) are two common medication classes used for heart failure treatment. The ADAHF (Automated Data Acquisition for Heart Failure) project aimed at automatically extracting heart failure treatment performance metrics from clinical narrative documents, and these medications are an important component of the performance metrics. We developed two different systems to detect these medications, rule-based and machine learning-based. The rule-based system used dictionary lookups with fuzzy string searching and showed successful performance even if our corpus contains various misspelled medications. The machine learning-based system uses lexical and morphological features and produced similar results. The best performance was achieved when combining the two methods, reaching 99.3% recall and 98.8% precision. To determine the prescription status of each medication (i.e., active, discontinued, or negative), we implemented a SVM classifier with lexical features and achieved good performance, reaching 95.49% accuracy, in a five-fold cross-validation evaluation.

Keywords:

Heart Failure; Angiotensin Converting Enzyme Inhibitors; Angiotensin II Receptor Blockers, Biomedical Informatics; Natural Language Processing.

Introduction

Heart Failure (HF) is characterized by the inability of the heart to pump blood at a rate sufficient to answer metabolizing tissues' needs. It is a frequent condition in the U.S. adult population, causing more hospitalizations than all forms of cancer combined [1]. HF treatment can include dietary and physical activity therapies and invasive therapies, but pharmacologic therapies are the most common. Among pharmacologic therapies, Angiotensin Converting Enzyme Inhibitors (ACEI) are a mainstay of treatment in patients who can tolerate them; for patients who cannot take these drugs, Angiotensin Receptor Blockers (ARB) agents offer an alternative. Assessment of the care HF patient's benefit from relies on detecting evidence of current treatment with these medications in clinical notes, along with analysis of the status of these medications. This information, combined with the functional assessment of the left ventricular function, is a key component of HF treatment performance measures.

This study was realized in the context of the ADAHF (Automated Data Acquisition for Heart Failure) project, a U.S. Department of Veterans Administration (VA) project that aims to automatically extract data for HF treatment performance measures from clinical notes. These performance measures include left ventricular ejection fraction (LVEF) assessments (their mention and measured values), medications (ACEIs and ARBs), or reasons not to administer these medications, as part of the Joint Commission National Hospital Quality Measures Heart Failure Core Measure Set the VA has adopted for use in Veteran care.

Previous efforts have focused on detecting LVEF mentions and values in clinical notes and determining their abnormality (LVEF < 40%) [2-4].

However, to assess whether each patient's clinical record substantiates proper treatment for HF, active medications should be considered as well. In this study, we focused on ACEIs and ARBs detection and classification of the status of these detected medications.

Clinical notes are mostly composed of unstructured text and have multiple different formats depending on specialties and institutions. Misspelled words and non-narrative text formats can be found in clinical notes, especially when directly typed into the system by healthcare providers. For example, one of the medications included in our study, "Losartan", was found with the following issues:

"Lorsartan" (misspelled word)

"Losartan30 mg" (tokenization problem: missing whitespace)

"L [newline] osartan" (word wrapping problem: word wrongly split)

These problems make medication detection based on a simple dictionary lookup more difficult.

Medications can be mentioned in multiple contexts in clinical notes. Most are currently taken by the patient (i.e., active), but some can be mentioned in the patient medical history as discontinued, or even mentioned as specifically not taken by the patient, because of an allergic reaction for example. This contextual information, the status of the medication, therefore, needs accurate analysis, and we designated three different categories: active (the patient currently takes the medication),

discontinued (the patient remains off the medication or is temporarily taken off the medication), and negative (the medication does not pertain to the patient or is negated).

The automatic extraction of medication information from clinical notes was the main task of the 2009 i2b2 NLP challenge [5]. It focused on the identification of medications and attributes including dosage, frequency, treatment duration, mode of administration, and the reason for the administration of the medication. Almost twenty teams participated in this challenge, and Meystre and colleagues built a system called Textractor that combined dictionary lookups with machine learning approaches and reached a performance of about 72% recall and 83% precision [6].

Patrick and Li trained a sequence-tagging model using conditional random fields (CRF) to detect medications with various lexical, morphological, and gazetteer features. Their tagger reached about 86% recall and 91% precision (the highest score in the challenge) [7].

No published research attempted prescription status classification, but some developed systems to recognize the context or assertions of medical concepts. Chapman and colleagues created the NegEx algorithm, a simple rule-based system that uses regular expressions with trigger terms to determine whether a medical term is negated. They reported 77.8% recall and 84.5% precision for medical problems in discharge summaries [8]. Chapman and colleagues also introduced the ConText algorithm, which extended the NegEx algorithm to detect four context categories: negated, hypothetical, historical, and not associated with the patient [9].

Kim and colleagues [10] developed a Support Vector Machines (SVM [11])-based assertion classifier for the 2010 i2b2 NLP challenge [12] and their system reached 94.17% accuracy by regulating un-balanced class probabilities and adding features to improve performance recognizing minority classes. Our system for medication status classification expanded this system with a simplified feature set.

In the following sections, we will describe the methods we used for medication detection and prescription status classification and present our experimental results.

Methods

Materials

The ADAHF project included the development of a large annotated corpus of clinical narrative text notes from patients with HF treated in a group of VHA medical centers in 2008. Each document in this corpus was annotated by two reviewers independently, and a third reviewer adjudicated disagreements.

We randomly sampled 3,000 clinical notes from our training corpus. The most common clinical note types were progress notes, discharge summaries, history and physical notes, cardiology consultation notes, and echocardiogram reports. These 3,000 notes included 6,007 medication annotations (4,911 ACEIs and 1,096 ARBs). Medications annotated in our project included all ACEI and ARB preparations available in the U.S. The distribution of the most common medications annotated in our corpus is presented in Table 1.

Each annotated medication was also assigned a status category: active, discontinued, or negative. Among annotated medications, 4,491 (74.76%) were active, 1,191 (19.83%) were discontinued, and 325 (5.41%) were negative. Even though the discontinued or negative status was not common, they have to be classified accurately.

Table 1 – Most Frequent Medications with Term Variants

Medication	Type	%	Frequent term variants
Lisinopril	ACEI	39.9	Lisinopril
ACEI	ACEI	16.7	ACE, ACEi, ACE inhibitor
Benazepril	ACEI	16.2	Benazepril, Lotensin
Losartan	ARB	8.2	Losartan
Fosinopril	ACEI	6.0	Fosinopril, Fos
Valsartan	ARB	5.0	Valsartan, Diovan
ARB	ARB	4.5	ARB, Angiotensin receptor blocker
Captopril	ACEI	1.6	Captopril
Enalapril	ACEI	0.8	Enalapril
Irbesartan	ARB	0.4	Irbesartan
Others		0.7	

Rule-Based Medication Detection: Our first approach was based on a dictionary lookup with pre-defined medication entries. We used a modified version of ConceptMapper,[13] a highly configurable UIMA [14] dictionary annotator.

To build this baseline system (**DL1 system**), the dictionary of medication terms had to be manually built. For each ACEI and ARB medication, we included generic names, brand names, and other frequently used name variations (from RxNorm and clinical experts' experience with clinical text).

Misspelled medication names are common in our corpus. For example, "Lisinopril", the most frequent medication had 21 different misspellings in our corpus:

Lisinipril	Lisinoppril	Lisnopril
Lasinopril	Lisiniprli	Lisinopiril
Lisinorpril	Linsinopril	Liinopril
Linsopril	Lisiniopril	Lisiniprol
Lisinoril	Lisinorpil	Lisinorpirl
Lisinpril	Lisionpril	Lisniopril
Lisnoril	Lisonopril	Loisinopril

To improve the sensitivity of our detection and include misspellings, we added fuzzy string searching for spelling variant replacement (**DL1 + fuzzy searching system**). We used the edit distance (or Levenshtein distance)[15], the minimum number of single-character edits needed to transform one word into another, to check whether each text token was a spelling variant of our pre-defined medication terms.

To reduce the number of false positive matches in a second version of our system (**DL2 system**), we only considered matched word tokens as medication name candidates when they met the following criteria: 1) the first character was matched or the last four characters matched one of our dictionary terms, and 2) the edit distance between the word token and one of our dictionary terms was less than two.

In addition to fuzzy searching for each word token, we also analyzed all tokens separated by a newline to reconstruct wrongly split words like "L [newline] osartan." After removal of the newline character between two word tokens, treating them as a one word token, we considered them as a correctly reconstructed word if they met the two-step criteria specified above.

These fuzzy searching strategies allowed detection of more medications even when they were misspelled or erroneously split by a newline character.

Machine Learning-Based Medication Detection: The second approach for medication detection was based on machine learning methods. We built a token-based classifier without sequential learning. A sequential tagger requires sentences as inputs and predicts the sequence of labeled tags with probabilities. In a Hidden Markov Model [16], a popular choice for sequence tagging, transition probabilities from one tag to the next tag are considered when learning a model with a dynamic learning algorithm like Viterbi path [17].

In token-based learning, the tagger only predicts a label for each token, independently from the previous tags. We used LIBLINEAR[18] with a linear SVM classifier to train our token-based model (**SVM system**). We used lexical features (the word itself, two words preceding it, and two words following it) and morphological features (prefix and suffix up to length of five) with B-I-O tags (B denotes the beginning of a term, I a token inside a term, and O a token outside a term). Because the classifier predicts each tag independently from the previous tags, we did some post-processing (using a few heuristic rules) to avoid undesirable tag sequences like a "B-ACEI" (token at the beginning of an ACEI name) followed by "I-ARB" (token inside an ARB name).

Finally, we combined the rule-based and machine learning-based methods by using DL2 system's predictions as new features for the SVM classifier (**SVM + DL2 system**). The feature vector was augmented with the DL-II system predictions for the current token, the two previous tokens, and the two following tokens.

Medication Status Classification: To classify medications as active, discontinued, or negative (details in the Introduction), pre-processing included tokenization with a modified version of the cTAKES [19] tokenizer. The prescription status classifier only used lexical features from the tokenizer (i.e., all word tokens). We also used LIBLINEAR for this task, with a wider context window than for medication detection (five preceding and five following words) and no morphological features.

Metrics and Statistical Analysis: Accuracy of the detection of medications is reported using typical metrics for information extraction or retrieval: *Recall* (equivalent to sensitivity in this context; equals true positives/(true positives + false negatives)), *Precision* (equivalent to positive predictive value on this context; equals true positives/(true positives + false positives), and the *F_1-measure* (harmonic mean of recall and precision; equals (2*recall*precision)/(recall+precision) when giving equal weight to recall and precision). These metrics were *macro-averaged* to obtain average values for each system (i.e., each metric was calculated for each document, and then averaged across all 3,000 documents).

Descriptive statistics are reported with 95% confidence intervals. Statistical analysis to compare our different approaches to detect medications was realized using the Student's t-test as well as the Mann-Whitney U test for its higher efficiency with non-normal distributions.

Results

Medication Detection: As an easily accessible baseline system for our evaluation, we used eHOST[20], the Extensible Human Oracle Suite of Tools, an open source text annotation tool, to detect medications with a pre-compiled dictionary of medication terms, as specified in our annotation guideline.

Table 2 – Five-fold Cross Validation Results for Medication Detection (macro-averaged percentages)

System	R	P	F
eHOST	83.7 ±1.1	87.2 ±1.1	84.8 ±1.1
DL1	94.8 ±0.7	96.7 ±0.6	95.3 ±0.6
DL1+fuzzy searching	96.6 ±0.5	97.0 ±0.5	96.5 ±0.5
DL2	99.2 ±0.3	98.6 ±0.3	98.7 ±0.3
SVM	97.9 ±0.4	97.4 ±0.4	97.5 ±0.4
SVM+DL2	99.3 ±0.2	98.8 ±0.3	98.9 ±0.2

R=Recall, P=Precision, F=F_1-measure. Percentages reported with 95% confidence intervals

This dictionary listed multiple terms for 44 different medications and general categories. eHOST reached moderate performance (Table 2, Figures 1 and 2).

However, many medications detected by eHOST would be considered true positives if partial span matches were counted. For example, medication names are sometimes attached to punctuation in our corpus (e.g., "Losartan;", "Losartan)") and punctuation (; or) in the same examples) should be excluded for exact matches, but eHOST detected these medications with the punctuation characters.

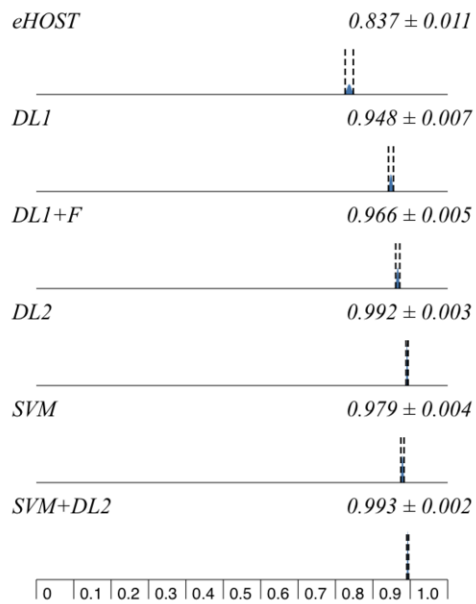

Figure 1 - Systems Recall Comparison

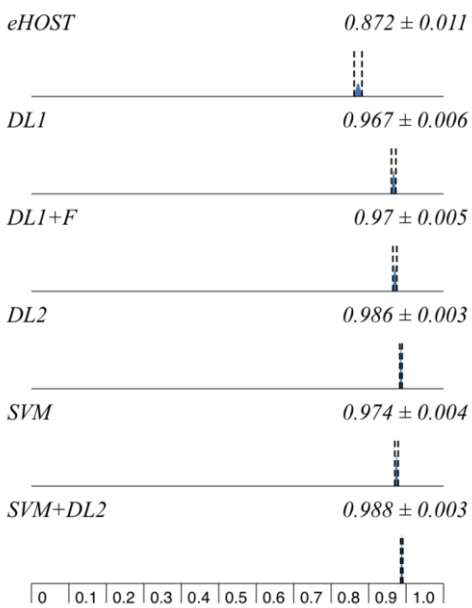

Figure 2 - Systems Precision Comparison

Our first dictionary lookup system (DL1) reached good performance, especially for precision (96.7%). Adding fuzzy string searching to DL1 increased recall to 96.6%. When adding wrongly split words correction (DL2), recall reached more than 99% by detecting medication names that contained newline characters.

When evaluating the machine learning-based system with a five-fold cross validation, the SVM classifier achieved lower recall and precision than the DL2 system, but closer to the DL1 system with fuzzy searching. SVM with DL2 output allowed for the best performance, with the highest recall at 99.3% and a 98.9% F_1-measure.

Table 3 – Systems Recall Pairwise Comparison

Recall	eHOST	DL1	DL1+F	DL2	SVM
DL1	*				
DL1+F	*	*			
DL2	*	*	*		
SVM	*	*	*	*	
SVM+DL2	*	*	*	0.368	*

Precision	eHOST	DL1	DL1+F	DL2	SVM
DL1	*				
DL1+F	*	0.411			
DL2	*	*	*		
SVM	*	0.047	0.233	*	
SVM+DL2	*	*	*	0.306	*

* <0.001

As indicated in Table 3, pairwise comparison and statistical analysis of the results reported in Table 2 and Figures 1 and 2 demonstrated that all differences were significant ($p<0.001$) except all metrics between DL2 and SVM+DL2 (p=0.306-368), and precision between DL1 and DL1+fuzzy searching (p=0.411), and between DL1+fuzzy searching and SVM (p=0.233).

Medication Status Classification: We also used a five-fold cross validation with the 6,007 medication annotations to measure performance of medication status classification (Table 4). The overall accuracy was 95.49%. Precision of each status was above 90%, and recall of the *discontinued* status was 86.23%. Interestingly, recall was higher than precision with the *negative* status, even though they were associated with only 5.41% of the annotated medications in our corpus.

Table 4 – Five-fold Cross Validation Results for Medication Status Classification

Medication Status	**R**	**P**	**F**
Active	98.0	96.3	97.1
Discontinued	86.2	92.9	89.5
Negative	94.2	93.3	93.7
Overall	95.5	95.5	95.5

R=Recall, P=Precision, $F=F_1$-measure.

Discussion

The dictionary lookup approach for medications detection was very efficient, and the fuzzy string searching boosted performance, especially recall. The main advantages of this method is that there is no need for manually annotated training examples and processing is fast. With the SVM classifier, morphological features helped detect misspelled medication names but didn't help with erroneously split medication names. We observed that a machine learning-based method could be applied successfully to this task without an external medical knowledge base. But it didn't add any significant performance improvement when compared to the improved dictionary-based and rule-based system (DL2). Overall, it and was probably not a worthy effort in our case, considering the requirement for annotated training examples to train the SVM classifier.

Medication status classification was satisfactory, and even though performance with *active* and *negative* cases was quite good, there is ample room for improvement with the *discontinued* status. A total of 230 (71+159) *active* or *discontinued* cases were misclassified as the other class (Table 5).

Table 5 –Medication Status Classification Confusion Matrix

	Classified as		
	Active	**Discontinued**	**Negative**
Active	4403	71	17
Discontinued	159	1027	5
Negative	12	7	306

One possible avenue for future work is to develop specific patterns or lexicons for this *discontinued* status, including terms like 'hold', 'discontinue', or 'd/c'. Recognizing clinical document sections or detecting phrases mentioning why the

patient was not on the medication might play an important role as the classifier.

Our experimentation with machine learning-based approaches to detect specific medications was limited to one method, SVMs. Other machine learning algorithms such as Conditional Random Fields have been successfully applied to similar tasks and could also be applied to detect ACEIs and ARBs.

Conclusion

This study showed that information extraction methods using rule-based or machine learning-based approaches could be successfully applied to the detection of ACEI and ARB medications in unstructured and somewhat messy clinical notes. We boosted medication detection performance with fuzzy string searching and combining the two approaches. The preliminary work to classify the status of each medication showed that the words surrounding medication names were the most beneficial features.

Abstract

In order to measure the level of utilization of colonoscopy procedures, identifying the primary indication for the procedure is required. Colonoscopies may be utilized not only for screening, but also for diagnostic or therapeutic purposes. To determine whether a colonoscopy was performed for screening, we created a natural language processing system to identify colonoscopy reports in the electronic medical record system and extract indications for the procedure. A rule-based model and three machine-learning models were created using 2,000 manually annotated clinical notes of patients cared for in the Department of Veterans Affairs. Performance of the models was measured and compared. Analysis of the models on a test set of 1,000 documents indicates that the rule-based system performance stays fairly constant as evaluated on training and testing sets. However, the machine learning model without feature selection showed significant decrease in performance.

Therefore, rule-based classification system appears to be more robust than a machine-learning system in cases when no feature selection is performed.

Keywords:

Natural Language Processing; Colonoscopy; Screening.

Introduction

Colonoscopy is a common procedure that aims to detect abnormalities of the colon through direct visual inspection [1]. One of the most common and important reasons to perform colonoscopy is to screen for colorectal cancer [2]. While regular colorectal cancer screening is widely recommended, recent studies have also raised concerns about overuse of screening colonoscopy [3]. As with any clinical procedure, colonoscopy carries risks of both minor and major complications, including death [4,5].

The appropriate timing of colonoscopy depends on the reason or indication for the colonoscopy. Previous studies of colonoscopy overuse have relied on administrative data to determine whether a colonoscopy was performed for a screening or non-screening indication [6]. But studies have repeatedly demonstrated that relying strictly on administrative codes achieves a relatively low accuracy for screening indication (sensitivity of 70.1% and specificity of 71.6%) [7,8]. And even when additional diagnostic codes were included in the algorithms, sensitivity went up only slightly to 83% and specificity to 76% in the Department of Veterans Affairs (VA) clinical setting [9].

The Quality Assurance Task Group of the National Colorectal Cancer Roundtable recommends a list of key areas that should be covered in colonoscopy procedure reports, one of which is a detailed description of procedure indication [10]. Recording the data in structured format is not always supported by clinical information systems to the extent needed for proper documentation of patient risk factors. Thus, these clinical reports are commonly recorded in narrative format and stored as unstructured text.

Background

Data Sources

As the largest integrated healthcare network in the United States, VA has health information on millions of Veterans for which it provides care. A benefit of the integrated healthcare system is seen in the comprehensive electronic medical record, the Veterans Health Information Systems and Technology Architecture (VistA), which was established in 1990's and is used across all VA healthcare facilities. Within the VA healthcare system, there are more than 1,400 hospitals, clinics, and nursing homes nationwide. Since US Veterans tend to receive a large proportion of their care within the VA system, the patient medical records contain a detailed history of care over the last 20 years. The records are aggregated into the VA Corporate Data Warehouse, which contains patient records from all VA facilities from October 1999 to present. These records are made available to VA-credientialed researchers with study approvals through the VA Informatics and Computing Infrastructure (VINCI), an analytic environment that combines access to nationwide VA patient records with computational resources and software tools.

Even though common infrastructure and unique patient identifier enable integration of all data at the database level, individual sites have the flexibility to modify data entry in VistA through templates and forms [11]. Because of the strict requirement to comply with interoperability requirements for structured data, the variability among different sites mostly affects free text entries [12]. The divergence of installations across all sites and the large number of clinicians across all facilities result in inconsistent format and large amount of information recorded in clinical notes in the system [13]. This same variation exists in the way documents are named – making it difficult to identify relevant documents.

Colonoscopy indication is typically recorded in procedure reports in narrative format and is available for extraction with natural language processing (NLP). Document level classification is an NLP task that utilizes the information contained in a document to assign a label from two or more labels to each document. Since each colonoscopy report presents information about a single colonoscopy procedure, determining the indication for the procedure as recorded by

clinicians can be treated as a classification task. Each document can be classified as containing evidence of the purpose for the procedure as being average-risk screening ("Screening") or high-risk screening, surveillance, or diagnosis ("Non-screening"). Detecting relevant documents is hindered by data entry variability and the lack of standard document titles, so another classification label, "Non-colonoscopy", was added to filter out documents that are not colonoscopy reports. A final classification label of "Unknown" was given when the indication of the colonoscopy was not given.

Classification algorithms

Detecting colonoscopy overuse at a population level and tracking the practice changes over time requires an automated system to perform extraction of colonoscopy indication from a heterogeneous dataset. A number of approaches have been used for document classification, including rules and a variety of supervised machine-learning algorithms [14]. Each of these approaches has its advantages and limitations.

The heuristic rule-based approach (also called knowledge engineering) is one of the most established computational methods for document classification [15]. This approach utilizes expertise of language engineers to design lexicons and classification logic in a form of "if-then" decision tree specifically for the target domain. The advantages of such an approach are a) the classification logic is intuitive and understandable for humans, b) the algorithm is straightforward to implement, and c) model development does not require a large annotated corpus [16.17]. It has been suggested that rule-based approaches can be applied on a new corpus without changes, because they rely on grammatical and lexical structures inherent to the specific natural language and not on distribution of specific features in the target corpus [18]. The main limitation of this approach is that the initial rule development is time-consuming and effort-intensive in case of a broad domain and highly variable language. However, the language used by clinicians is considered to be a sublanguage, and especially in such focused subdomain as colonoscopy, it can be expected to be lexically restricted [19].

Supervised machine learning approaches create a statistical model using computational methods applied on manually annotated corpora. The main benefit of this approach is that the resulting model is grounded in the objective mathematical representation of the target language. Availablitly of open source implementations of a number of algorithms in a variety of programming languages simplifies development of classification systems [20,21]. Minimization of the human effort requried in knowledge base development is often mentioned as a benefit of using a machine learning approach [15]. However, such a statement misrepresents the actual human effort required for successful implementation of a classification system. In order for the statistical algorithm to have a sufficient number of training examples, a relatively large number of documents have to be manually annotated. While generally speaking, the annotators' time is less expensive than the time of a highly qualified clinical expert and knowledge engineer, the need for a large, consistently annotated corpus puts a high time and effort demand on annotators for planning, training, and adjudication tasks. At the same time, machine learning approaches do not eliminate knowledge engineering burden, but rather shift it to feature engineering [14]. The easiest and the most popular feature set to implement is known as a bag-of-words model that simply uses the lexical shape of all tokens in a document as binary features [22]. Such models result in a large and very sparse feature space because each distinct token in the whole corpus becomes a feature and each document has only a subset of the lexicon. However, in order to make classification more efficient and accurate, thoughtful feature selection is required [23]. Depending on the feature set, additional annotations might be needed, increasing the human effort [24]. Another drawback of machine learning approaches is that typically a model is highly dependent on the distribution of the classes in the training dataset, therefore, adapting the model for a dataset with a different distribution will likely lead to a decreased performance. From the end user perspective, the machine learning models are hard to interpret and appear to be "black boxes" that can be mistrusted by clinicians [25].

The Automated Retrieval Console (ARC) is an information retrieval system developed in VA that allows binary document classification by applying a supervised machine-learning algorithm on a set of features derived through NLP [26]. ARC utilizes the Apache Clinical Text Analysis and Knowledge Extraction System (cTAKES) to define features without the need for customization [27]. ARC evaluates feature combinations and allows the user to select the highest performing feature set or any of the other feature set combinations for the classification model. By packaging NLP and machine learning components into a unified application, ARC shifts users' development focus to document selection and reference standard definition. Previous research has attempted to identify colonoscopy indication using ARC [28]. The dataset used, though, was manually selected to contain only pathology reports. The ARC model achieved sensitivity of 0.77 and specificity of 0.88 in classifying pathology reports. The manual selection of documents is only feasible for small projects and does not support ongoing monitoring of colonoscopy indications.

This paper describes the development of rule-based and machine-learning based models for classifying clinical documents with the type of indication for colonoscopy. The performance of these models is also compared with the use of ARC.

Methods

Manual Annotation

In order to create a system that is able to handle a continuous stream of heterogeneous data, the study cohort included all patients who underwent a colonoscopy procedure at the VA facilities in fiscal years 2009 to 2012, as identified using administrative procedure codes. We created a set of metadata filters using an iterative process of manual review to exclude notes with extremely low probability of being a colonoscopy procedure note. These filters were tuned to be inclusive of notes with any indication of relevance and were designed to be scalable for future large-scale implementation of the system. The filters excluded notes authored by staff of unrelated specialties, and included only notes created within a reasonable time frame of the procedure. From this enriched corpus, 2,000 notes were selected for manual annotation, ensuring that all VA facilities that perform colonoscopies were represented in the sample. Each document was independently reviewed by 2 chart abstractors and classified as "Screening", "Non-screening", "Non-colonoscopy", or "Unknown" using an open-source annotation tool eHOST [29]. Reviewers annotated the text span that was most informative in determining the classification. The annotators achieved inter-annotator observed agreement of 0.76 across all classes and 0.79 on Screening. Annotation disagreements were adjudicated by a gastroenterologist. Annotator inconsistency was noted when the same phrase was marked as being indicative of different categories. The conflicting documents were reviewed again by the gastroenterologist, and the

classification discrepancy was resolved. In addition, 1,000 documents were selected randomly from the enriched corpus and manually classified for validation. Table 1 presents the distribution of classifications in the training and validation sets.

Algorithms

The requirements of the project led us to develop a rule-based system as the core of a robust and accurate colonoscopy indications classification system. In order to compare performance of the final system to other approaches, though, we used the same annotated dataset to develop machine learning models.

Table 1 - Class distribution in the training dataset of 2,000 documents and validation dataset of 1,000 documents

Document label	Training Dataset		Validation Dataset	
	Count	Proportion	Count	Proportion
Screening	417	0.209	182	0.182
Non-screening	1018	0.509	388	0.388
Non-colonoscopy	526	0.263	407	0.407
Unknown	39	0.020	23	0.023

Rule-based model (RB)

Each document in the reference standard contained one annotation that reflected the human perception of the indication for the colonoscopy procedure. In addition to the class label, these annotations provided a string of text that was sufficient to make the label determination. We reviewed the distinct text strings in the annotated documents and created an initial rule set for classification. These rules were in the form of regular expressions to mark text containing evidence of colonoscopy indications and a logic module that analyzed the matches and applied heuristics to produce the document label. The first iteration system was applied on the reference set of documents and an error analysis was performed. Analysis of the mislabeled documents produced additional rules. Limiting indication phrase searches to only specific sections was determined to improve classification accuracy. Another rule set was added to filter out documents that were not colonoscopy reports. After implementing the additional rules, another error analysis was performed to confirm the improvement in performance. The last iteration focused on improving section segmentation and optimizing classification rules.

The final system was developed as an NLP pipeline based on the VINCI Leo framework, a set of libraries that enables rapid development and more efficient utilization of the Unstructured Information Management Architecture Asynchronous Scaleout (UIMA AS) [30,31].

The system has the following modules:

- Document type detection determines whether the document is a colonoscopy report or not based on mentions of other procedures or keywords such as “planned procedure”, “informed consent”, or “pre-procedure assessment”.
- Indication section identification was implemented as a two-step process and detects the beginning and the end of sections likely to contain colonoscopy indication if the document is a colonoscopy report. Keywords such as “indication”, “reasons for colonoscopy”, and “preoperative diagnosis” were used to find the beginning, and “consent”, “complications”, or double blank line to find the end of the section.
- Screening indication detection uses keywords and phrases within indication sections that are common to documents classified as “Screening”.
- Non-screening indication detection uses keywords and phrases within indication sections that are common to documents classified as “Non-screening”.

The rule-based classification labeled documents based on the presence of identified keywords and phrases. If a document contained evidence that it was not a colonoscopy report, the document was labeled as “Non-Colonoscopy”. If a document was determined to be a colonoscopy report, contained an indication section, and contained any mention of increased risk, it was labeled with the “Non-screening” class. If the document contained only mentions of average risk, the document was labeled with the “Screening” class. If the document contains an indication section, but the system did not find any evidence that the colonoscopy report was either for screening or non-screening purposes, the document was labeled as “Unknown”.

The system can accept narrative text either from a database or as text files and can output the document names and their corresponding labels to a database or a comma-delimited file. This rule-based approach will be referred to as RB.

Full document SVM model (ML1)

The first supervised machine-learning model was developed using a bag-of-words feature set. Bag-of-words is a commonly used classification approach that minimizes the need to perform expert-driven feature selection by using the presence of the specific words in a document. The feature set in these models are high-dimensional, because each feature stands for a distinct lexical form found in the corpus. The feature sets for this approach used the words from the entire document, which resulted in an average of 286 features per document. A support vector machine (SVM) is a machine-learning algorithm capable of processing large feature sets in multi-class classification tasks. LIBSVM, an open-source Java-based implementation of the SVM algorithm, was used to train a document classifier [20].

In order to use machine learning capabilities of the VINCI Leo architecture, a pipeline was developed to transform documents into their bag-of-words feature representation, to apply LIBSVM on the resulting feature set, to store the SVM model, and to apply that model on a new set of documents. The model created by this system will be referred to as ML1.

Limited context SVM model (ML2)

A second supervised machine-learning algorithm was developed to focus just on the indication section. By narrowing the feature set to only words contained in the indication section, algorithm efficiency and, possibly, accuracy could improve. The indication section identification functionality of the rule-based system was first applied to the document and a second SVM model was created that used a bag-of-words approach only of those words within the indication section. The size of the limited context feature set was reduced to an average of 9 features per document. The model created by this system will be referred to as ML2.

ARC

In order to compare expert-driven and computationally driven feature selection, we decided to use ARC to determine the best feature set for classification. One of the main limitations of ARC is that it is designed to automatically create binary classification models (not multi-class models). Therefore, we had to modify the classification problem to “Screening” versus all other categories. Applying ARC on the reference dataset resulted in a number of models that had various performances

based the selected features sets. Training ARC and determining the best feature set took over 14 hours to complete on the 2,000 training documents. The best-performing feature set was selected for the final model. The systems performances were measured using the standard definitions for document classification tasks as outlined in the figure below.

		Reference standard		
		Screening	Other	Accuracy'='(TP+TN)/'Total
System output	Screening+	True positive (TP)	False positive (FP)	PPV'='TP/(TP+FP)
				NPV=TN/(TN+FN)
	Other	False negative (FN)	True negative (TN)	Sensitivity'TP/(TP+FN)
				Specificity'TN/(FP+TN)

Figure 1 – Formulas used for performance analysis

Results

The models were run on the training dataset, and the training performance is presented in Table 2. ARC failed to process 3 files and they were excluded from the analysis. The four approaches were also applied to the validation set, and the standard performance metrics are presented in Table 3. The binary classification ("Screening" vs. all other labels) is presented in order to compare the models that allow multi-class comparisons with ARC.

Table 2 – Performance of four models on "Screening" versus other labels classification on training data

	RB	ML1	ML2	ARC
True positive	397	411	406	333
True negative	1537	1579	1574	1478
False positive	46	4	9	107
False negative	20	6	11	82
Accuracy	0.967	**0.995**	0.990	0.906
PPV	0.896	**0.990**	0.978	0.757
NPV	0.987	**0.996**	0.993	0.947
Sensitivity	0.952	**0.986**	0.974	0.802
Specificity	0.971	**0.997**	0.994	0.932

Table 3 – Performance of four models on "Screening" versus other labels classification on validation set

	RB	ML1	ML2	ARC
True positive	161	119	152	144
True negative	792	793	786	785
False positive	26	25	32	33
False negative	21	63	30	38
Accuracy	**0.953**	0.912	0.938	0.929
PPV	**0.861**	0.826	0.826	0.814
NPV	**0.974**	0.926	0.963	0.954
Sensitivity	**0.885**	0.654	0.835	0.791
Specificity	**0.968**	0.969	0.961	0.960

We used the standard definitions of classification performance metrics. Because of a narrow and fairly straightforward task definition (and large number of training cases), all four systems performed with a similar level of accuracy, but the rule-based system slightly outperformed others. The specificity of all four systems was not significantly different. However, sensitivity of the full document bag-of-words SVM model of 0.654, compared to the sensitivity of the rule-based system of 0.885, represents a significant difference ($p<0.01$). As the result, the overall accuracy of the rule-based model on test set was also significantly better than the accuracy of ML1 model. In addition to measuring accuracy, we also recorded the processing time required to evaluate the test dataset by each of the models. Processing with ARC took over one hour, and the other three models processed the 1,000 documents in 2 to 3 minutes.

Discussion

The overall system accuracy is only one of many factors to be considered when deciding what computational approach to use for the design of a document classification system. Depending on the purpose of the system, requirements for scalability, flexibility, processing efficiency, and available skill set of the research personnel have to be taken into account. We aimed to create a system capable of processing a large number of files and flag them with one of three labels. This goal set the following system requirements: 1) The system must be able to handle multi-class labeling; 2) The system must be able to process a large number of documents; and 3) The system must be relatively easy to update and maintain.

The demand for manual effort spent annotating reference standard, creating classification heuristics, and engineering a feature set varies by approach, and it must be considered. The narrow problem scope and the restricted nature of the clinical subdomain limited the language variability, making it feasible to develop classification rules manually.

The effect of feature selection on the performance of machine learning system emphasizes need for the thoughtful feature selection. The model that performed the best on the training set was the SVM model created on the full document ML1, achieving almost perfect accuracy. However, the same model performed the worst on the testing set and achieved significantly lower level of accuracy as compared to the training set ($p<0.01$). The main reason for such a large change in performance from training to testing datasets is overfitting. The ML1 model captured the idiosyncrasies of the training set notes and their distributions, but may have encoded features that are not meaningful for the overall problem. Even simple but meaningful feature selection is able to substantially improve performance of a machine learning model as illustrated by the difference in performance of ML1 and ML2 models on the validation set.

While ML2 and ARC both performed feature selection and achieved comparable level of accuracy, the amount of time consumed by ARC to perform classification was substantially longer. The reason for this additional processing time is that ARC runs documents through the default pipeline of cTAKES which results in a large number of features being generated that may not be used for classification.

Limitations

The main goal of the model comparison performed for this study was to compare the performance of the rule-based NLP system to performance of other models that could be created with a minimal investment of time. As a result, we created three machine learning models with different feature sets. Testing results between the rule-based system and the three machine learning systems show performance increase when expert time was invested in rule development. Performance comparison between ML1 and ML2 illustrates performance increase when expert-driven feature selection was performed at the cost of expert time to engineer the feature set. While the ARC model also employed feature selection, ARC's feature set was completely computer generated. ARC performance can be compared to the rule-based NLP system performance to illustrate the performance trade off when using a general-purpose tool as compared to a project specific custom tool.

Conclusions

NLP can be successfully used to detect colonoscopy procedure indications even in case of unknown document type. While machine learning systems are commonly regarded as the holy grail of computational analysis of text, achieving acceptable performance and interpreting the results is challenging. The results of this study indicate that narrow domain and limited scope problems are well suited to be evaluated using heuristic rule-based models rather than machine learning algorithms without thoughtful feature engineering.

Availability of off-the-shelf machine learning tools, such as ARC, makes these methods attractive for research projects. It may be in the combination of off-the-shelf and project specific customization using which the efficiency and accuracy can best be optimized.

Automatically Expanding the Synonym Set of SNOMED CT using Wikipedia

Daniel R. Schlegel, Chris Crowner, Peter L. Elkin

Department of Biomedical Informatics, University at Buffalo, SUNY, Buffalo, NY, USA

Abstract

Clinical terminologies and ontologies are often used in natural language processing/understanding tasks as a method for semantically tagging text. One ontology commonly used for this task is SNOMED CT. Natural language is rich and varied: many different combinations of words may be used to express the same idea. It is therefore essential that ontologies and terminologies have a rich set of synonyms. One source of synonyms is Wikipedia. We examine methods for aligning concepts in SNOMED CT with articles in Wikipedia so that newly-found synonyms may be added to SNOMED CT. Our experiments show promising results and provide guidance to researchers who wish to use Wikipedia for similar tasks.

Keywords:

Ontology; Natural Language Processing; Terminology

Introduction

Automated understanding of text within the medical domain relies heavily upon the coverage of clinical terminologies. One such terminology, SNOMED CT, has been used extensively for such tasks [1-10]. An observation which has been noted by researchers examining SNOMED CT's coverage of clinical problem lists is that it could benefit from a more expansive set of synonyms [11].

As of the March 2014 English release, SNOMED CT contains 403,465 concepts, organized into several hierarchies covering medicine and medicine-related domains. Each of the 403,465 concepts contains at least two textual representations – one which includes one of a few dozen semantic types for disambiguation purposes, and one without. To these, there are added 230,863 synonyms which generally consist of alternative names, abbreviations, and shortened forms.

Wikipedia [12] is a community-maintained encyclopedia, covering topics in nearly every imaginable domain. It has a large number of articles related to medicine and science [13], and its scientific articles are of similar quality as Encyclopedia Brittanica [14]. Subdomains of its medicine-related articles, such as mental health, have been shown to have similar accuracy when compared to curated web sources [15]. As of December 2014,[1] Wikipedia contained over 4.6 million articles in English. One source of synonyms in Wikipedia is page redirects.

Wikipedia is being used increasingly often in medicine. In certain subdomains it has shown to be useful as a patient education resource [16]. In 2009, 28% of pharmacists reported using Wikipedia for drug information [17]. It has also been shown to be useful in monitoring infectious disease [18]. Wikipedia is being used in medical research with increasing frequency. Google Scholar finds about 20,300 results for the terms "wikipedia" and "medical" since 2013, and only an extra 1,400 since 2010.

Every article in Wikipedia is tagged with one or more of over 900,000 categories, which form a directed graph ("hierarchy"). Unfortunately, Wikipedia's "hierarchy" of categories "is barely useful for ontological purposes" [19]. For example, *Cath lab* is a page in the category *Cardiac procedures*. A cath lab is certainly a *place* where a cardiac procedure may be performed, but it is not itself a cardiac procedure. Indeed the categorization of pages is often more similar to a collection of related topics, rather than a rigorous ontological classification. For this reason, the ontology alignment techniques which have previously been used with SNOMED CT (such as [20, 21]) are not helpful.

We develop a method for automatically matching SNOMED CT concepts to Wikipedia articles based on lexical matches between synonyms from both, using heuristics, and through alignment of useful portions of the Wikipedia category hierarchy with SNOMED CT semantic types. Previous research has categorized Wikipedia articles as being either health-and-clinically related, or not, using the Wikipedia category hierarchy [22].

Elkin et al. [8] have used a set of 2.5 million synonyms created through a knowledge engineering process in the iNLP system. They used word synonyms such as *cancer* for *neoplasm*, then propagated the synonym through all concepts using the original word, creating new term synonyms. So, the synonym *cancer of tonsil* is added for *neoplasm of tonsil*. One issue with this approach is that many of the synonyms may never appear in actual text. Wikipedia redirects, on the other hand, are created because they are believed likely to occur. We are, of course, not the first to extract synonyms from Wikipedia (see [23] for one of the earliest examples), but we believe we are the first to attempt to enhance SNOMED CT synonymy using heuristic based extraction methods with Wikipedia.

Methods

Wikipedia's redirect pages (henceforth, *redirects*) have no content; they only automatically redirect the user to a specific page. Redirects are designed to get the user to the most appropriate page given their search. Redirects may be: alternative names; plurals; closely related words; pointers from adjectives/adverbs to the noun form; less or more specific forms of names; abbreviations; alternative spellings and common misspellings; alternately punctuated forms; alternative capitalizations; and subtopics within a larger article

[1] We use version 20140614 in this study.

[24]. Page redirects appear to be the most common way to derive synonymy from Wikipedia.

There are other methods for deriving synonymy using Wikipedia. Bolded words in an article's lead section are often synonyms according to the Wikipedia Manual of Style [25]. Analysis of links between pages, and more complex linguistic analysis of the page may also be used. In this paper we focus on redirects, but recognize that the other options may be useful, and leave analysis of them to future work.

SNOMED CT concepts are matched with Wikipedia articles through lexical matches. For example, in Figure 1 you can see that SNOMED CT contains the concept *Entire helicis major muscle (body structure)* with two synonyms. One of those synonyms, *Helicis major*, is also in Wikipedia. Wikipedia then contributes two new synonyms: *Musculus helicis major* and *Large muscle of helix*.

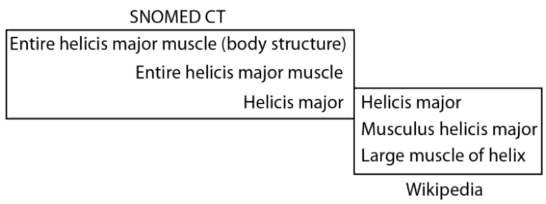

Figure 1 - A match between SNOMED CT and Wikipedia

We first performed an initial evaluation using the naïve matching strategy described above, generating the set of matches between SNOMED CT concepts and Wikipedia articles. We found that simply matching synonyms from SNOMED CT and Wikipedia does not produce very good results (see the Results section). However, analysis of the initial results led to the development of several heuristics, including a mapping between SNOMED CT semantic types and Wikipedia category "hierarchies". We hypothesized the heuristics and the mapping would improve the results.

In the remainder of this section, we discuss some preliminaries about Wikipedia's category hierarchy and what methods we used to make use of it. Then, the problems found with the initial evaluation are presented and solutions proposed. Finally methodology we used in the final evaluation is presented.

Wikipedia Categories

Every page in Wikipedia is a member of one or more categories, defined by the community according to the categorization guidelines [26]. Categories are organized into a directed graph which contains cycles, and includes edges between "hierarchies" from higher to lower level categories. The category graph also allows for multiple inheritance: a subcategory may have more than one supercategory. This structure is illustrated in Figure 2. These characteristics are so prevalent that often the closure of subcategories of an upper level category is all or most of Wikipedia.

To overcome these difficulties with the category graph, we use two independent approaches, with the results later combined. The first approach is naïve – it simply determines if the subcategorical closure of a category is all or most of the categories in Wikipedia. If it is, it recursively navigates up to *d* levels below the initial category, at each step checking again if the subcategorical closure is all or most of the categories in Wikipedia. At the point where the subcategorical closure is not all or most of Wikipedia, or depth *d* is reached, the algorithm cuts subcategory links. For this study, we used *d*=2.

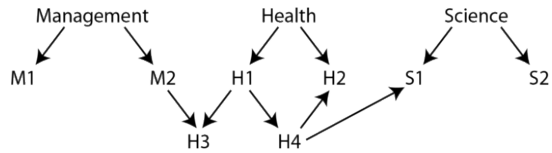

Figure 2 - An illustration of the structure of the Wikipedia category "hierarchy".

The second approach we use is similar to that of [22]: using a breadth-first approach we traverse the graph down from the top-level category (*Articles*) assigning each category a number for its depth. If a category has a subcategory which has a depth less than that of the category itself, that relation is removed.

Alignment

During careful analysis of the initial results, we determined that poor matches and synonyms occurred for five reasons. For each of these we have proposed a solution.

1. Problem: Many incorrect matches between SNOMED CT and Wikipedia (those where none of the resulting synonyms are relevant) occur because a SNOMED CT synonym matches with a Wikipedia redirect for a page outside the appropriate domain.
   Example: The SNOMED CT concept *articular surface of bone* has the synonym *joint*. In Wikipedia, *joint* is polysemous. One use is for drugs, where synonyms such as *dooby* are found.
   Solution: We use the mapping in Table 1 to ensure the domain is maintained. Only the included semantic types are matched on. We require 50% of an article's categories to be in the SNOMED CT semantic type of choice. This value was chosen based on work by [22] categorizing health data in Wikipedia.
2. Problem: Related, but incorrect, redirects often are exact matches of other SNOMED CT terms.
   Example: In Wikipedia, *cutaneous sarcoidosis* redirects to the article *sarcoidosis*. In SNOMED CT, these are two distinct (but related) concepts.
   Solution: Eliminate redirects which match other SNOMED terms from the results.
3. Problem: Acronyms are very polysemous, even within subdomains.
   Example: The acronym *ED* can stand for: eating disorder, effective dose, emergency department, erectile dysfunction, and others.
   Solution: Acronyms are excluded from match criteria, but not results.
4. Problem: If there are more than 10 new synonyms found for SNOMED CT terms outside substances, products, disorders, and observable entities, the new synonyms are often unreliable.
   Example: The SNOMED CT concept *Malus* (the genus for apple trees) when matched against Wikipedia results in 47 new "synonyms", many of which are subtypes like *Malus domesticus*, parts such as *Appleblossom* or even related topics like *apples and teachers*. Out of the 47, only 5 were actual synonyms.
   Solution: These are removed from the results.

Table 1 - Mapping between SNOMED CT semantic types and Wikipedia categories

SNOMED CT Hierarchy	SNOMED CT Semantic Type	Wikipedia Categories
Body Structure	body structure	Anatomy
	cell structure	Cell anatomy
Clinical Finding	finding	Health
	disorder	Health
Geographical location / Environment	geographic location	Geography
	environment	Types of healthcare facilities, Buildings and structures, Human habitats
Event	event	Events
Observable entity	observable entity	Medical signs, Health care
Organism	organism	Organisms
Pharmaceutical / biologic product	product	Drugs, Proteins, Chemical substances, Body fluids
Physical force	physical force	Force, Physical quantities
Physical object	physical object	Physical objects
Procedure	procedure	Medical tests, Health care, Management
	regime/therapy	Medical treatments
Qualifier value	qualifier value	Articles
Record artifact	record artifact	Medical records, Documents, Technical communication
Social context	social concept	Human behavior, Society, Personal life
	ethnic group	Ethnic groups
	racial group	Race (human classification)
Specimen	specimen	Biological specimens, Analytical chemistry
Staging and scales	tumor staging	Cancer staging
	staging scale	Medical scales, Cancer staging
	assessment scale	Medical scales
Substance	substance	Human proteins, Chemical substances

5. Problem: Some subhierarchies of SNOMED CT semantic types contain data not within Wikipedia, and any matches will likely be incorrect.
   Example: The subhierarchy *adjectival modifier* below *qualifier value* contains many adjectives, while adjectives are not well covered by Wikipedia
   Solution: The subhierarchies *adjectival modifier*, and *specific site descriptor* are excluded.

Final Evaluation Methodology

Evaluation was performed again after the solutions in the Alignment section were applied. Two researchers, DRS and PLE, independently created the ground truth used in this study. One-hundred matches and all of their resulting synonyms were randomly sampled and scored. Both annotators classified each new synonym as either being: correct; incorrect, but a subtype; incorrect, but a supertype; incorrect, but related otherwise; or incorrect and unrelated. If a synonym was incorrect but also would never occur in the domain it was excluded from the evaluation results. If a synonym was correct, annotators would classify the synonym as one of: morphological variant – those which a stemmer would find equivalent; spelling variant; capitalization variant; shortened or extended form; eponym; structured coding; or word or term synonym. The number of correct and incorrect synonyms found by DRS and PLE were compared using Cohen's kappa coefficient to measure inter-annotator agreement (κ=.77). Discrepancies between the two annotation results were examined by DRS, and the most correct annotation result was accepted. If a most correct option was not obvious, DRS and PLE discussed the discrepancy until a consensus could be reached.

Results

Initial Evaluation

In this trial we found 43,580 exact lexical matches between SNOMED CT and Wikipedia with 42,958 of those having new synonyms. From these we extracted 446,053 new synonyms. We sampled 100 of the matches (consisting of 988 new synonyms). A single researcher examined these results carefully and found that only 407 (41.2%) of the new synonyms were valid. An additional 360 synonyms (36.4%) were related to the SNOMED CT concept, but were incorrect. These were often related to a higher or lower level concept. The remaining 221 (22.4%) were completely unrelated.

Final Evaluation

After elimination of SNOMED CT concepts from semantic types we do not believe are covered well by Wikipedia (those not in Table 1), there are 272,613 SNOMED CT concepts. Using the heuristics and matching techniques detailed in the methodology section, our system matches 30,781 SNOMED CT concepts. Of those which are matched, 26,580 have new synonyms. Out of the box, SNOMED CT contains 230,863 synonyms. To those, we add an additional 183,100.

Of the 517 synonyms analyzed, we found that 452 (85.6%) of them were correct (true positives), 76 (14.4%) of them were related but incorrect, and 1 (0.2%) was incorrect and unrelated. These percentages are significantly better than the initial evaluation, as visualized in Figure 3.

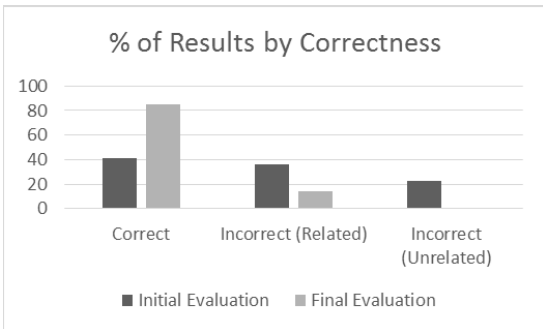

Figure 3 –Percent of correct, incorrect but related, and incorrect and unrelated results in the initial and final evaluations.

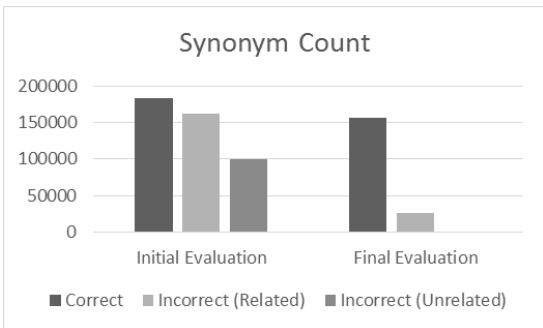

Figure 4 –Correct, incorrect but related, and incorrect but unrelated results in the initial and final evaluations.

Not only did precision improve as a result of our matching technique, few of the correct synonyms found in the initial evaluation were incorrectly eliminated (Figure 4). If we take the sample percentages and apply them to the total number of found synonyms, then compare the initial to final evaluations, we find that the number of correct synonyms decreased from 183,748 to 156,744 (14.7% change), incorrect but related decreased from 162,529 to 26,305 (83.82%), and incorrect and unrelated decreased from 99,775 to 346 (99.65%).

Of the correct results, we found that 61.95% were either word or term synonyms, 4.65% were shortened or extended forms, 0.44% were eponyms, 0.22% were word order variants, 14.60% were various structured codings, and the final 18.14% were capitalization, spelling, or morphological variants. Of the incorrect but related results, we found that 11.84% were subtypes and an additional 24.36% were supertypes. Very few of the synonyms we evaluated would never occur in the domain – only 7 of the total evaluated (1.3%).

Most matches are from the semantic types *body structure* (13.5%), *disorder* (17.9%), *organism* (22.4%), *product* (8.7%), and *substance* (26.4%). Our 100 sampled matches closely followed these percentages. In order to better understand the characteristics of the matching algorithm in these categories, we had an annotator examine random additional examples from these categories until we had around 40 matches from each (see Table 2).

The relative lack of unrelated incorrect results in this table shows that our matching method is correctly matching SNOMED CT terms with Wikipedia articles for the exact concept or a closely related concept.

Table 2 - Statistics for common semantic types

Type	Match Count	Correct Syns.	Incorrect Related	Incorrect Unrelated
body structure	40	126	25	0
disorder	40	174	42	1
organism	40	117	1	1
product	38	628	39	0
substance	40	293	0	0
all others	40	151	85	1

Comparison with Previous Work

We compared the synonyms created using our process with those from Elkin et al.'s iNLP system. We found that only 8,222 of our new synonyms were in their expanded synonym set. We did not use a knowledge engineering approach as they did, which likely would have inflated this number greatly.

Discussion

Using community-sourced data is difficult, because the level of rigor used in its creation is not always of the highest level. The methods we've discussed do not give perfect results, though they are much better than a naïve approach. To help understand what made our system imperfect, we have conducted error analysis on incorrect synonyms.

We have identified three major classes of reasons for incorrect but related synonyms. First, in some cases Wikipedia has redirects from the looked up SNOMED CT term to a related article in which discussion of the concept is only a small part of the article. For example, symptoms of a disease might redirect to a closely associated disease. Consider that *black vomit* redirects to *yellow fever*, since vomit containing blood is a major symptom of yellow fever (and in Spanish, yellow fever is known as *vomito negro* for this reason).

The second reason for incorrect but related synonyms is that a mid-level SNOMED CT concept matches a Wikipedia page which has redirects from more specific or closely associated terms or topics without pages themselves. For example, the page for the genus *Diaptomus* has a redirect from *Diaptomus rostripes* which is a species in that genus with no page itself.

The final reason is that SNOMED CT sometimes has synonyms which are more vague than the concept they stand for. For example, SNOMED CT has a concept for *lower leg*, which is usually defined as the lower extremity from the knee, to the ankle. One of the synonyms is simply *leg*. This is not really a synonym, and that it matches with a more general Wikipedia article should not be surprising.

Incorrect and unrelated terms occurred generally for two reasons. In some cases Wikipedia simply had incorrect redirects. For example *SkyUnion* redirected to *Immunoglobulin G*, while *Sky Union* appears to be a video game company. Some semantic types in SNOMED CT are extremely broad, most notably *qualifier value*. There are many subhierarchies of *qualifier value* which match Wikipedia very well, but some do not. We made an effort to eliminate bad subhierarchies which contained mostly adjectives, but there are others which are problematic. Specifically, it seems that matches from the concepts under *context values* are particularly low quality (*e.g.*, the concept *Done* matches a Wikipedia page about an album named *Done)*. In very broad categories, our matching heuristics have only a small impact.

Some Wikipedia categories such as *Organisms* and *Chemical substances* seem to have articles with very high quality redirects. Chemical substances in particular often have articles for very specific substances instead of redirecting to classes of substances, even if the specific article has little text. Many articles in these categories include codings such as enzyme codes and molecular formulas.

Future research should explore methods to expose deep semantic understanding of articles to both extract more synonyms and ensure correctness. We believe deeper understanding of Wikipedia articles, combined with using parents and children of a SNOMED CT concept being matched, may improve our results. We will also explore methods for attaching provenance and confidence to synonyms. Eventually it is our goal to release frequently updated versions of our synonym set publicly,[2] and use crowdsourcing techniques to continually increase quality.

Conclusion

It is well known that the more synonyms which are available for terminological concepts, the more easily ontologies and terminologies may be used for natural language processing and understanding tasks. We have used Wikipedia redirects as a source to increase the number of synonyms in SNOMED CT by 183,100 with precision of 85.6%. Our techniques for matching SNOMED CT concepts against Wikipedia articles have produced a significant improvement over naïve approaches. Moreover, our experiences with using Wikipedia in this research project may be a valuable resource for other researchers looking to use Wikipedia as an enrichment source.

Abstract

Rapid growth in electronic health records (EHRs) use has led to an unprecedented expansion of available clinical data in electronic formats. However, much of the important healthcare information is locked in the narrative documents. Therefore Natural Language Processing (NLP) technologies, e.g., Named Entity Recognition that identifies boundaries and types of entities, has been extensively studied to unlock important clinical information in free text. In this study, we investigated a novel deep learning method to recognize clinical entities in Chinese clinical documents using the minimal feature engineering approach. We developed a deep neural network (DNN) to generate word embeddings from a large unlabeled corpus through unsupervised learning and another DNN for the NER task. The experiment results showed that the DNN with word embeddings trained from the large unlabeled corpus outperformed the state-of-the-art CRF's model in the minimal feature engineering setting, achieving the highest F1-score of 0.9280. Further analysis showed that word embeddings derived through unsupervised learning from large unlabeled corpus remarkably improved the DNN with randomized embedding, denoting the usefulness of unsupervised feature learning.

Keywords:

Clinical Natural Language Processing; Named Entity Recognition; Neural Network; Deep Learning; Chinese Clinical Text.

Introduction

The wide use of health information technologies has led to an unprecedented expansion of electronic health record (EHR) data. EHR data have been used not only to support operational tasks in clinical practice (e.g., clinical decision support systems), but also to enable clinical and translational research. However, much of the important patient information is dispersed in narrative clinical documents, which are not directly accessible for computerized applications that rely on structured data. Therefore, clinical natural language processing (NLP) technologies, which can extract important patient information from narrative clinical text, have been introduced to the medical domain and have demonstrated great utility in many applications [1].

Originating from the Sixth Message Understanding Conference (MUC-6) [2], Named Entity Recognition (NER), which aims to identify boundaries and types of entities in text, has been one of the well established and extensively investigated tasks in NLP. In the medical domain, NER for important clinical concepts (e.g., problems, treatments, or lab tests) is also a fundamental step for many clinical NLP systems. Many existing clinical NLP systems use dictionaries and rule-based methods to identify clinical concepts, such as MedLEE [3] - one of the earliest and most comprehensive clinical NLP system developed by Carol Friedman et al. at Columbia University, the MetaMap system [4, 5] - a general biomedical NLP system developed by Aronson et al. at National Library of Medicine, as well as cTAKES [6] - an open source comprehensive clinical NLP system developed based on the Unstructured Information Management Architecture (UIMA) framework and OpenNLP natural language processing toolkit. More recently, a number of challenges on NER involving shared tasks in clinical text have been organized, including the 2009 i2b2 (the Center of Informatics for Integrating Biology and the Bedside) challenge [7] on medication recognition, the 2010 i2b2 challenge [8] on recognizing medical problems, treatments, and tests entities, the 2013 Share/CLEF challenge [9, 10] on disorder mention recognition and normalization, and the 2014 Semantic Evaluation (SemEval) challenge on disorder mention recognition and normalization. For the 2009 i2b2 challenge on medication recognition, although different approaches including rule-based methods, machine learning (ML)-based methods, as well as hybrid methods have been reported, seven out of the top ten ranked systems were rule-based systems that rely on existing biomedical vocabularies to identify medication concepts [7], such as the MedEx system developed at Vanderbilt University [11]. At the 2010 i2b2 challenge for recognizing problems, treatments and lab tests, the organizers provided a large annotated corpus. Therefore, many participating teams including all the top five systems used ML-based methods [12-14]. Many state-of-the-art clinical NER systems implement supervised ML algorithms, such as Conditional Random Fields (CRFs) [15] and Structural Support Vector Machines (SSVMs) [16], with extensive investigation on comprehensive features [17].

In addition to previous NER work on clinical text written in English, there is a growing interest in studying NER of clinical text written in Chinese. With the rapid growth of EHRs implemented in China, there is an urgent need to extract important patient information from Chinese clinical text to accelerate clinical research in China. Conventional ML-based methods have been applied to Chinese clinical NER tasks. Wang et al. [18] conducted a study using CRF, support vector machines (SVM), and maximum entropy (ME) to recognize symptoms and pathogenesis in Chinese medical records. Another study by Wang et al. [19] investigated CRF and different feature sets for recognizing symptom names from clinical notes of traditional Chinese medicine. In 2004, Xu et al. [20] proposed a joint model that integrates segmentation and NER simultaneously to improve the performance of both tasks in Chinese discharge summaries. A more recent work by Lei et al. [21] compared different machine learning algorithms and various types of features for NER in Chinese admission notes and discharge summaries. In summary, current efforts on NER in Chinese clinical text primarily focus on investigating different machine learning algorithms or

optimizing combinations of different types of features via human engineering.

Recently, there is increasing interest in designing deep learning based NLP systems that could automatically learn useful feature representations from large-scale unlabeled corpora through unsupervised learning [22-24]. Deep learning [25, 26] is a research area of machine learning that can learn high-level feature representations by designing deep neural networks. It has achieved state-of-the-art performances in a number of different applications across multiple domains, such as image processing [27], automatic speech recognition [28] and machine translation [29]. Instead of spending a great amount of time on selecting task-specific features, NLP researchers have developed deep neural networks (DNNs) to automatically learn useful features from vast amounts of unlabeled data. Researchers have shown that deep learning approaches can learn useful linguistic features as well as capture semantic meanings through word embedding [30], hence improving the performances of a number of NLP tasks in general English domain. A DNN-based system developed by Dr. Ronan Collobert [23] successfully achieved the state-of-the-art performances on a number of NLP tasks, including POS tagging, Chunking, NER and Semantic Role Labeling, using only one single deep neural network.

In this study, we propose to investigate the use of deep neural network in NER from Chinese clinical text. We developed a deep neural network (DNN) approach for NER in Chinese clinical text and compared it with the traditional CRF-based NER system at the minimal feature setting. To the best of our knowledge, this is the first study to investigate deep neural network in Chinese clinical NER.

Methods

Datasets

Two Chinese clinical corpora were used in this study. The first dataset is an annotated corpus from a previous study by Lei et al. [21], which contains 400 randomly selected admission notes from the EHR database of Peking Union Medical College Hospital in China. For each admission note, four types of clinical entities - problems, lab tests, procedures, and medications were annotated by following the annotation guidelines developed in the study. Details about creation of this dataset can be found in Lei et al. [21]. In summary, a total of 24,433 problems, 2,171 procedures, 11,168 tests and 1,201 medications were annotated in 400 Chinese admission notes. We further divided the 400 admission notes into a training set of two-thirds (266) of the notes and a test set of one-third (134) of the notes. Table 1 shows the distribution of the clinical concepts among the training and test set.

Table 1 – Description of annotated Chinese admission notes

	Training	Test
# Notes	266	134
# Sentences	20,506	10,287
# Characters	277,701	139,885
# Problems	16,253	8,180
# Procedures	1,500	671
# Tests	7,414	3,754
# Medication	840	361

Another dataset, which includes 36,828 unlabelled admission notes (383 Megabytes in total) from the same institute in China, was used for learning word embeddings. Only minimal pre-processing steps (e.g., removing the empty lines) were applied to these notes. As we trained the embedding matrix using individual Chinese characters, word segmentation was not included in the preprocessing.

Experiments and evaluation

In this study, we compared three different NER approaches: 1) the traditional CRF-based NER method, as described in Lei et al. [21]; 2) a DNN-based NER method that uses a randomly initialized word embedding matrix; and 3) another DNN-based NER method that uses the word embedding matrix derived from the unlabelled corpus. All three models were trained using the training set and their performance on the test set are reported. Similar to other deep learning studies, we evaluated the three NER systems at the minimal feature setting, which uses only the word feature. The details of the CRFs model and the DNN models are introduced in the following subsections.

We used the standard micro-average precision, recall and F1-score to evaluate all the three NER systems. All scores were calculated using the Conll 2000 challenge official evaluation script[1]. Wilcoxon signed-ranks test was used to test the statistical significance between two classifiers.

CRF vs. DNN Appraoches

CRF-based NER

The CRFs model decodes the sequence labeling problem by undirected Markov chain and Viterbi algorithm with a training criteria of maximizing the likelihood estimation of conditional probability of the output variable y given the observation x. Here, the observations are the word and its context words in the sentence and the output is its label (e.g, B, I, or O: B - beginning of an entity; I - inside an entity; O - outside of an entity). CRFs was intrinsically designed for sequence labeling problem as it models the relationships between neighboring tokens in sequence. Thus, it has been widely used in various NER tasks and has achieved state-of-the-art performances in both open domains and the biomedical domain. Therefore, CRFs serves as a strong baseline for comparing with the DNN-based NER approaches. More specifically, we used CRF++ package, one of the most popular implementations of CRF (http://crfpp.googlecode.com/svn/trunk/doc/index.html). The parameters for CRFs were optimized using the training set. The details of the CRF-based approach implemented in this study can be found in Lei et al. [21].

DNN-based NER

Researchers have proposed different approaches of designing deep neural networks for NLP systems. In this research, we adopted one of the popular architectures from Dr. Ronan Collobert – the sentence level log-likelihood approach [23], which consists of a convolutional layer, a non-linear layer using the hard version of the hyperbolic tangent (HardTanh), and several linear layers. This structure has been widely used in various NLP tasks and achieved state-of-the-art performances. Figure 1 shows the DNN architecture as well as the propagate function for each layer.

When calculating the classification score for a word, the context words within a specific window size W of the target word are taken as inputs. For the words near the beginning or the end of a sentence, a pseudo padding word will be used to form a fixed length input vector. Each word in the input window can be mapped to an N-dimension vector (N is the embedding dimension) using an embedding matrix. Then, a convolutional layer generates the global features represented as a number of global hidden nodes. Both the local features and the global features are then fed into a standard affine

[1] Available at http://www.cnts.ua.ac.be/conll2000/chunking/conlleval.txt

network trained using back propagation. The lost function is defined using the following sentence level log likelihood:

$$S(X_1^M, T_1^M) = \sum_{t=1}^{M} [H(T_{t-1}, T_t) + DNN(X_t, T_t)] \quad (1)$$

where, $S(X,T)$ is the sentence level log-likelihood score that the sequence of tag T was asigned to the input sequemce X, $H(T_{t-1},T_t)$ is a global transition score from tag T_{t-1} to tag T_t, and the $DNN(X_t, T_t)$ is the score of asigning the tag T_t to an input word X_t assigned by the DNN.

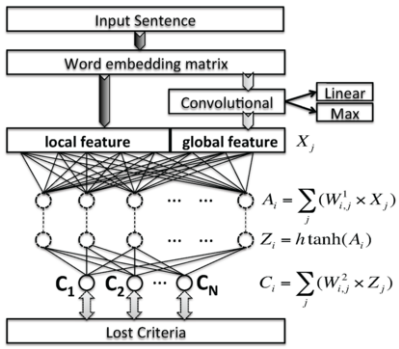

Figure 1 - The sentence approach DNN

Word embedding is a popular method to enrich the traditional bag-of-word representation through mapping the words into real value vectors. Previous research shows that the embedding space is more powerful than the one-hot representation (e.g., bag-of-words) as it conveys more semantic meanings. We adopted the ranking-based embedding method developed by Collobert. The ranking-based embedding treats a sequence of words naturally occurring in the free text as a positive sample. For example, we can form a fixed length positive sample $X=\{w_{L2}, w_{L1}, w_0, w_{R1}, w_{R2}\}$ *for* each word in a sentence given the window size of 5, *where,* w_0 *is the target word,* w_{R1} *and* w_{R2} *are the right-side context words,* w_{L1} *and* w_{L2} *are the left-side context words.* The embedding procedure will generate a negative sample $X^*=\{w_{L2}, w_{L1}, w^*, w_{R1}, w_{R2}\}$ by replacing the central word (w_0) with another word (w^*) that is randomly picked from the vocabulary and try to minimize the ranking criteria with respect to:

$$MAX\{0, 1 - DNN(X) + DNN(X^*)\} \quad (2)$$

The DNN parameters were updated following the standard stochastic gradient descent, as shown in equation 3.

$$\theta = \theta - \lambda \Delta_\theta \quad (3)$$

Where, λ is the learning rate and Δ_θ is the gradient.

We implemented two DNN-based NER approaches for Chinese clinical text. The first model starts with a random initialized word embedding matrix, which will then be updated during the back propagation training procedure. The other DNN model starts with the word embedding matrix derived from the unlabeled notes. The DNN parameters are tuned by splitting one-fifth of the training samples as a validation set using early stopping strategy. Following the work by Collobert [23], we fixed the learning rate at 0.01 and the word embedding dimension at 50. The hidden node number was set to 100, as we tested the numbers from 50 to 500 and noticed that 100 achieved the best performance on the validation set and no further significant improvement was observed when increasing the number of hidden nodes. The window sizes for training the word embedding and sequence labeling were fixed at 11 and 5, respectively. All DNN parameters were updated using the standard stochastic gradient descent through back propagation.

Results

Table 2 shows the performance on the test dataset for the CRFs, the DNN with random initialized word embedding, and the DNN with word embedding derived from the unlabeled corpus. All evaluation scores were based on exact-matching criteria. At the minimal feature setting, the baseline method (CRFs) achieved an F-1 score of 0.9197. The DNN with randomly initialized word embedding achieved an F1-score of 0.9071, which was not better than the baseline performance. The F-1 score of the DNN approach was remarkably improved to 0.9280 by using the word embedding derived from the unlabeled corpus. The best DNN-based NER system outperformed the CRFs by more than 0.8% on F1-score. The Wilcoxon test showed that the best DNN-based NER system outperformed the CRFs with a significant p-value of 1.832e-07. Table 3 shows the performance of the best DNN system for each entity type. The DNN system with word embeddings achieved the highest F1-score of 0.9489 for lab tests and the lowest F1-score of 0.8113 for procedures.

Table 2 – Performances of machine learning methods

	Precision	Recall	F1-score
CRFs	0.9265	0.9130	0.9197
DNN	0.9007	0.9136	0.9071
DNN+Embedding	0.9237	0.9321	**0.9280**

Table 3 – Performances for each entity type (DNN + embedding)

	Precision	Recall	F1-score
Problems	0.9267	0.9356	0.9311
Procedures	0.8119	0.8107	0.8113
Medications	0.8604	0.8366	0.8483
Lab Tests	0.9427	0.9553	0.9489

Discussion

In this study, we examined a novel deep learning method for NER tasks in Chinese clinical text. When only word feature was used, our DNN-based NER system that utilizes word embeddings derived from another unlabeled corpus achieved better performance than the traditional CRF-based NER system, indicating the potential of using DNN for clinical NER in Chinese clinical documents. To the best of our knowledge, this is the first study that investigated deep learning technologies for NER tasks in clinical documents written in Chinese.

We conducted further analysis of the DNN-based NER system and found that the performance improvement was from the semantic information automatically captured by the DNN-based word embeddings. Table 4 shows some examples of semantically related words captured through word embeddings. The nearest neighbors were derived by calculating the cosine similarity using word embeddings. Most of the neighbors in Table 4 are related to the target words, and such semantic relatedness was captured in the embedding space. However, they may not have any relation in the representation space like bag-of-words.

Table 4 – Examples of nearest neighbors captured in word embeddings

一 (one)	左 (left)	肢 (extremity)	喉 (larynx)
三 (three)	右(right)	颌(jaw)	颞(temporal)

As NER is an extensively studied task in NLP, many types of features, including the orthographic information, the prefix and suffix, part-of-speech (POS) tags, syntax from parse trees, and existing knowledge bases, have been proved to be useful. On the same dataset, the state-of-the-art CRFs-based NER system that was optimized through manual feature engineering could achieve the best F1-score of 0.9353 [21], which was higher than the DNN-based NER developed in this study. However, the DNN-based NER approach uses word feature only and it requires a minimal effort on feature engineering. The simplicity of the DNN-based approach not only reduces human time on feature engineering, but also makes the implementation of NLP systems easier. For example, obtaining syntax features by parsing sentences could be time consuming and sometimes not feasible in certain real-time applications. However, by using DNN-based approaches, an NER system could still achieve reasonable performance even without running parsers to get the syntax features. Moreover, we believe that the unsupervised feature learning from large unlabeled corpora would significantly reduce NLP researchers' time on task-specific feature engineering, thus enabling efficient development of NER systems for different tasks in various domains.

In the future, we plan to investigate different approaches to further improve the performance of DNN-based NER systems for Chinese clinical text. A straightforward approach is to increase the size of the unlabeled clinical corpus, as previous work has shown that the DNN model benefited from a larger unlabeled corpus. For example, Collobert et al. used the entire English Wikipedia and the Reuters corpus to derive word embeddings. Another appealing research direction is to integrate other linguistic or domain-specific features with the DNN model built on word embeddings to further improve the performance. A previous study by Wang et al. [31] revealed that low dimension continuous space representation works significantly better in DNN than in the traditional systems (e.g., CRFs). However, high dimension discrete feature representation works better in the traditional systems than in the DNNs. Incorporating the high dimension discrete features into the deep neural network remains a challenge. Recent research from Ma et al. [32] showed that the performance of DNN based POS tagging system can be improved by combining a dense embedding feature based neural network with a discrete feature based neural network using a shared output layer. We will further investigate new methods that could combine the two types of feature representations in the future.

Conclusion

In this study, we investigated deep neural network for NER from Chinese clinical text. Our results showed that DNN outperformed CRFs at the minimal feature setting, achieving the highest F1-score of 0.9280. Further analysis showed that the performance improvement was from the semantic information automatically captured by the DNN-based word embeddings, indicating the usefulness of unsupervised feature learning.

Abstract

About 1 in 10 adults are reported to exhibit clinical depression and the associated personal, societal, and economic costs are significant. In this study, we applied the MTERMS NLP system and machine learning classification algorithms to identify patients with depression using discharge summaries. Domain experts reviewed both the training and test cases, and classified these cases as depression with a high, intermediate, and low confidence. For depression cases with high confidence, all of the algorithms we tested performed similarly, with MTERMS' knowledge-based decision tree slightly better than the machine learning classifiers, achieving an F-measure of 89.6%. MTERMS also achieved the highest F-measure (70.6%) on intermediate confidence cases. The RIPPER rule learner was the best performing machine learning method, with an F-measure of 70.0%, and a higher precision but lower recall than MTERMS. The proposed NLP-based approach was able to identify a significant portion of the depression cases (about 20%) that were not on the coded diagnosis list.

Depression; Natural Language Processing; Text Classification; Machine Learning'

Introduction

Nearly 1 in 10 adults in the United States have been reported as suffering from clinical depression [1] and similar percentages are reported worldwide [2]. The associated personal, societal, and economic costs are significant [3]. In the U.S., over 15% of depressed people commit suicide, accounting for 30,000 deaths each year. Annual economic consequences are estimated at $83 billion in the U.S. due to higher healthcare utilization and decreased worker productivity [4]. People who have suffered from chronic diseases such as heart disease or diabetes are at greater risk for depression than the overall population. Importantly, those with both depression and other chronic diseases also have worse health outcomes and significantly increased costs compared to their non depressed counterparts [5]. Recently, depression has also been recognized as a major hospital readmission risk factor, and the 30-day readmission rate for mood disorders has been reported at about 15% [6]. A recent study found that 16% of hospitalized adult patients screened positive for mild depressive symptoms and another 24% for moderate or severe depression [7].

Fortunately, most patients with depression can be reliably diagnosed and successfully treated by non-specialists. Only a fraction of patients with major depression require more complex interventions by mental health specialists [8]. Research shows that about 80% of patients with depression will improve after first-line treatment [9]. However, a significant portion of patients do not receive or benefit from depression treatments; only one third of depression patients receive treatment and as many as half of depression cases will go underreported or under-diagnosed [10-13]. Because many complex medical conditions (e.g., heart failure, coronary artery disease, and dementia) are comorbid with depression, it is not surprising that many patients with depression are missed or under-treated as these other issues may take priority during a patient visit. Systematic methods to identify at-risk individuals have the potential to improve patient well-being and quality of life as well as decrease morbidity and suffering.

One strategy to improve this under-treatment is appropriate documentation of a depression diagnosis in electronic health records (EHRs) to better identify depressed patients; and provide evidence-based treatment in a timely fashion. However, emerging evidence shows that using only structured EHR data (such as diagnoses and medications), which are mostly collected for billing purposes, often identifies only a fraction of all documented depression patients. Rather, much of the depression related information is documented in clinical notes [14]. As a result, we need new strategies to more consistently identify depressed patients, particularly those with comorbid medical conditions. Modern information technology methods, such as natural language processing (NLP) can potentially improve the identification and treatment of depression, as well as enable more accurate quality metrics and support new care models targeted at high-risk patients.

Early evidence suggests that NLP methods may be very effective. Few previous studies have focused on the application of NLP technologies to extract psychiatric and mood disorder information from clinician notes [14-16]. A recent study created and validated an NLP application to extract symptomatic remission and treatment resistance information from outpatient psychiatric provider notes for patients with major depressive disorder [15]. Another pilot study has used Twitter data to identify mental health

symptoms for several conditions, including depression [16]. Fischer et al [14] identified depression among diabetes patients using an NLP-based approach by recognizing depression terms and negations from office notes. The authors compared these extracted cases with administrative database codes and found that almost a third more depression cases were identified through NLP only.

The goal of this study is to identify patients with depression using discharge summaries by applying a general NLP system and machine learning classification algorithms. This work is a part of two greater efforts: one study is using NLP to improve patient problem lists by identifying depression diagnoses from free-text notes; and the other utilizes unstructured data from clinical narratives to identify patients at high risk for hospital readmission, augmenting existing methods based on structured administrative data. Depression is of particular interest because it is a risk factor that can enhance the predictive power of existing models of risk-stratification.

Methods

Our methods are summarized in Figure 1. We first manually reviewed a random sample of discharge summaries, identified depression cases, and created a gold standard with the help of domain experts. We then trained and tested our NLP system (known as MTERMS [17]) and classification algorithms. Finally, we assessed our automated approach by comparing system-generated classification against the gold standard. We also compared depression cases extracted from free-text data versus coded diagnoses.

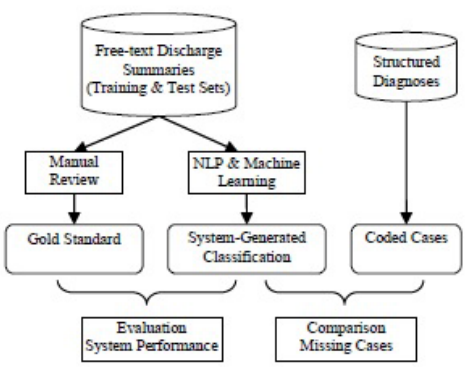

Figure 1-Methods Overview

Data Collection

We used a retrospective cohort of patients from our readmission study. Patients in this cohort had a history of ischemic heart disease. They were hospitalized between 01/01/2011 and 12/31/2013 at different hospitals in Partners HealthCare, a large integrated healthcare network in Boston, Massachusetts, US. We randomly selected 1,200 patients, each with one discharge summary. We then randomly selected 600 discharge summaries for training and used the remaining 600 for testing. At these institutions, discharge summaries include a complete copy of admission note, as well as standard discharge summary information including detailed hospital course, discharge medications, and plan of care.

Identifying Depressed Patients

A pharmacy doctoral student in consultation with an internal medicine physician reviewed both training and testing cases. They classified these cases as depression with high, intermediate and low confidence, based on information in the discharge summary. Twenty randomly selected patient medical records in each classification category were reviewed by one of the clinician authors. This was to validate each category and confirm whether there was enough clinical evidence in the record to support a diagnosis of depression. These findings were then used by the research group to modify our classification algorithms introduced below as needed.

- **High confidence** cases were asserted when depression diagnosis terms were present in notes (e.g., depressive disorder or depression was listed in Past Medical History), indicating a history of depression.
- **Intermediate confidence** cases were identified when combinations of antidepressant treatment (e.g., medications for depression), psychiatry consultation (e.g., referrals to a mental health specialist), or depressive symptomatology were documented. Combinations of above situations can provide clinicians with more information than singular instances when reviewing notes. More specifically, intermediate confidence cases were identified when one of the following scenarios were mentioned in discharge summaries: 1) at least one depressive symptom (e.g., suicidal ideation) and a psychiatric consult was involved (e.g., psychiatry was consulted); 2) at least one symptom of depression was present and an antidepressant medication was prescribed (e.g., citalopram) that did not have an indication in instructions for another problem (e.g., for insomnia); 3) an antidepressant medication was present that did not have an indication in instructions for another problem and a psychiatric consult was involved.
- **Low confidence** cases were asserted when depression diagnosis terms or synonyms were absent and none of the criteria for intermediate confidence case were satisfied. The lack of documentation related to depression cannot exclude a history of depression, but in the scope of discharge notes these were considered as negative or unknown cases.

NLP and Classification Algorithms

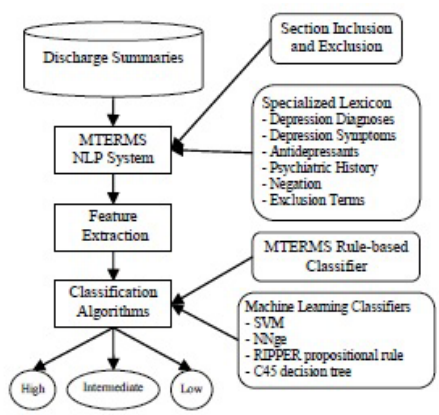

Figure 2 - Overview of NLP and Classification Algorithms

As shown in Figure 2, we first used the MTERMS NLP system [17] to identify relevant sections of the discharge summaries. We included sections that contained medical history, diagnoses, and treatments (e.g., "History of Present Illness", "Social History", "Assessment" and "Medication"). We excluded sections such as "Discharge Instructions", which may mention depression-related terms but do not indicate that the patient actually has depression (e.g., "Call your doctor if you have...suicidal feelings...").

We then created a specialized lexicon containing terms related to depression. For depression diagnoses (e.g., "depression", "depressive"), we used terms that SNOMED-CT (September 2014 Release) classified as preferred terms and synonyms of depression [18]. We identified a list of symptoms (e.g., "insomnia", "suicidal ideation") from criteria listed in Diagnostic and Statistical Manual of Mental Disorders, 4th Edition (DSM-IV) [19] and phrases derived from the Patient Health Questionnaire – 9 (PHQ-9) [20], as well as from our previous clinical experience. We used a list of antidepressants (e.g., "amitriptyline", "citalopram") provided by Lexicomp [21], augmented with brand names from the National Library of Medicine's DailyMed website [22]. We also included terms related to a patient's psychiatric history (e.g., "counselor", "psychotherapist"), that we found previously. In addition, we identified terms related to medical electrocardiogram (EKG) findings (e.g., "ST depression") that we found in the training data, since they often contain the word "depression" but are not related to mood disorders. We used MTERMS to extract terms in our specialized lexicon as well as negation terms (e.g., "denies", "no", and "absent").

We then used these terms as features for our classification algorithms, experimenting with both rule-based (within MTERMS) and machine learning classifiers. For machine learning classifiers, we used Weka open-source toolkit [23]. We used 10-fold cross-validation on the training set to select the four best-performing machine learning algorithms to compare on the test set: a support vector machine (SVM) using sequential minimal optimization algorithm [24], a generalized nearest neighbor (NNge) classifier [25], a Repeated Incremental Pruning to Produce Error Reduction (RIPPER) propositional rule learner [26], and a C4.5 decision tree learner [27]. We also manually created a decision tree using Weka's interactive UserClassifier (see Figure 3). At each vertex of the tree, we chose the feature that splits training data most accurately, as long as it was consistent with our clinical knowledge. For example, rules such as "if a symptom is negated, then classify as depression with high confidence" were considered idiosyncrasies of training data, and were therefore not included. We subsequently incorporated our decision tree into MTERMS' classification logic.

System Performance Evaluation

We used standard metrics to evaluate system performance which included precision (p), recall (r), and the F-measure (f). For each category (high and intermediate confidence cases), let TP, TN, FP, and FN be number of true positives, true negatives, false positives, and false negatives, respectively. Then p=TP/(TP+FP), r=TP/(TP+FN), and f=2pr/(p+r). The F-measure is harmonic mean of precision and recall represents their combined quality.

Comparison of Coded vs. Free-text Identification of Depression Patients

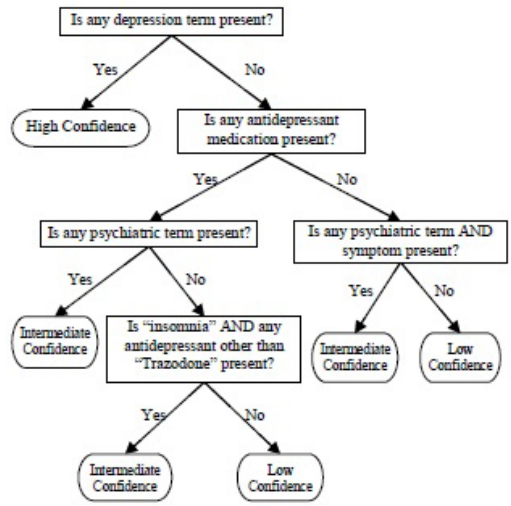

Figure 3- A Knowledge-based Decision Tree

In order to measure how the NLP-based approach in addition to using structured data can enhance the detection of depressed patients, we calculated the percentage of cases that were additionally identified by our NLP system. Coded identification was done with structured diagnosis data which was retrieved from inpatient discharge diagnoses as well as patient problem lists from our outpatient EHR system, when available. We also compared the discrepancies between these data sources.

Results

System Performance

The gold standard established by manual review indicated that out of 600 training cases, 89 depression cases were identified with high confidence and 22 with intermediate confidence; out of 600 test cases, 79 were identified with high confidence and 31 with intermediate confidence. On high confidence cases, all of the algorithms we tested performed similarly; with MTERMS' knowledge-based decision tree slightly better than the machine learning classifiers, achieving an F-measure of 89.6%. MTERMS achieved highest F-measure on intermediate confidence cases, 70.6%. The RIPPER rule learner was the best performing machine learning method, with an F-measure of 70.0%, and a higher precision but lower recall than MTERMS. Full results on our test set are shown in Table 1. The confusion matrix for our knowledge-based decision tree is shown in Table 2.

Comparison of Coded vs. Free-text Data

Using both coded diagnoses and discharge summaries, 140 (23.3%) of the 600 patients in the training set were identified with depression with high confidence, while depression rate in test set was 20.8%, as shown in Table 3.

Even though about 80% of diagnoses were documented in structured data, a significant portion of diagnoses (approximately 20%) were only mentioned in discharge

summaries that were identified by our NLP system. Additionally, for cases identified with intermediate confidence from discharge summaries, more than a quarter (6 of 22 cases in training set and 8 of 31 in test set) were documented in coded diagnosis list, indicating that those intermediate cases that were not on the diagnosis lists may help capture more depressed patients and serve as a good screening candidate for depression.

Table 1- System Performance on Test Set

		High confidence (n=79)			Intermediate confidence (n=31)		
		Precision	Recall	F-measure	Precision	Recall	F-measure
MTERMS decision tree		86.9%	92.4%	89.6%	64.9%	77.4%	70.6%
Machine learning methods	C4.5	87.8%	91.1%	89.4%	64.0%	51.6%	57.1%
	NNge	87.8%	91.1%	89.4%	75.0%	29.0%	41.9%
	RIPPER	85.7%	91.1%	88.3%	72.4%	67.7%	70.0%
	SVM	86.7%	91.1%	88.9%	65.2%	48.4%	55.6%

Table 2-Confusion Matrix for our Knowledge-based Decision Tree

Gold Standard	Knowledge-based Deision Tree		
	High confidence	Intermediate confidence	Low confidence
High confidence	73	2	4
Intermediate confidence	1	24	6
Low confidence	10	11	469

Table 3- Depression Cases Identified using both Coded Diagnoses and NLP

	Coded Diagnoses n (%)	Discharge Summaries & NLP* n (%)	Total Patients with Depression n (%)
Training Set	114 (81.4)	26 (18.6)	140 (23.3)
Test Set	99 (79.2)	26 (20.8)	125 (20.8)

**cases only mentioned in discharge summaries and identified by NLP*

Discussion

This study applied NLP and machine learning classification algorithms to identify clinical depression cases based on discharge summaries. We found a high (over 20%) prevalence of depression among hospitalized patients with a history of ischemic heart disease, consistent with clinical observations that acute myocardial infarction is associated with high risk for on-going depression. Compared to the structured problem list, our automated approach identified about 20% additional depression cases. In Fischer's study [14], 10% of diabetes patients were identified with depression using both administrative data and an NLP method, and an additional 5.3% were identified through NLP alone. While other studies [28] used structured EHR fields (such as billing diagnoses, problem list and medication list) to identify a diagnosis of depression by the primary care physician, our approach can serve as a complementary means to recognize additional cases, particularly in high-risk individuals such as those with ischemic heart disease.

Our study used discharge summaries which are primarily focused on acute medical problems related to the reason for admission. While depression was often clearly documented as a medical problem, we could not always confirm this diagnosis using more comprehensive criteria such as DSM-IV diagnostic criteria or positive results on the PHQ-9 due to limitations in documentation, even when accessing the full medical record. A few previous studies have used psychiatric notes for identifying depression patients. However, most studies do not have access to psychiatric notes, which are often blocked to other providers or are in a separate medical system because of their sensitive content; an algorithm based on this kind of note has limited generalizablity. Our study used a much more pragmatic approach by utilizing a common and readily available type of clinical note; therefore, our methods can be easily replicated within hospitals or primary care practices. By focusing on discharge notes, we also identify patients in a particularly vulnerable time window – after an acute event requiring hospitalization and within the post-discharge period.

Our system achieved an F-measure of 89.6% in identifying high confidence cases and 70.6% for intermediate confidence cases. MTERMS' performance was slightly better than machine learning classifiers. Recall was higher than precision (92.4% vs. 86.9% for high confidence cases and 77.4% vs. 64.9% for intermediate confidence cases), which indicates that such a system will be useful for retrieving relevant instances. Identified cases can then be reviewed by clinicians and researchers. By examining the classification errors made by the system, we found that there were several cases in which our knowledge-based system classified a patient who did not have depression as depressed with either high or intermediate confidence. In some of these false positive cases, a depression-related term was negated, but the negation was outside our NLP algorithm's scope. For example, in the sentence "Negative for fevers / chills / sweats / ... (many other symptoms) ... / depression / ...", the word "depression" was extracted because the negation was too far away. In other cases, depression-related words were used to describe non-mood disorders (e.g., "mild depression of the lateral tibial plateau", "moderate depression of systolic function"). Our lexicon was able to correctly discover some but not all of these phrases. In addition, there were a few cases in which a patient possibly having depression with intermediate confidence was not identified by our system. These false negative cases occurred mainly because the system did not identify symptoms outside our lexicon (e.g., "becomes angry / altered mood"). Our study has a few limitations. First, we only used clinical narrative reports from a single institution's EHR system, thus our results may not be generalizable to other healthcare institutions. We may also have missed terms that physicians use in other institutions. Use of unsupervised algorithms to identify these other terms may be helpful in the future.

Second, we only used discharge summaries. Future work will include applying our system to other types of clinical notes, such as clinic visit notes in outpatient settings. Lastly, patients included in this study had ischemic heart disease and hence results may vary for a general patient population.

An Approach for Automatic Classification of Radiology Reports in Spanish

Viviana Cotik[a], Darío Filippo[b], José Castaño[a]

[a] *Departamento de Computación, Facultad de Ciencias Exactas y Naturales, Universidad de Buenos Aires, Argentina*
[b] *Hospital De Pediatría, Prof. Dr. Juan Pedro Garrahan, Argentina*

Abstract

Automatic detection of relevant terms in medical reports is useful for educational purposes and for clinical research. Natural language processing (NLP) techniques can be applied in order to identify them.

In this work we present an approach to classify radiology reports written in Spanish into two sets: the ones that indicate pathological findings and the ones that do not. In addition, the entities corresponding to pathological findings are identified in the reports.

We use RadLex, a lexicon of English radiology terms, and NLP techniques to identify the occurrence of pathological findings. Reports are classified using a simple algorithm based on the presence of pathological findings, negation and hedge terms.

The implemented algorithms were tested with a test set of 248 reports annotated by an expert, obtaining a best result of 0.72 F1 measure. The output of the classification task can be used to look for specific occurrences of pathological findings.

Keywords:

Natural language processing; Radiology reports; Pathological findings, Negation detection; Text classification.

Introduction

Automatic detection of relevant terms in medical reports is useful for educational purposes, for clinical research and for comparison of findings between institutions.

According to [1], approximately half of the medical conditions described in the medical domain are negated. There also exist hedges (uncertain facts). Being able to differentiate which conditions are present and which are absent in a medical report is a current topic in the area of natural language processing (NLP) [2,3].

We describe here an approach to identify reports containing pathological findings. We work on a set of medical reports of imaging studies (usually called *radiology reports*) in Spanish. Identifying which reports contain pathological findings will allow the indexing of relevant documents only and discard those which are not relevant (do not contain pathological findings).

In order to test the results of our classification algorithm we use a Test Set annotated by a radiology physician, one of the authors of this paper. The Test Set consists of 248 ultrasonography reports that are annotated indicating medical findings and their anatomical location. We obtain an F1 of 0.72, a recall of 0.83 and a precision of 0.63.

We use NLP tools and techniques such as lemmatization, frequency of bigrams and trigrams, part-of-speech tagging (POS tagging), and hedge and negation tagging, in order to process our data. We also used a radiology ontology. Then we tested some simple algorithms to determine whether there is a factual pathological finding in a report.

There exist different ontologies, terminologies and coding systems in the medical domain such as SNOMED CT[1], MeSH[2], ICD-10[3], LOINC[4], UMLS[5] and RadLex[6]. The latter has specifically been developed to satisfy standardized indexing and retrieval of radiology information. It satisfies the needs in this domain by adopting features of existing terminology systems as well as producing new terms to fill critical gaps. It unifies and supplements other lexicons while it also has mappings to them. However, there is no radiology ontology or machine readable dictionary data that can be used to identify terms that denote pathological findings in Spanish. Using a machine translation from an English ontology presents a number of difficulties:

- Some terms frequently used in Spanish with synonyms are less frequently used in English. For example *arteria mamaria interna* for *internal mammary artery* is commonly used in Spanish, while in English it is referred to as *internal thoracic artery*.
- Sometimes adjectives are preferred to nouns in Spanish. For example, *folículo ovárico* for *ovarian follicle* is commonly used, while in English *follicle of ovary* is the preferred term.
- Terms of interest can be composed of more than one word, which often leads to problems in the order of the translated words.

We use RadLex as the main source of information to detect pathological findings.

Given the amount of annotated text is small, it is not possible to use machine learning (ML) techniques to improve the classification algorithm.

Current results enable physicians to quickly detect diagnoses in the reports and, in the future, images related to them. These

results are planned to be used by physicians in a public hospital in Argentina.

Related work

There are several works addressing related problems. There are existing systems process texts in English and there is some work performed for German.

Khresmoi project[7] uses information extraction from unstructured biomedical texts in a cross-lingual environment. They used RadLex.

MoSearch [4], RADTF [5] and Render [6] allow searching for terms in radiology reports taking into account negation and modality information and using NLP techniques. In the last two, results are linked with images from a picture archiving and communication system (PACS). In RADTF, if the user searches for a RadLex term, it returns its RadLex id. They are mainly used for education and research.

RadMiner [7] retrieves images in radiology reports based on NLP techniques. Bretschneider et al. [8] use a grammar-based sentence classifier to distinguish 'pathological' and 'non-pathological' classes. They report 0.74 recall and 0.54 precision measures. Both are implemented for German and use a German available version of RadLex as a linguistic resource. RadMiner adds new terms taken from the annotation performed by a specialist.

MetaMap [9] recognizes UMLS concepts in medical texts written in English.

Bioportal[8], a repository of biomedical ontologies, provides a tool that tags text based on an ontology selected by the user. There are no Spanish ontologies available. A UMLS semantic type can be selected.

LEXIMER [10] uses information theory to classify English radiology reports on the basis of the presence or absence of positive findings. They report precision of 0.98 and recall of 0.99.

Negex[1] is a simple algorithm to identify negations in medical texts written in English. It has been implemented in several languages [3,11,12]. Diverse techniques, such as pattern matching, machine learning and a combination of techniques have been applied to negation identification [2,13,14]. Some challenges have been performed: 2010 i2B2/VA Challenge for clinical text[9], ConLL 2010 for biomedical texts[10], and BioNLP 2009 for biological texts[11].

As far as we are aware of, there are no available systems that identify RadLex terms in Spanish radiology reports.

The rest of the paper is organized as follows. The Methods section presents the approach used in this work as well as data, specific techniques and tools used. The Results section explains metrics and shows current results. Final sections are Discussion and Conclusions.

Methods

The proposed solution is composed of several interconnected but independent modules (see Figure 1).

The *syntactic analysis* module does segmentation, lemmatization, normalization and POS tagging as well as parsing. The *entity recognition* module does dictionary lookup, non-exact recognition, and the *hedge* module identifies hedges and negations. Finally, the classification module classifies texts based on the results of previous modules.

The output of these modules is used with the available data to identify pathological findings that might be of interest for physicians.

In the rest of this section we explain in detail the components of each module and the data used. RadLex data has to be obtained, filtered and translated to Spanish. We explain how we filtered the data, and the translation methods used. We also present the annotation process performed by a specialist, and finally, the methods and techniques used to perform each test.

Figure 1–Modules of the proposed solution

Data

We have about 130,000 medical reports from three different studies: ultrasonography (US), computed tomography (CT) and magnetic resonance imaging (MRI). Table 1 shows the number of available reports of each type.

Table 1– Number of reports available of each type of study

Type of Study	Number of Reports
MRI	14635
CT	29327
US	85621

Reports are in non-structured format (the first part is semi-structured). They are brief (approximately 5 lines each) and they state what was found in the study performed on the patient. An example of an annotated ultrasonography report can be seen in the Annotation section.

RadLex, has different versions[12]. We decided to use version 3.6 since it has improvements over the previous ones and it has been used in other works, such as Bioportal, which allows us to compare results. Furthermore, it is being translated by physicians. Version 3.6 has more than 30,000 terms, that are classified[13], among others, by *imaging modality*, *procedure*, *object*, *imaging observation*, *non-anatomical substance*, *anatomical entity* and *clinical finding*. We selected the terms corresponding to *clinical findings* (what we call pathological findings) and *anatomical entity* type (see the section Technical Details).

Translation

As far as we know, there is no complete RadLex translation to Spanish (the translation mentioned in RadLex reference[14] is partial and not every term is precise). In order to be able to use RadLex with Spanish text we had to obtain a translated version.

All RadLex terms were translated to Spanish with Google Translate[15]. We also used 1) a mapping of RadLex and UMLS terms and through UMLS we obtained the corresponding translation of RadLex terms and 2) a mapping

of English-Spanish Wikipedia[16] terms. Table 2 shows the number of terms translated using different types of translation sources.

Table 2– Number of English-Spanish RadLex translated terms. The second column refers to the number of RadLex terms translated, and the third column to the number of RadLex terms translated of pathological and anatomical type.

Source of translation	Number of RadLex terms	Anat. and pathological terms
Google Translate	30,000	10,357
UMLS	1304	857
Wikipedia	1620	896

In the Entity Recognition section we explain how we used the translations obtained from different sources.

Preprocessing and syntactic analysis

In the syntactic analysis module all the words of radiology reports were normalized. Freeling[17] was used to perform tokenization and lemmatization. We also used Python[18] to process all radiology reports to obtain frequency of words (unigrams), bigrams, and trigrams.

Entity recognition

In order to detect anatomical and pathological entities, we identified in the reports words that are part of some RadLex term. For example: *vessel* does not appear as a RadLex term but is part of more than 100 RadLex terms (as in *blood vessel*), so the term is included as a *term of interest* to be identified in reports.

Each word appearing in a RadLex term was indexed using an inverted index. Each word in the inverted index points to a set of RadLex terms in which the word occurs. Each RadLex term in this set contains their entity class information, i.e. whether they are anatomical or pathological. Using this information, the entity class is assigned to the indexed word. Then, for each report a decision is automatically made to decide whether the word is a single or multi-word term, and the resulting term is tagged with its entity class. In this step stop words are not considered.

The output of this module is the radiological report with the anatomical and pathological terms automatically annotated according to RadLex terms. A set of common pathological terms compiled by the radiologist is also used to identify *interesting* terms in reports.

All the pathological terms identified in the set of 129,583 reports were stored and the most frequent ones were analyzed. Some of them did not appear to be pathological, so we analyzed bigrams and trigrams containing them and the inverted index in order to check if they were incorrectly tagged as pathological findings. We compiled another dictionary with those terms that we considered to be non-pathological, and we used this dictionary to filter out these terms in the tagging process.

Negation and hedge detection

To detect negated terms and hedge signals we compiled a set of negations and a set of hedges (based on a translation to Spanish of RADTF negations and hedges). These two sets of words were used in a simple dictionary lookup to tag these words in the reports. This is very similar to the approach used by NegEx[1]. If one term is contained in another we get the largest of the two terms, for example if *no* and *no se encontró* are in the negation dictionary and *no se encontró* is in the report we will tag this phrase, rather than the phrase *no*.

Classification

Reports are tagged with pathological entities, negations and hedges. Only those reports that contain positive findings are considered relevant. We defined three simple algorithms in order to determine it.

- Algorithm 1. If there is some pathological finding in the report we identify the report as pathological. It is not taken into into account whether or not there are negations in the text.
- Algorithm 2. If there is a pathological finding identified in the report and there is a negation or hedge somewhere in the report (might be in another sentence), the report is identified as non-pathological.
- Algorithm 3. A report is identified as pathological only if it has at least one sentence with a term indicating a pathological finding and no negation or hedge (in the same sentence).

Annotation

In order to test the results of our classification algorithms, we needed some annotations performed by an expert. We elaborated annotation guidelines stating the criteria to be used for the annotations. A number of annotation-revision iterations were performed until the annotations were as expected. Three experts annotated two sets of 17 and 12 reports. The F-measure of the annotations agreement was 0.7. Once the final version of the annotation guidelines was defined, a radiologist annotated 248 ultrasonography reports with the Callisto[19] annotation tool. These 248 reports were used as a Test Set to evaluate the strategies we implemented. Each report was automatically searched for the presence of *pathological findings* annotations, and based on this it was classified as pathological (if there was at least a pathological finding annotated in the report) or non-pathological (if there was no pathological finding annotated in the report).

An example of an annotation in Spanish and it's translation to English can be seen below:

33289|16a4m|20070807|A27611 HIGADO:<RADLEX> lobulo caudado aumentado de tamano</RADLEX>, resto de higado de ecoestructura conservada. VIA BILIAR intra y extrahepatica: no dilatada. VESICULA BILIAR: alitiasica. Paredes y contenido normal. PANCREAS: tamano y ecoestructura normal. <RADLEX>BAZO: minimamente aumentado de tamano</RADLEX>. Diametro longitudinal:13.5 (cm) RETROPERITONEO VASCULAR: sin alteraciones. No se detectaron adenomegalias. No se observo liquido libre en cavidad. Ambos rinones de caracteristicas normales.

33289 |16y 4m |20070807|A27611 LIVER: <RADLEX> caudate lobe with increased size </ RADLEX>, the other lobes of the liver appear normal. Intra and extrahepatic BILIARY TREE: not dilated. GALLBLADDER: no gallstones were seen. Wall and content appear normal. PANCREAS: normal size and echotexture. <RADLEX> SPLEEN: minimally increased in size </ RADLEX>.

[19] Callisto annotating tool http://annotation.exmaralda.org/index.php/Callisto

Longitudinal diameter: 13.5 (cm) VASCULAR RETROPERITONEAL COMPARTMENT: unremarkable. No lymphadenopathy was detected. No free fluid in the peritoneal cavity was observed. Both kidneys unremarkable.

Technical details

RadLex was downloaded in Protégé format. The selection of anatomical and pathological RadLex has been performed with the help of the tutorial performed by MantasCode[20].

Freeling was used for the syntactic analysis module and Python for implementing the remaining modules.

Results

Table 3 shows the results of evaluation of the three algorithms used to identify reports containing pathological findings against the Test Set. As a reference we describe formulas of calculated metrics. They are accuracy (acc): (TP+TN)/(TP+FN+FP+TN), precision (prec): (TP/(TP+FP)), recall: (TP/(TP+FN)), F1: 2*(prec * recall)/ (prec + recall).

Table 3 – Results of comparison of three algorithms with the Test Set. Algorithm 1: negations are not taken into account. Algorithm 2: negations are taken into account on a report basis. Algorithm 3: negations are taken into account on a sentence basis. References: acc.: accuracy, prec: precision, alg.: algorithm TP: true positives, FN: false negatives, FP: false positives, TN: true negatives.

Measure	alg. 1	alg. 2	alg. 3
acc.	0.60	0.57	**0.67**
prec.	0.56	**0.74**	0.63
recall	**0.96**	0.25	0.83
F1	0.71	0.38	**0.72**
TP	122	32	106
FN	5	95	21
FP	95	11	62
TN	26	110	59

Discussion

Algorithm 3 is the one with best results, since it has the best F1 (a measure that balances precision (those identified as positive and how many are really positive) and recall (the proportion of the positive findings that were retrieved) and the best accuracy (rate of correctly classified documents)). Algorithm 1 has naturally a greater amount of TP, but also of FP, that are decreased with Algorithm 3. This is consistent with the algorithm used because all the findings were tagged independently of the occurrence of negations or hedges.

These results show that there is room for improvement, in particular regarding precision results, and they are promising considering that we are working with very noisy data given that terms used to identify pathological findings were obtained through automatic machine translation. We can assume that as a first step to identify reports with pathological findings, the results are good.

LEXIMER has better results for English and our work has better results than that of Bretschneider et al. for German, but in both cases the results are incomparable, since they have been obtained with different data and for different languages.

Conclusion

Although there are tools that generate structured radiology reports aiming at easier information retrieval, unstructured text is still preferred by most radiologists. It allows a better formulation of their ideas, and writing the report as a continuum, instead of doing it with check boxes and templates [15]. Given that situation, NLP is incorporated as a promising resource for information extraction in this context.

Identifying the frequency of findings and diagnoses found in the different imaging modalities, through the use of information extraction from unstructured radiology reports, should improve aspects of diagnosis and patient care within an institution.

The possibility of linking these findings with corresponding images through PACS makes the radiologist's task easier when he has to evaluate studies and prepare reports. It allows comparison with previous studies that may have similar findings. This set of images and text provide an excellent support for decision making.

We are not aware of existing solutions for Spanish reports. Once the work is finished it could be used in the reports of other Spanish speaking hospitals.

In terms of NLP, the challenges are the application of existing techniques to Spanish, the non-availability of RadLex in Spanish, and the scarcity of resources (annotations) that do not allow us to use ML techniques to improve the classification algorithm.

Future Work

Currently we are working on a number of subjects: 1) improvement of translations (performed by radiologists). This might provide a resource for achieving better entity recognition in the future, 2) enlargement of the manually annotated Test Set. This will allow us to use ML techniques to improve our classification algorithm. The use of boosting is being considered, 3) detection of scope of negation to improve classification (i.e. knowing what is actually being negated). Dependency parsers and ML techniques can be used to identify the scope of negation and hedges. We are also working on the implementations of Negex to Spanish, and 4) evaluation and improvement of detection of findings. We will compare the results of our algorithm with the use of additional resources, such as SNOMED CT and ICD-10 instead of RadLex.

As future work it would also be important to do automatic anonymization of radiology reports. Information about the physician who performed the study and medical record number of the patient should be removed. It is an important task because we are working with sensitive information. Nowadays we are not working with image information from PACS, but we have the keys to relate the reports to their corresponding images. A separate project is being carried out by other people in order to relate the information extracted from reports with the associated images.

Abstract

Clinical notes contain important temporal information that are critical for making clinical diagnosis and treatment as well as for retrospective analyses. Manually created regular expressions are commonly used for the extraction of temporal information; however, this can be a time consuming and brittle approach. We describe a novel algorithm for automatic learning of regular expressions in recognizing temporal expressions.

Five classes of temporal expressions are identified. Keywords specific to those classes are used to retrieve snippets of text representing the same keywords in context. Those snippets are used for Regular Expression Discovery Extraction (REDEx). These learned regular expressions are then evaluated using 10-fold cross validation. Precision and recall are very high, above 0.95 for most classes.

Keywords:

Electronic Medical Record, Machine Learning

Introduction

Temporal expressions are a special type of named entity. In clinical notes, temporal information is often critical to the interpretation of findings. The time order of events is an essential factor in assessing causation and in evaluating co-occurrence [1]. For example, an adverse reaction to a treatment can only be shown if the reaction occurred after the treatment. Additionally, drug-drug interactions can only be shown if the drugs were taken within the same time frame.. In prior studies that extracted temporal expressions, regular expressions are commonly used [2]. While regular expressions are powerful, they do typically need to be manually created based on chart reviews. This creates a challenge for maintenance and adaptation. In this paper, we describe the use of a simple and novel learning algorithm to discover temporal expressions. While the expressions we discovered are specific to the set of training data employed by this study, the algorithm is generalizable to other training datasets and to other types of expressions.

Background

The temporal information in medical records is important for both clinical decision support and general medical research. This information exists as both structured data and unstructured narrative data. Extraction of temporal information from structured data is trivial but is much harder from the narrative data [3]. For instance, temporal expression extraction was part of the task proposed by the 2012 i2b2 NLP for Clinical Data challenge [4].

Earlier studies have attempted to identify the temporal information using NLP techniques in a simplified form, e.g., "historical" vs. "current" [5,6]. More recent studies have shown that it is feasible to extract the exact temporal expressions from clinical narratives. For example, in one study [7] a system called Med-TTK was developed for detecting temporal expressions in medical narratives by extending an existing system called Temporal Awareness and Reasoning Systems for Question Interpretation Toolkit (TTK) [8]. TTK is an open-source software package developed for extracting temporal information in news articles. The Med-TTK system achieved an overall F-score of 0.85 on a set of 200 U.S. Department of Veterans Affairs (VA) clinical notes. Another study [9] combined rules and machine learning for the extraction of temporal expressions and achieved a micro F-score of 0.90 on a set of 320 clinical notes provided by the 2012 i2b2 challenge.

Methods

Corpus

We used a Pittsburgh EHR dataset (Pitts Data) for this study [10]. Pitts Data is composed of 100,866 de-identified clinical notes and was used in the Text Retrieval Conference (TREC) Medical Track [11], an annual event for encouraging the development of medical information retrieval techniques.

Keyword Identification

An initial set of temporal keywords were constructed from TIMEN, a temporal expression normalization tool [12]. We used 193 keywords that included time of a day, month, season, decade, and holidays. Sample keywords are shown in table 1.

Table 1 – Sample Temporal Expression Keywords

Snippet Extraction

The set of temporal keywords were used to extract a set of snippets from the document corpus. We used snippets to refer to the keyword and the context surrounding the keyword in the document. In this study, each snippet consisted of the matched keyword, the 10 words preceding the keyword in the document, and the 10 words following the keyword in the document. We progressively extracted all snippets containing the keywords from documents until we surpassed our target of 1,000 snippets for annotation. This resulted in an annotation set of 1,008 snippets from 13 documents.

Annotation

Human annotation using VTT [13] was performed to indicate the exact temporal expression in each snippet and the class of the temporal expressions (figure 1). The classes were DATE, TIME, DURATION, SET, and OTHER, with examples given in table 2. The temporal expression was marked in each snippet (referred to as the "labeled segment"), and it's temporal class assigned, by two independent annotators. To reach agreement, two rounds of annotation testing were performed on subsets of data. The kappa for the second round was 94%. Afterwards one annotator performed the annotation for the remaining documents.

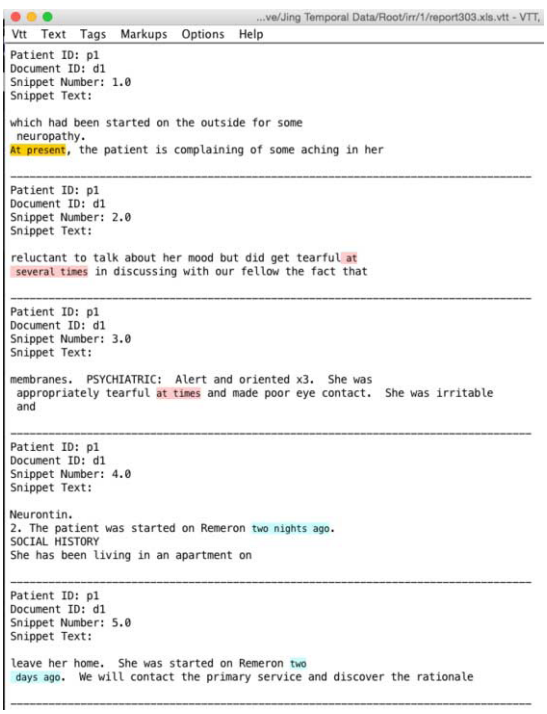

Figure 1 – Sample of VTT annotations.

Information Extraction

We trained a regular expression discovery Extraction (REDEx) algorithm on the annotated snippets. The REDEx algorithm is a novel process we have developed that automatically learns regular expressions that capture the value of the annotated labeled segment and the context surrounding it. We have used previous versions of REDEx for various value extraction tasks, including body weight [14]. We implemented REDEx in Java, making extensive use of the java.util.regex.* core libraries. It is open source and licensed under the Apache License, Version 2.

Table 2 – Temporal Expression Classes

Class	Description	Examples
DATE	Regarding a specific day.	Jan 14 2007
TIME	A specific time point.	14:04:28
DURATION	A period of time.	40 minutes
SET	A set of several temporal expressions.	Monday and Wednesday
OTHERS	Temporal expressions with vague resolution.	past

The current version of REDEx is represented as pseudo-code in Figure 3. Briefly, each annotated snippet was first split into 3 parts: the "labeled segment (LS)", which is the piece of text marked by the annotator; the "before labeled segment (BLS)", which is the text between the beginning of the snippet and the start of the LS; and "after labeled segment (ALS)", consisting of the text between the end of the LS and the end of the snippet (figure 2). Each BLS-LS-ALS triplet was then generalized to a regular expression by replacing all punctuation, whitespace, and digits with corresponding regular expressions: \p{Punct}, \s{1,50}, and \d+ respectively. The BLS-LS-ALS triplets were then iteratively generalized by successive rounds of trimming from the front of the BLS and the end of the ALS until one or more false positives were observed. We interpreted a false positive to be a case were REDEx predicted a value where there was none in the manual annotations. Duplicate triplets were removed, and then the triplets were combined into a single regular expression. The LS was marked as a capture group in order to retrieve the matched value. Sensitivity was then calculated for each regular expression by dividing the count of matched snippets by the total number of snippets.

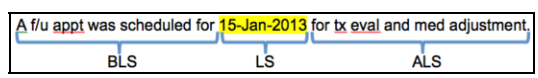

Figure 2 - Before Labeled Segment (BLS), Labeled Segment (LS), and After Labeled Segment (ALS) of a date expression in a phrase.

Evaluation

Evaluation of the regular expressions was performed using 10-fold cross validation, with final scores being the mean of those from each of the folds. Evaluation measures of precision, recall, F1-score, and accuracy were calculated for each class, along with the number of snippets in each class and the number of unique regular expressions generated by REDEx. We defined predictions as true positive (TP) when the regular expressions extracted a value from a snippet that matched the annotated value, false positive (FP) when the extracted value did not match the annotated value, false negative (FN) if the regular expressions failed to extract a value but there was an annotated value, and true negative (TN) if there was not an extracted value and there was no annotated value.

Results

1,008 snippets were extracted for annotation using 193 keywords from the corpus. These snippets were human annotated to identify the temporal expression spans and classified as DATE, TIME, DURATION, SET, or OTHER. Regular expressions and their sensitivities were then automatically generated using the RED extraction algorithm for each class. Samples of the resulting regular expressions are shown in table 3.

Evaluation measures of precision, recall, F1-score, accuracy, number of snippets in each class, and the number of unique regular expressions generated by REDEx are presented in table 4. Evaluation metrics were very high in most cases. Date, Time, and Set classes were all ≥ 0.97 for precision. Recall was ≥ 0.96 for Date, Time, Duration, and Other. The only measures below 0.90 were for the Set class, where recall and accuracy were 0.83 and the sample size was very small at 18.

Table 3 – Examples of REDEx Regular Expressions

Class	Regular Expression

Figure 3 - Pseudo-code describing the RED Extraction algorithm

Discussion

This study has demonstrated the feasibility of automatically discovering temporal expressions. Given the moderate amount of training data, we were able to achieve a very high level of sensitivity and specificity. The machine-generated expressions are humanly readable, though often not as succinct as the expression a senior programmer would have written. It is also worth noting that, the REDEx algorithm does not require seed patterns to begin with.

The REDEx algorithm can be applied to other use cases as well. We have, for instance, used REDEx to extract weight value and unit, with the same level of sensitivity and specificity as for temporal extraction [14]. When using REDEx, we trade the time required for writing and testing regular expression with the time required for annotation. In the use cases of temporal information and weight value/unit, we found the trade-off to be a beneficial. In these two cases,

research assistants and researchers who do not have programming knowledge did the annotations very quickly (100 to 150 annotations/hour after the inter rater agreement is established). The amount of time it takes REDEx to generate expressions was trivial comparing to the manual generation of expressions, thus REDEx can potentially incorporate many more examples. The development of REDEx itself did take time. It, however, can be re-used. For the purpose of future maintenance, we felt that it would be much easier to create additional annotations than to manually revise the expressions.

There are many machine learning algorithms for text classification, including for context classification. There are considerably fewer learning algorithms that we can readily use for the discovery of specific (regular) patterns. With REDEx, we can learn to recognize sequential patterns with numbers, symbols and letters. Although developed and evaluated using the English alphabet, this should be directly applicable to other Latin alphabets using Arabic numerals.

The Pitts dataset used for training and testing is relatively uniform. Our concern is that it does not contain sufficient variations of the temporal expressions. We plan to extend the learning and testing to other clinical notes and create a larger set of temporal expressions. In addition, we plan to evaluate the REDEx algorithm in comparison to manually created regular expressions and possibly the Med-TTK. Other future experiments are to evaluate with other corpora, and to determine the accuracy of regular expressions discovered in one corpus when applied to a different corpus.

We performed the progressive snippet selection method which did not differentiate between the temporal classes at the time of selection. This resulted in small sample sizes for the Set and Other classes. In future studies the selection method can be improved to provide better representation of all classes. This can be done using a similar progressive selection method, but counting the snippets separately for each class. Or by extracting all snippets, stratifying them by class, then randomly sampling an equal number from each stratum. This would have the added advantage of providing class cardinality across the corpus as well as better representation of samples.

The temporal expressions discovered in this study have been incorporated into a v3NLP Framework NLP module [15] to look up temporal text from clinical notes. Additional classes of temporal expressions, in particular intervals, are planned as additions. When extended and tested on other datasets, the NLP module will be released as open source software.

Conclusion

We have developed and tested a simple and novel REDEx algorithm for the discovery of temporal expressions, with good sensitivity and specificity. The REDEx can be applied to other types of information extraction tasks, because it does not contain any built-in information about temporal data.

Abstract

Social media sites, such as Twitter, are a rich source of many kinds of information, including health-related information. Accurate detection of entities such as diseases, drugs, and symptoms could be used for biosurveillance (e.g. monitoring of flu) and identification of adverse drug events. However, a critical assessment of performance of current text mining technology on Twitter has not been done yet in the medical domain. Here, we study the development of a Twitter data set annotated with relevant medical entities which we have publicly released. The manual annotation results show that it is possible to perform high-quality annotation despite of the complexity of medical terminology and the lack of context in a tweet. Furthermore, we have evaluated the capability of state-of-the-art approaches to reproduce the annotations in the data set. The best methods achieve F-scores of 55–66%. The data analysis and the preliminary results provide valuable insights on identifying medical entities in Twitter for various applications.

Keywords:
Social media, data set generation, medical entity recognition.

Introduction

The volume of data on social media sites, such as Twitter, is so vast that it would almost be surprising if it did not contain useful medical information. If we could successfully mine even a small percentage of this, there would be many potential uses, including biosurveillance (e.g. monitoring of seasonal flu) and identification of potential adverse drug events. Previous work exists on biosurveillance based on emergency department notes [1], news data [2], and search data [3], while additional work exists on the detection of adverse effects extracted from forum data [4-6] and Wikipedia [7].

While there has been some work on medical text mining in social media (i.e. identification of relevant tweets for adverse drug events [8]), a critical assessment of performance of current text mining technology has not been performed. It has already been established that Twitter itself presents unique challenges for text mining in the open domain [9,10].

In this work, we have developed an annotated data set from Twitter feeds that can be used to train and evaluate methods to recognise mentions of diseases, symptoms, pharmacologic substances in social media, and particularly microblogs. Furthermore, we have evaluated the performance of existing state-of-the-art entity recognition approaches on this data set. Overall, methods based on conditional random fields allow high precision entity recognition, while additional work is required to improve the recall.

[*] The first and second authors contributed equally to this paper

Materials and Methods

This section presents the development of the Twitter data set and the annotation process, as well as the methods used to automatically reproduce the annotation.

Data Collection And Filtering

We obtained our data using Twitter Stream API from 13/05/2014 to 28/05/2014, collecting 43 million tweets in total. An inspection of random samples indicated that most tweets do not contain medical entities. We pre-filtered tweets using a list of medical terms. We considered three types of entities: *diseases*, *symptoms,* and *pharmacologic substances* to match the particular entities we were targeting for annotation. The list of these biomedical entities comes from the Unified Medical Language System (UMLS) [11] Metathesaurus, which integrates over 100 biomedical terminologies and ontologies. The concepts in the Metathesaurus are assigned one or more semantic types from the UMLS Semantic Network[i] [12]. We downloaded the UMLS version UMLS2014AA and used the default installation. Within this network, we selected the following semantic type mappings:

- T047 (*Diseases or Syndrome*) for diseases,
- T184 (*Sign or Symptom*) for symptoms,
- T121 (*Pharmacologic Substance*) for pharmacologic substances.

From the Metathesaurus, we only retained concepts linked to one of the preceding semantic types, and then extracted the union of terms corresponding to these concepts.[ii] Furthermore, only terms in English and non-obsolete entries were kept. Table 1 shows statistics for each entity type. Disease and pharmacologic substances contain a large number of concepts and terms, while the list of symptoms is comparatively small.

Table 1 – Statistics of the concepts and terms extracted from the UMLS for the three entity types.

Entity	Concept-term pairs	Unique terms	Unique concepts
Disease	201,916	201,013	46,993
Pharm. Subs.	279,261	278,390	120,330
Symptom	19,927	16,865	3,850

[i] UMLS Semantic Network site: http://semanticnetwork.nlm.nih.gov
[ii] We joined the relevant Metathesaurus tables ('MRCONSO' and 'MRSTY') to determine this information.

We filtered the Twitter data to keep the volume manageable. Only tweets with two or more entity types (e.g. a *symptom* and *disease*) were kept, ensuring the filtering is fairly precise (while potentially reducing recall). The lists of UMLS terms extracted, as described above, contain very frequent terms that are primarily used in a non-medical sense, such as *said* and *water*. To avoid a large number of false positives in the filtering stage, we used the frequency of UMLS terms in filtered tweets from the previous step and ranked them in decreasing order of frequency. We then manually removed common terms with a non-medical primary sense from the top 200 terms in each type.

We further removed duplicates in the filtered tweets and removed non-English tweets using LANGID.PY [13]. This filtering pipeline ultimately yielded 11,647 tweets. To investigate whether our filtering (particularly our requirement of the presence of two entity types) erroneously excluded relevant tweets, we examined 1,000 randomly selected tweets. In this sample, we found no relevant tweets—that is, tweets containing biomedical entities of interest—which would have been excluded, suggesting that this pre-filtering methodology is fairly reliable for including all possibly relevant data.

Data Set Annotation Procedure

Four annotators with no medical training annotated the data set with entities from the three semantic types, using BRAT [14]. We created the guidelines iteratively as described here in chronological order.

We prepared an initial set of guidelines based on manual examination of a small subset of the data which was not used for later annotation. We then had all four annotators use these initial guidelines to annotate the same set of 100 tweets as a calibration set.

We checked the inter-annotator agreement on the calibration set and found that it was too low to be appropriate for what we would like to consider a high-quality data set. On the basis of discussions between the annotators, we then refined the guidelines to attempt to resolve frequently observed points of ambiguity in the calibration set. A subsequent round of annotation with the new guidelines improved the inter-annotator agreement, but still not to a level we considered acceptable. At this point we moved to a system of having all tweets annotated by two annotators, then merging the annotations and having the annotators resolve all disagreements in discussion.

This double annotation methodology led to a higher-quality data set with very respectable figures for inter-annotator agreement as shown below. The cost, of course, was that we were able to obtain less data per hour of annotation time. In practice we found the merging and discussion process was generally fast (roughly 20% of the annotation time itself), meaning that overall annotation efficiency was reduced by a factor of around 2.4 by the double annotation methodology. However, for future iterations of the data set, we will leave open the option of augmenting this high quality data set with a lower-quality data set annotated only by a single annotator (possibly assisted by automatic pre-annotation).

Since we settled on double-annotation, the relevant comparison for inter-annotator agreement is to calculate agreement on a subset of the data, which has been annotated twice in the manner previously described. That is, the four annotators were grouped into two pairs, and each pair annotated and merged the same subset of 100 tweets using the methodology described above. We then calculated agreement figures between the two sets of annotations, obtained using BratEval[iii] [15].

Table 2 – Inter annotator agreement for each one of the entity types.

Entity	Precision	Recall	F1
Disease	0.8400	0.8750	0.8571
Pharm. Subs.	0.9500	0.8261	0.8837
Symptom	0.8246	0.8393	0.8319

Inter annotator agreement, as shown in Table 2, is reassuringly high, particularly for such a potentially ambiguous task, and displayed similar levels of agreement to other biomedical annotation tasks [16]. Most of the disagreements were terms inadvertently missed by the annotators, and in a few cases the words were arguably non-medical terms, which can sometimes be difficult to distinguish. For instance, terms like *chill* or *weak* often carry a non-medical meaning. Other disagreements included different interpretations of the subtleties of the guidelines, such as whether *pill* was sufficiently specific to be included.

Annotation Guidelines

After the two rounds of annotation calibration, we settled on a final set of annotation guidelines. These stipulated that we are interested in annotating three kinds of entities: pharmacologic substances, diseases, and symptoms. In addition to traditional entities, which correspond to noun phrases, we also broadened the scope of the annotation to allow for short phrases headed by verbs (such as *I **coughed** all morning*) and adjectives (such as *felt **light-headed***), which indicate diseases or symptoms. If the part-of-speech of the head-word of an annotated item is not a noun, the annotation was marked as an adjective or verb as appropriate in a separate attribute.

We also found that in many cases a concept being mentioned, which may have looked superficially medical, was unlikely to truly refer to a medical concept. In particular, mentions may be metaphorical, figurative, or purely humorous, and in these cases annotators were instructed to apply the 'figurative' attribute. There was also another slightly distinct class of items, one in which the terms have an informal and non-clinical meaning in addition to the clinical one. If the non-clinical meaning is clearly being used, annotators were to apply the 'non-medical' attribute, such as in ***depressed** about my exam results*.

The guidelines also instruct annotators to annotate the most specific entity possible (e.g. *codeine syrup* rather than *syrup*) and to include as many tokens as possible as long as they are part of a fixed expression referring to a particular kind of entity (e.g. *disgusting* would not be part of the entity in *disgusting codeine syrup*). It was also specified that entities which do not distinguish anything more specific than the base entity category should not be annotated, as the very general information in these is unlikely to be specific enough to be useful in downstream applications. In addition, it was also permitted to have overlapping annotations, so while *pain medication* would most sensibly be annotated as a pharmacologic substance, the token *pain* within it should also be annotated as a symptom.

Correctly identifying medical concept mentions and categorising them is sometimes a difficult task for annotators without formal medical training as there is a large terminology space. So it may be difficult to determine whether a particular token refers to a valid concept (e.g. Should *prune juice* be

[iii] BratEval site: https://bitbucket.org/nicta_biomed/brateval

considered a pharmacologic substance? Is *dextromethorphan* a real drug name?), or which of two categories it should refer to. In particular, the division between the disease and symptom categories can be very uncertain in many cases. For example, it may not be clear initially whether *amnesia* is a disease or a symptom. So, the annotators were advised to refer to the UMLS in cases of uncertainty, essentially using the UMLS as a substitute for in-depth domain knowledge. In particular, the UMLS semantic type is important, so generally the semantic types should obey the same mapping as described in 'Data collection and filtering' (for example, *disease* entities should have semantic type 'T047').

Even if the UMLS was not the perfect resource for making these decisions, it is in widespread usage (incorporating many standardised terminologies), and at least provides a common basis for decision-making, ensuring consistency of the annotations. In some cases, the context may make it clear that a strict interpretation of UMLS semantic type, as described above, is not appropriate; in these cases, annotators were free to apply their own more appropriate categorisation instead.

It is of course difficult to codify every possible annotation decision in a static set of guidelines. Inevitably, certain borderline cases had to be decided on the basis of the annotators' intuitions in ways that are difficult to encode specifically. However, the procedure of double annotation that we adopted and the high inter-annotator agreement we achieved at least suggests that the annotations are reasonably internally consistent, and thus presumably repeatable.

Data Set Statistics

The final data set contains 1,300 annotated tweets in 13 files with 100 tweets each. As shown in the following table, *symptom* is the most frequent type with no significant difference between disease and pharmacologic substance. We can see that entities are typically composed of a single token for *symptoms*, while *diseases* and *pharmacologic substances* more frequently span multiple tokens.

Table 3 – Statistics for the entities in the data set. Entities annotated as non-medical have not been considered.

Entity	No Entities	Avg. length	Avg. Tokens
Disease	253	10.40 ± 5.83	1.41 ± 0.62
Pharm. Subs.	233	9.83 ± 4.35	1.39 ± 0.58
Symptom	764	6.66 ± 2.96	1.13 ± 0.40

Table 4 shows the number of non-medical and figurative terms annotated. The number of pharmacologic substances and symptoms that are not medically related are significantly larger; it seems these terms are more often used informally, rather than with their medical definition. In addition, almost 10% of the symptom mentions are used figuratively.

Table 4 – Number of non-medical and figurative entities.

Entity	Non-medical	Figurative	Medical Figurative
Disease	1 (0.40%)	5 (1.98%)	4 (1.58%)
Pharm. Subs.	20 (8.58%)	2 (0.86%)	2 (0.86%)
Symptom	122 (9.65%)	124 (9.81%)	44 (3.48%)

Table 5 – Part-of-speech of the annotated entities. Entities annotated as non-medical have not been considered.

Entity	Noun	Adjective	Verb
Disease	246 (97.2%)	7 (2.8%)	0 (0.0%)
Pharm. Subs.	233 (100.0%)	0 (0.0%)	0 (0.0%)
Symptom	454 (75.5%)	262 (20.7%)	48 (3.8%)

Almost all entities annotated are nouns as noted in Table 5. It is logical that pharmacologic substances are nouns. There are only a few mentions of diseases that appear as adjectives (e.g. *blind*, *obese,* or *overweight*). For symptoms, over 20% appear as adjectives (e.g. *breathless*, *hungry,* or *sick*) and a smaller quantity appear as verbs (e.g. *fainted*, *coughing,* or *shaking*).

Table 6 shows the top 10 terms by frequency per entity type. There is a large number of individual posting on Twitter and we can identify multiple topics in our data set, which shows the possibilities of exploiting Twitter data and the complexity of extracting relevant signals from it. Some of these terms denote concerns about diseases that affect a large part of the population (e.g. *diabetes*) but also highlight recent breakthroughs in medicine (e.g. a new *malaria vaccine*). We also find mentions of recreational drugs (such as *marijuana* and *cannabis*), which are not related to any specific news item. In addition, there are mentions like *heroin* linked to news when the tweet was posted (e.g. *NYPD officers to carry heroin overdose antidotes*). Furthermore, we find a large number of symptoms that are not linked to any specific disease, which could be monitored as signals for biosurveillance.

Table 6 – Top most frequent terms per entity type.

Disease		Phar. Sub.		Symptom	
diabetes	14	marijuana	12	tired	136
heart disease	10	cannabis	12	pain	93
stroke	10	alcohol	11	hungry	61
cold	8	heroin	8	stress	50
asthma	6	pain meds	7	headache	36
malaria	6	vitamin c	4	sore	15
allergy	4	chill pill	4	sick	14
migraine	4	malaria vaccine	4	cough	13
aids	4	caffeine	4	exhausted	12
obesity	4	calcium	4	hangover	11

Named Entity Recognition

After annotating a data set, we investigated how applicable standard approaches to named entity recognition (NER) would be to this data. This indicates how unique the data is, and helps us to predict how difficult it will be to reliably reproduce these annotations automatically on unseen data, which is our ultimate goal. Three methods were used to annotate the data set with the three entity types.

The first uses MetaMap [16], which is developed at the US National Library of Medicine that maps spans of text to UMLS Metathesaurus concepts and is considered state-of-the-art for this task. It uses parsing to identify spans of text in which entities could appear and then smart dictionary matching to identify the concepts [16]. We used MetaMap 2013, with its default configuration, to perform experiments with and without word sense disambiguation (WSD) [18]. MetaMap output was filtered to keep only concepts belonging to the three semantic types under consideration, and the output was converted to BRAT standoff format for evaluation.

In addition to MetaMap, we considered two systems based on machine learning (ML). Firstly, we created a custom NER tagger for this data set, called 'Micromed' (since it tags medical concepts in microblog posts), to provide an in-house solution. It uses conditional random fields (CRF) [19] as its underlying machine learning algorithm. CRFs are frequently used in state-of-the-art named entity recognizers, including those in the biomedical domain. For its CRF implementation, Micromed uses CRFSuite [20]. The features were derived

*Table 7 – Results of all automatic annotators over all entity types. Statistical significance at p < 0.01: * vs MetaMap; † vs SNER.*

		Disease			Pharm. Substance			Symptom

	Micromed	0.7987	0.5020	0.6165*†	0.8142	0.3948	0.5318*	0.7439	0.6234	0.6783*
	Micromed +Meta	0.8049	0.5217	**0.6331***†	0.7220	0.6041	**0.6578***	0.7450	0.6234	**0.6788**

from those commonly used in NER, and tuned somewhat to this particular task:

- Part-of-speech tag and relative position in a context window of three tokens each side
- Token surface form and relative position, in a context window of two tokens each side
- Token prefix and suffix character N-grams of all lengths up to eight
- Whether the token appears in a list of synonyms for concepts with the appropriate semantic type extracted from UMLS
- (In some configurations) whether MetaMap annotates the token as a concept with that semantic type

Since the goal was to evaluate how similar the task was to standard NER, we did not add particularly radical features. For tokenising and POS-tagging, we used TweetNLP [21]. We trained a CRF model for each category (*diseases*, *pharmacologic substances,* and *symptoms*), treating them as distinct annotation tasks. The output of the CRF engine was converted to BRAT standoff[iv] format for evaluation.

Secondly, we used the Stanford NER tagger (SNER) [22] as another strong baseline to study how difficult the task is for existing NER tools and help identify effective features. This also underlyingly uses a CRF. We reformatted annotations into SNER format and applied the limited default features to train taggers for each of the three categories, which included character n–grams and word tokens in fixed context windows (the primary feature difference from Micromed being the absence of custom lookup lexicons).

Results

To compare the performance of the annotation methods, we used two different evaluation profiles. Exact match requires a given entity from the classifier output to have the same start and end span as the reference entity to be considered a match. Partial match considers entities as matching if there is any overlap at all between the entity produced by the classifier and the gold standard. After counting matches, we calculated precision, recall, and F1 in the usual way. Entity annotations marked as non-medical were ignored in training and testing. Statistical significance of the results shown in Table 7 was computed using a two-sample *t*-test with randomization over the cross-validation folds.

Machine-learning methods were trained and evaluated using 13-fold cross validation, based on 13 sections of the data set, each containing 100 tweets. That is, at each of the 13 iterations, 1200 tweets (12 sections) were used for training, while the remaining 100 tweets were used for evaluation. MetaMap, however, was simply applied to the whole data set, so the results are comparable. We evaluated Micromed, both with and without features based on MetaMap (the former case is denoted "+Meta"), to evaluate how well it could perform without relying on an external tool with a significant overhead. Results of the overall methods are presented in Table 7.

MetaMap results without WSD have much higher recall, but poorer precision. Entities missed include terms that are not in the UMLS (e.g. *painkillers addiction*) or terms in the UMLS that are not in the categories of interest (e.g. *cold* as *symptom*). False positives include non-specific terms annotated by MetaMap (e.g. *drugs*), which are excluded by the annotation guidelines, terms bearing a non-medical meaning (e.g. *I'm sick and tired of negativity),* and WSD mistakes (e,g. *cannabis* was annotated as *plant* instead of *substance)*.

The ML methods usually outperforms MetaMap. SNER's accuracy is lower over *Disease* but substantially higher over *Pharmacologic Substances* and *Symptom*. Micromed has higher F-score again, with statistically significant increases over SNER except for *Symptom.* SNER has lower recall since it lacks the implicit domain knowledge from the UMLS-derived features of Micromed and Micromed+Meta (including MetaMap). We know, from Table 1, that the *Symptom* category has a smaller vocabulary; thus, relevant information can be learned from the training data alone. Moreover, some symptom entities, which SNER detects, are missed by Micromed; in many cases, these are not in the UMLS (e.g. *magnesium-deficient*). The increase in recall of partial match compared to exact match is not especially significant, except for *Symptom*.

Discussion

The data set was annotated with high inter-annotator agreement. Extra considerations were required for Twitter compared to biomedical literature, e.g., the *Figurative* attribute and extending the concept of entities beyond nouns, which might make traditional NER approaches perform poorly.

MetaMap was not trained on this data set as the other two methods were, but still shows a competitive performance with higher recall, while Micromed and SNER are generally more precision-biased and have a higher F-score overall. The

[iv] Brat standoff format: http://brat.nlplab.org/standoff.html

difference in performance of the methods is scientifically interesting in what it tells us about the nature of the data set. MetaMap is widely used for medical NER due to the respectable performance it achieves over research articles and clinical text. MetaMap has not been tuned for Twitter data and was outperformed in this work by ML-based classifiers, which could be effectively trained on a relatively small in-domain corpus. SNER even lacked in-domain knowledge, while Micromed used mostly standard NER features. This difference between MetaMap and ML methods suggests that the data set here has different characteristics to NER tagging in other domains.

The difference may also reflect different design considerations to be considered to tune MetaMap to work with Twitter data. In our work, the current performance of Micromed, as well as its lower computational cost[v] are likely to be advantageous in processing large volumes of social media data. The computational cost must, of course, be low if we hope to process a significant fraction of a high-volume data stream in real time. In addition, the smaller number of false positives generated by a higher precision system should lead to greater acceptance by users of the system output. Since the volume of data available in social media is relatively large with a high degree of redundancy with respect to overall trends, slightly lower recall is less of a concern in these applications.

Conclusion

In this work, we have presented the development of a Twitter set annotated with medical entities, showing that it is possible to perform high-quality annotation despite the complexity of medical terminology and the lack of context in a tweet. We have made the dataset publicly available[vi] to encourage further research. Furthermore, we have evaluated the capability of some state-of-the-art approaches to reproduce the manual annotations. The approaches demonstrate reasonable accuracy (with interesting variations between the methods), although further work is needed to identify additional features that might improve the performance of the annotators. We have focused on creating a data set and evaluating state-of-the-art annotators. We plan to use these annotators to process a live data stream from Twitter or some other source for biosurveillance and detecting adverse drug reactions.

Abstract

Chronic diseases are an important field to tackle due to increasing healthcare risk factors, including population nutritional habits, lack of physical exercise, and population aging. Diabetes mellitus, hypertension, and obesity currently affect millions of people, and this statistic grows every year and is responsible for numerous deaths everyday. Many of those deaths could be delayed by following a steady monitoring strategy over such a population, which would prevent vital signs from reaching critical stages and providing knowledge for these patients about their health. This paper introduces Mobilicare, a mobile health promotion system designed to: (i) monitor remotely a patient´s vital signs in real time; (ii) support a health service in a Healthcare Center; and (iii) allow self-awareness of the disease and improve motivation. Our approach was applied to two distinct chronic patient management programs. The results showed the commitment of elder patients and the contribution of Mobilicare to the maintenance of a patient´s health stability.

Keywords:

Chronic disease management; eHealth; mHealth; cloud computing; tele-vital signs; tele-homecare.

Introduction

Access to medical care is sometimes difficult for citizens living in distant and underserved areas. However, even citizens living in large cities in developed countries may find it hard to reach medical services. Not being able to access primary medical care when illness, injury, or potential health problems arise may lead to a late diagnosis, delay in treatment, and possible future consequences. The problem gets even more serious in developing countries, such as the BRICS countries (Brazil, Russia, India, China, and South Africa).

With the goal of eliminating distance barriers, telemedicine is a multidisciplinary research area that integrates not only several computer science fields, but also medicine and healthcare. Its aim is to improve health services and quality of life, as well as provide remote medical training. Recently, telemedicine has been helped by advances in mobile communication and the adoption of tablets and smartphones. For example, it is currently easier to reach older or homecare patients whose medical access could be hampered by physical constraints. For example, mobile communications and portable devices permit monitoring of vital signs, no matter the patient's location.

Targeting one of the most critical chronic diseases, in 1985, there was an estimated 30 million adults living with diabetes mellitus. This number grew to 135 million in 1995, and then to 173 million in 2002 [1]. Currently, there are more that 371 million people living with diabetes between the ages of 20 to 79 years. This number rises every year in practically all countries, and 50% of the people with diabetes do not even know their clinical condition [2]. About two-thirds of these people live in developing countries, where the epidemic has more intensity, and with a growing rate in younger citizens [1]. Nevertheless, people with diabetes mellitus are living longer due mainly to advances in medicine [3].

As a consequence, both public and private healthcare costs for treating these types of patients are increasing due to higher average lifetime expectations worldwide. Additionally, both the number of medical doctors and their geographical distributions cannot cope with the quickly growing number of patients with chronic diseases. Finally, patients unaware of their clinical condition are not treated preventively and endure worse consequences since diabetes can be considered a “silent sickness”. They usually show greater resistance in following correct treatment since it is for the rest of their lives and demands daily care.

In Brazil, private health care operators offer Chronic Patients Management Programs to monitor patient clinical condition, mainly due to the possibility of income taxes reduction. In order to keep operational costs low, however, most of these programs only contact the patient once a month, either at home or through a phone call. If the patient does not feel well, he/she can call a monitoring center usually during working hours and speak with specialized nurses and doctors. This scenario limits the notion of the patient’s clinical condition. For patients with Type 2 diabetes, the medical protocol can lead to a possibly incorrect idea that they are clinically stable most of the time.

We present a mobile system – called Mobilicare – that is used by patients at home to collect and transmit patient data (e.g., glucose measurements) at specific dates and times. Through the system, the health center can remotely monitor a patient’s condition and even contact them. The main goals are to provide: a) a remote just-in-time pro-active and preventive health service to the patient, based on vital signs; b) graphs and alarms when vital signs are out of threshold for the health center and also the patient; c) video conference with doctors and family; d) patient risk analysis; and e) educational videos about diseases, food, and exercise habits. We observed that these features impact the way the treatment is performed, from reactive to active (i.e., anticipating an event). In order to analyze system outcomes over different scenarios, two case studies were conducted – one related to diabetes, and another to health promotion.

Methods

The Mobilicare System

The Mobilicare system is composed of three main entities, as depicted in Figure 1: a) the mobile kit at the patient's home; b) cloud storage; c) the medical/health care center.

Figure 1- General view of Mobilicare.

The mobile kit in the patient's home

The mobile kit is composed of a 3G/Wi-Fi tablet and a number of vital monitoring medical devices according to their chronic diseases (Figure 2). Electrocardiograms, scales, blood pressure meters, oximeters, thermometers, glucometers, pedometers, and spirometers are connected via Bluetooth to a tablet or smartphone. This device transmits information over the network to a Cloud storage system in which a medical center has access and analyzes such data for decision-making. The most common sensors are Glucometer (for diabetes), Blood pressure (for hypertension), and Scale (for weight control).

Figure 2. Medical devices supported by Mobilicare.

Figure 3 (left) shows a glucometer attached to a device that convert the measurement to Bluetooth, sending it to the tablet. For instance, the interface is configured only for diabetes measurements. Figure 3 (right) shows a graph of the vital signs – in this case for glucose – in which patients can follow and verify the disease stability over time.

Figure 3- Use for the tele-glucose meter (left) and glucose graphics (right).

Figure 4 depicts the video conference interface that includes the following features: access to the healthcare center, health coach for remote training, family, and a social network for people with the same disease. The goal of the social media part is so that patients can exchange with and motivate one another.

Figure 4- Mobilicare video conferencing and social network modules.

Cloud Storage

Mobilicare works as a service, i.e., it follows the SaaS (Software as a Service) technology and business model. The Cloud is used to store all the information and allow transparent web access through the Internet using RESTful APIs. Over the Cloud, the system both receives and automatically compares the measurements against a set of thresholds (upper as well as lower limits) prescribed by the responsible physician. These limits are individualized for each patient according to different clinical profiles.

By using cloud computing, medical professionals can communicate with several medical centers if needed via Web services. They can also manually analyze the vital signs (visualized using Java applets), perform a diagnosis, send alerts to the tablet application, and even contact patients via teleconference - all of that using a web browser at the medical center. The goal is not to replace a medical consultation, but rather complement and expand the service, offering guidance and monitoring from a distance.

The Medical Center

The medical center aggregates all patient data. If there is an alarm on a patient, their data appear at the beginning of the list and a sound is generated, followed by a yellow message. If the patient does not perform a prescribed measurement, the call center gets a "non-measurement alarm" and follows a protocol to question the patient for reasons for this behavior. If the measurement exceeds either a higher or a lower limit of the associated clinical profile, the call center both receives a "clinical alarm" (e.g., emergency, urgency) and executes the medical protocol.

Figure 5 shows the health care real-time dashboard as patients performance charts, contact, contact of close people, name of physicians, medicines took, and visit records, among others.

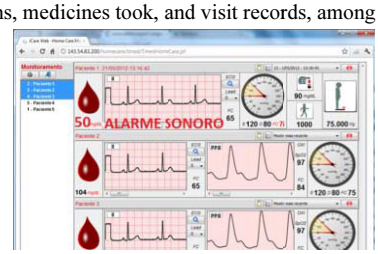

Figure 5- Mobilicare Medical Center dashboard.

Case study 1: 100 Diabetes participants over one year

Based on a Randomized Controlled Trial [7], 100 type two diabetes patients were classified into three distinct groups:

- GC (Control Group): received usual chronic disease management services only, which consisted of a call made by the health center attendant once a month to check patients' stability;

- GI1 (Intervention Group 1): used an offline glucose meter only, being managed by the patient himself;
- GI2 (Intervention Group 2): used a tablet with Android 4.0 and a glucose meter with a Bluetooth converter. These patients were monitored in real-time using Mobilicare by the healthcare provider.

Figure 6 shows the methodology workflow. First, 100 type two diabetes patients were selected from one of the largest home care providers in Brazil – Globalcare health center – and were chosen following the criteria of similar representation for all age groups and genders. Then, patients were randomized and distributed into the three subgroups (GC, GI1, and GI2). Eventually, a slight change was made among groups to keep a similar age distribution. Next, patients were asked to participate in the program (recruitment). In the case of a candidate refusing, another participant with a similar profile was chosen.

Once the set of patients were distributed into the three groups, a phase called "Intervention" took place. In this phase, patients had glycated hemoglobin collected for future comparisons. Afterward, the Follow-up, Data Collection, Data Processing, and Statistical Analysis phases were deployed (details in next section). The pilot lasted from October 2013 to September 2014.

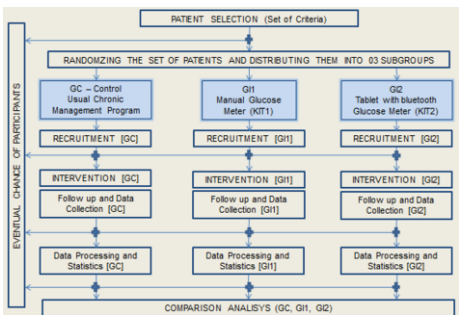

Figure 6- RCT – Randomized Control Trial Workflow.

Results

Diabetes

Figure 7 shows the monthly average levels of glucose measurements for the set of patients in GI2. It is possible to observe that the levels dropped from 118 to 111 using Mobilicare. For the other groups, there is no such a measure since they do not send their glucose levels to the health center. However, with the glycated hemoglobin levels reported, it was possible to verify the same behavior before the intervention.

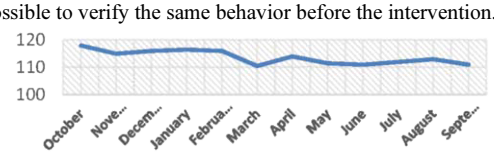

Figure 7- Mean value of glucose levels for GI2.

The number of "clinical alarms" among GI2 patients was around 62. Most alarms were triggered during typical vacation months, in which people often do not follow the specified diet. After a "clinical alarm", the average number of measurements to a GI2 patient to come back to an acceptable blood glucose level was 1.16, or a little more than two days. This quick return to a normal condition was a consequence of the medical protocols triggered by the alarms. For the other groups, they rarely reported an anomaly during the center calls.

Figure 8 shows the mean number of measurements for GI2. In the first months, there was instability due to system patient adaptability, which generated a high number of "non-measurement" alarms. Later, measurements became regular and stable with each patient performing about six measurements a week.

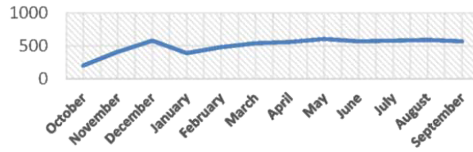

Figure 8- GI2 mean number of measurements per month.

The age average of the GI2 group is 69 years old, however this fact seems to have little influence in their adherence to the program, regardless of previous experience in using a tablet.

Also, one important result concerning the other two groups (GI1 and GC) is that less than 3% of the expected measurements were spontaneously reported to the "call center". This result can drive an assumption that these people could be under-watched and need a higher consciousness of the disease, as was provided for the patients of GI2.

Table 1 shows that the number of GI2 patients who went to the emergency room was 80% less when compared to GC patients in the same period. Also, GI1 patients were hospitalized 25% more times than GI2 patients and GC patients 50% more than GI2. The Unitcare Medical Services has details of the protocols, including ethical aprovement and agreement terms of patients.

Table 1: Emergency and hospitalization numbers.

	GI2	GI1	GC
Emergency Room	1	3	5
Hospitalization	4	5	6

Case Study 2: Health Promotion

This observational study intended to verify the Mobilicare performance for health promotion, i.e., the improvement of quality of life. This study has been carried out during a 4-week period, involving three people with different profiles:

- Patient 1: 56 years old, male, overweight and acquired diabetes type 2;
- Patient 2: 67 years old, male, overweight and Parkinson;
- Patient 3: 60 years old, female, overweight and hypertension.

During the first visit to the patient, a caregiver performed a training and also measurements for weight, blood pressure, and glucose. The results allowed the professional to get some indexes of the patients, like body mass index, body fat percentage, and waist to hip ratio. We also made an interview about their eating habits and physical activities during the last four weeks to better understand how the system could influence them.

After four weeks, the caregiver repeated the initial measurements and performed a final interview. After six months, another visit was made to verify self-health stability, without the Mobilicare influence. It is important to note that for statistical validation, this case study needs further investigation due to a restricted sample, but the preliminary results work as an indication of the system usability [15].

Health promotion

The patients in this study had to walk at least 5,000 steps daily and send the data, or else the system would show a "non-measurement" alarm to the health center. Figure 9 depicts the mean glucose and blood pressure variation of the patients. The glucose levels were high at the beginning of the experiments, and decreased to normal levels while the blood pressure levels, which were normal, remained normal. At the beginning of the experiment the glucose levels were about 120 in average, and at the end of the experiment they were about 100 in average, with a reduction of around 20%.

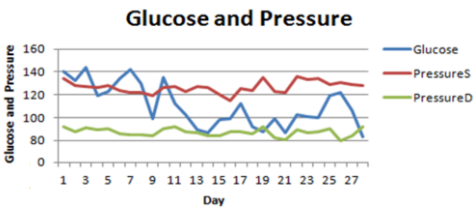

Figure 9- Patients mean glucose and pressure levels.

At the end of the experiment, the set of measurements was repeated. Table 2 presents the results for weight. All patients reduced their total weight, and additionally some of them increased in lean weight, reducing their percentage of body fat further. Fat weight and lean weight provide valuable information since they show that the intervention was probably producing significant results.

Table 2- Weight results.

	Total weight	Fat weight	Lean body weight	Body Fat (%)
P1_ini	85.00	16.14	68.86	18,99
P1_final	82.70	14.70	68.00	17.72
P2_ini	83.50	20.79	62.71	24.90
P2_final	82.00	16.50	65.50	20.12
P3_ini	73.10	25.56	47.54	34.96
P3_final	71.10	21.58	49.52	30.35

Other monitored results were the main corporal indexes, shown in Table 3: BMI (Body Mass Index), WHR (Waist to Hip Ratio) and BAI (Body Adiposity Index). The results showed a reduction the indexes for all patients. However, it is important to note that all participants still need to keep lowering most of their indexes in order to reach international health standards [4, 5, 6].

However, it is very hard to identify whether the benefits came from their motivation to adhere to the health program, and they internalized the learning, or by the pressure caused by the technology system itself. In order to minimize the error, the participants were contacted and measured again after six months of the experiment. Two of them had diminished the weight (6 kg and 2,3 kg), and the third was steady, with the diabetes controlled. The sample was only 3 participants, but the results are considered very promising.

Table 3- Main corporal indexes

	BMI	WHR	BAI
P1_ini	30.11	1.04	27.46
P1_final	29.30	1.01	26.54
P2_ini	29.94	1.00	29.72
P2_final	29.40	0.96	29.63
P3_ini	27.17	0.74	34.37
P3_final	26.43	0.74	33.51

Discussion

This paper presented Mobilicare – a new mobile monitoring for health promotion system. The front-end module works on any browser, being suitable for a variety of platforms, like computers, tablets, and mobile devices. One important goal was to encourage prevention and health promotion through the patient's interaction with advanced technological tools. In line with the concept of social networks, the developed tele-homecare model lets patients interact with other people who have similar medical situations, encouraging information exchange and commitment to self-care. Patients are encouraged to take an active role in their healthcare. For example, a diabetic patient could periodically check his blood sugar and adjust his or her behavior, such as in the case of an excessive intake of sugar. Additionally, the patient can optionally subscribe to an exclusive social network offered by the solution/health provider. There, patients can interact, post disease educational videos or materials for common access, discuss their health problems, and even compete with each other as they post their measurements and the disease remains stabilized over time.

Though it is still too early to be conclusive, we have collected significant evidence that remote measurement of vital signals, when integrated with awareness and healthcare support, might help leverage quality of life in the short term and delay the undesired side effects of chronic diseases like diabetes. Not only can the patient can get benefits using Mobilicare or similar systems, but also health care operators will probably be able to reduce emergency and therefore hospital costs.

We conducted two case studies, one for diabetes, and another focusing on health promotion. Related to the diabetes study, only 17% of GI2 patients have left the program after the end of the one-year experiment. Here, we observed that remote regular monitoring led to the earlier identification of more serious changes in glucose levels and also to an earlier reaction by health care personnel. As a consequence, patients' measurements were brought back to acceptable levels sooner. Related to the health promotion study, from the first day it was clear that motivation increased. Being constantly monitored brought a new mood to the participants. The system changed the routine of these people, and they worked out much more when compared to the time prior to monitoring. Now they had goals to reach, and someone to help them with their doubts and questions.

Results in both cases showed that a monitoring and educational system can improve the health of the monitored people. Moreover, we detected a real improvement in the knowledge of the patients about their health situation and what to do in order to grow old in a healthy way.

As counter-intuitive as it might be, elderly people can learn to use new technologies relatively quickly, and for a significant number of them the access to their measurement curves resulted in a positive feedback and led to greater adherence to the healthcare program. In this sense, the use of technologies that improve the quality of preventive health and reduce medical costs has become a necessity since the costs of secondary and tertiary care are very high and constantly growing. In BRICS countries, where there is significant heterogeneity in access to and quality of offered medical services, this market is expected to reach $418.4 million in 2014. In Brazil, it is estimated that less than 5% of hospitals are providing telemedicine services, indicating a high potential for expanded use of telemedicine solutions in healthcare.

Conclusion

Of course, data interoperability, security considerations, and privacy issues remain. Health information must be protected by the standard transmission protocols (Continua Health Alliance: http://www.continuaalliance.org) and security layers of the cloud provider to not only prohibit unauthorized access to patient records, but also to guarantee data integrity and make sure that transmitted data are not maliciously modified. Finally, privacy is addressed by the management system, which assures that data is only accessed by the physician and related medical team of the patient provided by the patient's permission.

Calculation of Cardiac Kinetic Energy Index from PET images

John Sims[a], Marco Antônio Oliveira[b], José Claudio Meneghetti[b], Marco Antônio Gutierrez[a]

[b] *Department of Nuclear Medicine and Molecular Imaging, Heart Institute (InCor) Sao Paulo, Brazil*

Abstract

Cardiac function can be assessed from displacement measurements in imaging modalities from nuclear medicine Using positron emission tomography (PET) image sequences with Rubidium-82, we propose and estimate the total Kinetic Energy Index (KEf) obtained from the velocity field, which was calculated using 3D optical flow(OF) methods applied over the temporal image sequence. However, it was found that the brightness of the image varied unexpectedly between frames, violating the constant brightness assumption of the OF method and causing large errors in estimating the velocity field. Therefore total brightness was equalized across image frames and the adjusted configuration tested with rest perfusion images acquired from individuals with normal (n=30) and low (n=33) cardiac function. For these images KEf was calculated as 0.5731±0.0899 and 0.3812±0.1146 for individuals with normal and low cardiac function respectively. The ability of KEf to properly classify patients into the two groups was tested with a ROC analysis, with area under the curve estimated as 0.906. To our knowledge this is the first time that KEf has been applied to PET images.

Introduction

Cardiac pathologies can affect the normal motion of the left ventricle; accurate quantification of this movement can therefore assist in diagnosing disease. The variational Optical Flow (OF) technique proposed by Horn and Schunck (HS) [1] can provide automatic motion quantification, in which the motion field is estimated from a sequence of images.

Optical flow is a computer vision technique which estimates the motion field from spatiotemporal patterns of image intensity [2], and HS requires that the image brightness, E, at a given point in the brightness pattern does not change with time, t, as shown in Equation 1.

$$\frac{dE}{dt} = 0 \tag{1}$$

The motion field is estimated through the solution of a system of equations which is large and sparse, and iterative methods such as Gauss-Seidel are suitable choices for its solution [1]. In 4d images (a time sequence of 3d volumes) these equations have the form shown in Equation 2; for brevity only the x component of velocity (u) has been shown.

$$u^{k+1} = \bar{u}^k - \frac{E_x(E_x\bar{u}^k + E_y\bar{v}^k + E_z\bar{w}^k + E_t)}{\alpha^2 + E_x^2 + E_y^2 + E_z^2} \tag{2}$$

Here k is the iteration index; $\bar{u}, \bar{v}, \bar{w}$ are mean velocities in x, y, z; E_x, E_y, E_z are the partial derivatives of image intensity E(x,y,z,t) and α^2 is a regularization parameter.

The motion field estimated from cardiac image sequences is difficult and time consuming to interpret, since each volume element (voxel) has a time-varying three-dimensional vector value. Gutierrez et al. [3], applied optical flow techniques to estimate the velocity field from single photon emission computed tomography (SPECT) images and then used the velocity estimates to calculate kinetic energy (KE) for each voxel of the image using Equation 3.

$$KE = \frac{1}{2}m(v_x^2 + v_y^2 + v_z^2) \tag{3}$$

Here v_x^2, v_y^2, v_z^2 are the components of the velocity vector in x, y and z directions respectively for a voxel at position (x,y,z), and m is the voxel mass, approximated by the voxel intensity in the 3D volume image [4].

The resulting KE field can be summed within each frame to provide total KE per frame and then represented graphically over the cardiac cycle to produce a KE curve. An indicator of cardiac function was proposed in [3], called kinetic energy index (KEf), shown in Equation 4.

$$KEf = \frac{KE_{max} - KE_{min}}{KE_{max}} \tag{4}$$

where KE_{max} and KE_{min} are maximum and minimum values of the total kinetic energy per frame respectively [3].

The present study has the objective of evaluating KEf for the classification of patients with normal or low/altered cardiac function from PET images.

The images come from an image database of 666 individuals with normal and low/altered cardiac function who underwent a rest and stress examination in the Department of Nuclear Medicine at the Heart Institute, Sao Paulo. Images were acquired with the PET radioisotope Rubidium-82 (^{82}Rb).

Methods

Image acquisition

After being situated in the Philips Gemini PET/CT scanner[1], ^{82}Rb was administered for 60 seconds. The individual was left for 60 seconds for perfusion of ^{82}Rb, then resting acquisition performed from minutes two until eight. Cardiac stress was then induced pharmacologically, ^{82}Rb administered a second time during 60 seconds, followed by another 60 second wait for perfusion, and finally the stress image acquired from minutes two until eight.

The electrocardiogram (ECG) signal was simultaneously recorded by the Philips Gemini during image acquisition (gated PET) so that a sequence of image volumes could be constructed from detected photon events collected over several hundred RR intervals. Each RR interval defines the times between R peaks of the ECG, and relates to a single

[1] Philips Gemini TF 64 TOF, Series number 7535, Manufactured Jan 2012 by Philips Medical Systems (Cleveland) Inc., Cleveland, Ohio, USA, Identification code MN 0183, HC 147938

complete cardiac cycle; the length of RR intervals vary constantly during the examination as the cardiac frequency of the individual varies.

Sixty three images were selected from the image database to create groups of individuals with (i) normal cardiac function (n=30) and (ii) low/altered function (n=33). For this preliminary study, the criterion for inclusion in the normal group was ejection fraction (EF) > 50 and the low/altered group was EF < 50, both as determined by the stress examination. Figures 1 and 2 show the variation in EF for individuals as measured by stress and rest examinations.

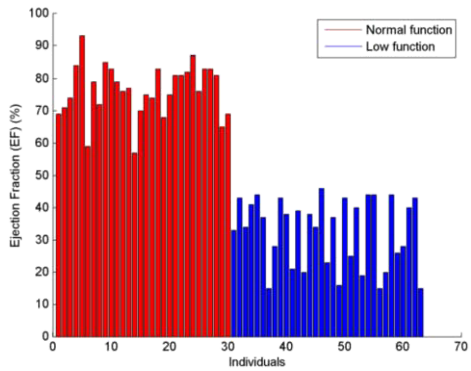

Figure 1– Ejection fraction in stress for the 63 individuals

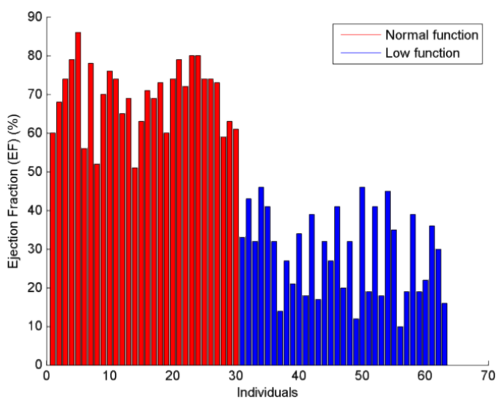

Figure 2– Ejection fraction in rest for the 63 individuals

Calculation of KEf

We developed software in MATLAB[2] to produce an automated image processing routine for calculating KE*f*, comprising stages of preprocessing, optical flow calculation, and postprocessing as shown in Figure 3.

Input images were a sequence of 8 volumes, with each volume containing 128 slices, each of which is 128x128 pixels. The slice thickness was 4mm and pixel size 4mm x 4mm. 8 gated frames were produced rather than 16 since the acquired count is low for ^{82}Rb and it was thought that spreading the count over 16 frames would cause unacceptably high levels of noise.

[2] MATLAB Release 2013a, The MathWorks Inc., Natick, Massachusetts, United States

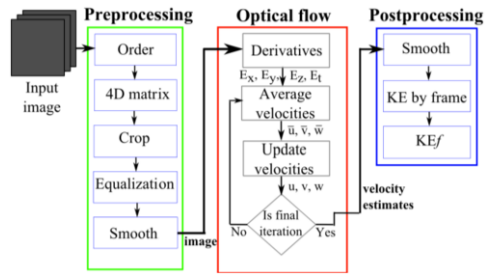

Figure 3– Scheme for calculation of KEf

The preprocessing stage comprised the following:

- Order: DICOM images were renamed in sequential order from the first slice of the first volume to the last slice of the last frame.
- 4D Matrix: DICOM images were converted and stored in a binary MATLAB 4D matrix format.
- Crop: An automatic crop was performed to reduce the size of the input image volumes to include only the left ventricle (LV). A Hough circle transform was used to locate the LV in slices of the short axis plane, cropping the image to include a minimum of structures not belonging to the LV
- Equalization: Images were adjusted to equalize total brightness per frame after cropping, as detailed below.
- Smooth: Images were low pass filtered by averaging over the 27 neighbourhood of each voxel.

The optical flow stage of processing used a version of the HS scheme adapted to 4d images, as described in [2]. A total of 200 iterations of the algorithm were performed with a value of α^2=10, found by experiment.

- Derivatives: Partial derivatives of image intensity were calculated using centred differences.
- Average velocities: In each iteration of the algorithm, average velocities were calculated for each component of velocity (u,v,w), for each voxel, over its 18 neighbourhood.
- Update velocities: an update step was applied to produce the new values of velocity component (u,v,w).

The post-processing stages were:

- Smooth: The optical flow field was median filtered in the 27 neighbourhood to remove outliers.
- KE by frame: KE was calculated for each voxel using Equation 3 and then KE contributions summed for all voxels within each frame.
- KEf: KEf was calculated using Equation 4 from maximum and minimum values of KE by frame. Our studies excluded the values belonging to the first and last frame from this calculation since these frames have a single neighbour in time, increasing the error in the estimate of partial derivative in time.

After an analysis of initial results, it was discovered that the total brightness (i.e. photon count) of the image varied substantially between frames. This was unexpected since the number of photons emitted at any given moment is dependent only on the random radioactive process. In order to quantify brightness variation, the vector B_{total} was formed whose elements represent the total brightness in each frame of the sequence, as shown in Equation 5.

$$B_{total} = [\sum_{v=1}^{X} E_v^1, \sum_{v=1}^{X} E_v^2, \ldots, \sum_{v=1}^{X} E_v^N \ ] \quad (5)$$

where N is the number of frames in the sequence, X is the number of voxels in each frame, E is the intensity of the vth voxel. Let f be the frame index, so that the fth element of B_{total} is B_{total}^f.

Total brightness per frame was analyzed over the cardiac cycle and a brightness equalization module added to make total brightness in each frame constant over the cardiac cycle, as shown in the preprocessing phase of Figure 3. The algorithm followed the steps:

1. Form the vector B_{total} for all frames .
2. Identify the maximum element of B_{total}, max(B_{total}).
3. Calculate new intensities using Equation 6.

$$E_{NEW(i,j,k)}^f = E_{(i,j,k)}^f \cdot \frac{\max(B_{total})}{B_{total}^f} \quad (6)$$

KE curves, showing the variation of total kinetic energy by frame, were plotted and KEf calculated for individuals with normal (n=30) and low/altered cardiac function (n=33) in rest and perfusion images. KE Curves were produced with and without the brightness equalization step so that any improvements created by the new module could be assessed.

Statistical analysis

In order to investigate the relationship between EF and KEf in rest, linear regression was performed on the pairs of values (KEf, EF) formed for each individual.

In order to evaluate the ability of KEf as a classifier of cardiac function, sensitivity and specificity tests were performed. Sensitivity was defined as the fraction of individuals with normal function who were correctly classified by KEf and specificity as the fraction of individuals with low/altered function who were correctly classified by KEf. A receiver operating characteristic (ROC) curve [5] was generated by varying a KEf threshold, T, from 0.01 to 1.0 in intervals of 0.01. For each threshold, the number of true positives (TP), false negatives (FN), false positives (FP), and true negatives (TN) were calculated, and from these values true positive rate (TPR), false positive rate (FPR) and Accuracy (A) calculated as described in reference [5]. Accuracy is the total number of true classifications as a fraction of the total number of patients. The area under the ROC curve (AUC) was estimated using the trapezoidal rule.

Results

Values of KEf were generated for 63 individuals with normal and low/altered cardiac function.

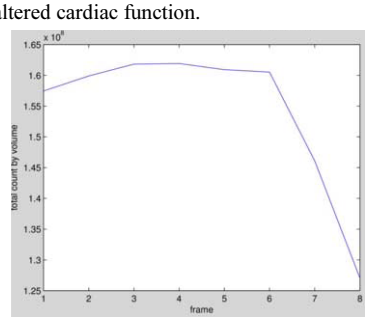

Figure 4– Brightness curve for an individual with low cardiac function (Rest EF = 33%)

Figures 4, 5 and 6 were produced for one of the 33 individuals with low/altered cardiac function and ejection fraction at rest of 33%.

Figure 4 shows the total brightness curve, which has a sharp brightness decrease in both frames 7 and 8. Figures 5 and 6 show the KE curve without and with brightness equalization performed in the preprocessing stage. The large peak in frame 7 of Figure 5 is greatly reduced in Figure 6.

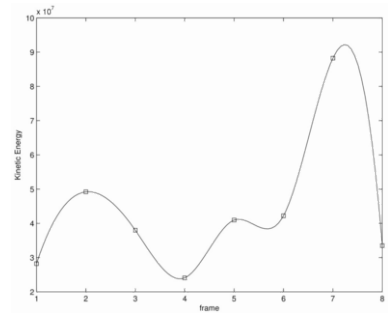

Figure 5– KE curve without brightness equalization (KEf = 85.69%)

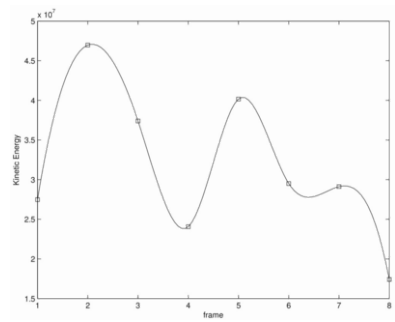

Figure 6– KE curve with brightness equalization (KEf = 50.15%)

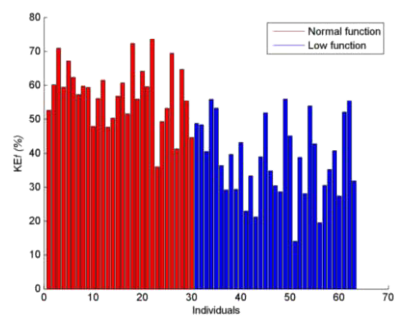

Figure 7– Bar chart showing KEf for rest perfusion images for the 63 individuals in the study

Figure 7 shows the values of KEf calculated for every individual in the study. It can be observed that individuals with normal function have higher KEf than those with low or altered function in general.

Mean and standard deviation of KEf calculated for these two groups and are shown in Table 1. The mean values of the two groups are separated by 19.2%.

Table 1– KEf values obtained from rest perfusion images

	KE*f* in Rest
Normal (n=30)	0.5731±0.0899
Low/altered (n=33)	0.3812±0.1146

Table 2 is a frequency table showing the frame in which minimum brightness occurred for individuals with normal and low/altered cardiac function. The most common frame was frame 8, with a total of 46.0% over the two groups.

Table 2– Frequency table showing the frame in which minimum brightness occurred for the two groups of cardiac function

Frame	1	2	3	4	5	6	7	8
Frequency (normal)	4	2	2	3	3	2	3	11
Frequency (low/altered)	2	3	1	2	2	2	3	18

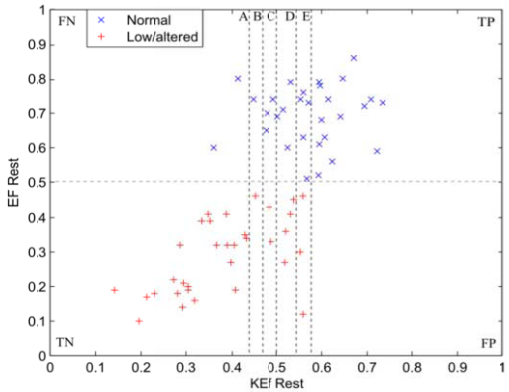

Figure 8– Plot of EF against KEf for the 63 individuals

Statistical analysis was performed on the data. Figure 8 shows a plot of the values obtained for KEf at rest against EF at rest. Regression analysis was performed using MATLAB Statistics Toolbox v.8.2, finding an intercept with the vertical axis of -0.077 and gradient of 1.185. R-squared and adjusted R-squared were 0.546 and 0.538 respectively, with a P-value of 4.79e-12.

Figure 8 is divided into two clusters, with the blue 'x' markers showing the group with normal cardiac function and the red '+' markers showing the group with low or altered function. A horizontal line at EF at rest of 50% divides the two groups. Five thresholds, marked A,B,C,D,E, were manually drawn, and TPR and FPR calculated for each in order to test the ROC curve generated in MATLAB. A summary of the test results is shown in Table 3, where the threshold letter is shown together with the threshold value in the first column. The quadrants of Figure 8 have been labeled as TP, FN, FP, TN, (respectively top-right, top-left, bottom right, bottom left) to indicate how testing was performed; the number of detections in each of the four quadrants were summed for each threshold A, B, C, D, E.

Table 3– Test of thresholds used in ROC curve

T	TP	FN	FP	TN	TPR	FPR	A
A (0.43)	28	2	23	10	0.933	0.333	0.81
B (0.46)	27	3	9	24	0.900	0.273	0.81
C (0.50)	24	6	7	26	0.800	0.212	0.79
D (0.54)	20	10	3	30	0.667	0.091	0.79
E (0.58)	15	15	0	33	0.500	0.000	0.76

Figure 9 shows the ROC curve for KEf. AUC was determined to be 0.906 and placing the threshold at KEf = 49% creates the point in the ROC curve closest to the point (0,1) with a distance of 0.270. Thresholds A-E have been marked and a manually fitted curve drawn.

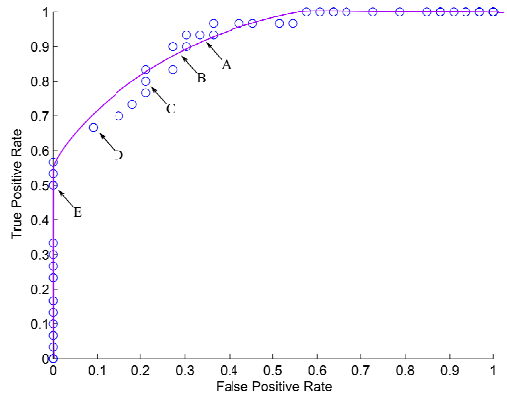

Figure 9–ROC curve for sensitivity and specificity test for classifying normal cardiac function based on KEf

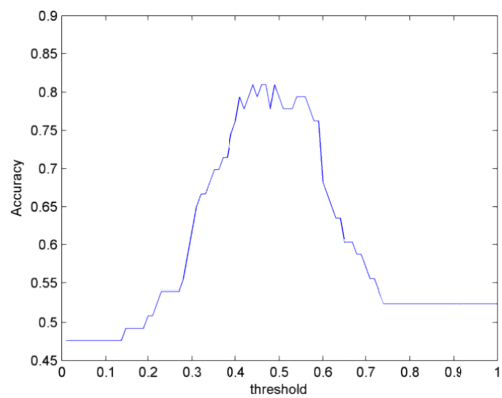

Figure 10– Accuracy against threshold

Figure 10 shows the value of accuracy as the threshold is varied. Accuracy has a maximum value of 0.810 when the threshold is in the region 0.43 to 0.49.

Discussion

Gutierrez et al. [3] showed the expected form for KE curves by averaging KE per frame over 30 individuals with normal cardiac function in SPECT studies. The KE curve seen in Figure 6 has a similar form, with the global maximum in frame 2, a local maximum in frame 5 and a local minimum of velocity between these peaks in frame 4. The temporal resolution is not sufficient to precisely identify cardiac phases. The exact frames in which these events are observed was seen to vary between individuals.

The KE curve without brightness equalization, Figure 5, shows a very large peak in the seventh frame which is not seen after equalization, Figure 6. The corresponding brightness curve, Figure 4, has a sharp drop in brightness in the eighth frame, which corresponds to the position of the large peak. As we showed in Equation 1, the HS method requires objects in the image to have constant brightness, and errors in velocity estimation occur when brightness of objects varies. Since brightness equalization causes the large peak of the KE curve to disappear, giving rise to a curve more similar to those shown in [3], we conclude that the brightness change causes the large peak in Figure 5 and that the equalization module is

able to improve the suitability of the image sequence for the calculation of KEf in this case.

Extra or altered maxima and minima in the KE curve can cause errors in the value of KEf calculated. The calculated value of KEf from Figure 5 and 6 were very different, with values of 85.69% and 50.15%; the global maximum without brightness equalization, from Figure 5, belongs to the large peak, but with brightness equalization, Figure 6, to the first smaller peak. This decrease in KE_{max} reduces the value of KEf.

The cause of the drop in brightness is not easy to ascertain since the formation of the image takes place within proprietary hardware and software. We believe the origin of this phenomenon lies in the process of image construction from varying lengths of RR intervals, since those individuals with the largest variation in cardiac frequency during acquisition also tend to have the greatest variation in brightness by frame and the minimum brightness is most likely to occur at the end of the sequence (Table 2). We hope to better understand how to avoid this change in brightness so that our images are more suitable for motion estimation.

Table 1 shows KEf mean and standard deviation for resting perfusion images of individuals with normal and low/altered cardiac function. There is a separation of 19.2% between the means of the two groups. Figure 7 shows KEf results in bar graph form, showing some overlap between the two groups in terms of KEf.

The selection of individuals for this preliminary study was performed using a simple criterion which could produce mixed groups in terms of cardiac function, reducing separation between the groups and increasing standard deviation. After discussion with medical experts, more rigorous criteria were suggested to categorize the individuals in the image bank, combining measurements of ejection fraction, perfusion, and coronary blood flow. It was also suggested that the image bank be divided into subcategories, perhaps based on a particular cardiomyopathy or degree of disease, as assessed by experts in nuclear medicine.

The HS method requires small voxel displacements between frames and a temporal resolution of 8 frames per cardiac cycle means that the voxel displacements could be inappropriately large. Reconstruction could be performed with 16 frames, but the low count in the Rubidium images means that the signal to noise ratio might become unacceptably low, since the HS method is also sensitive to noise.

The brightness equalization was seen as a necessary step to eliminate inaccuracies in the optical flow estimation; however noise in frames which have low total brightness will be amplified and could cause errors in the estimation of partial derivatives and subsequently in the velocity estimate.

Linear regression shows a gradient close to 1.185 with an intercept on the vertical axis close to -0.077. The R-squared values show that there is some correlation EF and KEf, but it is not very strong. There is a definite trend of KEf increasing as EF increases, but the dispersion of the points is quite large and there are several outliers.

AUC provides the probability that a classifier will rank a positive instance, chosen at random, higher than a negative instance, chosen at random. An AUC of 0.5 means the classifier result is only as good as a guess [5]. Here the AUC is 0.906, indicating that KEf rest has performed reasonably well in classifying individuals with normal from low/altered cardiac function. It should be noted that the value of AUC for KEf at rest does not relate directly with correlation with EF at rest.

Conclusion

In this study KE index (KEf) was evaluated as an indicator for classifying individuals in normal and low/altered cardiac function groups from PET images, with the study showing reasonable results for its ability.

Variation in brightness through the image sequence was seen to cause inaccuracies in the estimation of velocity, which in turn causes significant errors in KEf. We showed how equalization of brightness can reduce errors in KEf.

Future work will involve a more rigorous selection of individuals in the normal and low/altered cardiac function groups, including larger group sizes, and comparing KEf results obtained from images formed from 8 and 16 gated frames.

The results presented were obtained from perfusion rest image sequences, but future investigations could include calculating KEf for the stress image sequences.

The ability of KEf to properly classify patients into the cardiac function groups was tested with a ROC analysis, with area under the curve estimated as 0.906.

To our knowledge this is the first time that kinetic energy index has been applied to PET images.

Abstract

Large-scale human cancer genomics projects, such as TCGA, generated large genomics data for further study. Exploring and mining these data to obtain meaningful analysis results can help researchers find potential genomics alterations that intervene the development and metastasis of tumors. We developed a web-based gene analysis platform, named TCGA4U, which used statistics methods and models to help translational investigators explore, mine and visualize human cancer genomic characteristic information from the TCGA datasets. Furthermore, through Gene Ontology (GO) annotation and clinical data integration, the genomic data were transformed into biological process, molecular function, cellular component and survival curves to help researchers identify potential driver genes. Clinical researchers without expertise in data analysis will benefit from such a user-friendly genomic analysis platform.

Keywords:

Data Mining; Genomic Alterations; Driver Genes.

Introduction

Many large-scale human cancer genomics projects offer huge quantities of genomic data from tumor samples, such as The Cancer Genome Atlas (TCGA) and the International Cancer Genome Consortium (ICGC). TCGA provides a platform for researchers to search, download, and analyze datasets including clinical information, genomic characterization data and high level sequence analysis of the genomes of nearly 50 tumor types [1]. Many researchers use statistical methods and algorithms on clinical and high throughput genomic data, including copy number alterations (CNAs), mRNA and small RNA expression, somatic mutation, and methylation data to find potential driver mutations and genes to improve the prevention, early detection, and treatment of cancer [2-9]. There are many clinical researchers without enough data analysis and bioinformatics training who face an embarrassing situation if they don't have the professional abilities to appropriately manipulate the downloaded data. In recent years, web-based analysis tools such as the Cancer Genome Workbench, Integrative Genomics Viewer, cBioPortal for Cancer Genomics, and Broad Firehose have been used by clinicians and researchers to search meaningful genomic alterations to develop targeted and personalized clinical treatments [1, 9].

To help clinical cancer researchers fully benefit from the TCGA datasets through a simple and user-friendly tool, we developed a web-based platform named as TCGA4U. TCGA4U is an intuitive web-based analysis tool to analyze high-level genomic data of different TCGA samples in distinct cancer types. Currently, the platform offers statistical analysis results and graphical views to help users find interesting results for further investigation. Besides providing the specific gene or gene list, it also provides a genomic characteristics query service, such as CNAs, Somatic Mutation, Gene Expression and DNA Methylation. Furthermore, TCGA4U also integrates the clinical data, the Gene Ontology and data mining results with the gene level data to provide more insights for clinical investigation.

Materials and Methods

TCGA4U Database

Genomic Data

All the genomic analysis data in TCGA4U were downloaded from TCGA's open-access data tier. In this study, two cancer types (Lung adenocarcinoma (LUAD) and Lung squamous cell carcinoma (LUSC)) were used. For each cancer type, TCGA has multiple data types and data levels available for open access, such as Copy Number, Somatic Mutation, and DNA Methylation. Five types of data were used in this study:

1. Copy Number Variants (CNVs) datasets which account for at least 10% of genetic variation and CNVs amplification and deletion may be responsible for many cancers [10, 11]. The level 3 CNVs datasets of LUAD and LUSC were downloaded on Feb 18, 2014.
2. Somatic mutations datasets provide important genomic information and are essential for tumor occurrence [3]. The somatic mutation datasets of LUAD and LUSC were downloaded on Apr 16, 2014.
3. Expression-gene datasets provide interesting expression patterns under different biological conditions for investigators. The expression-gene datasets of LUAD were downloaded on Mar 31, 2014. The LUSC datasets were downloaded on Apr 3, 2014.
4. DNA methylation datasets play a critical role in the regulation of gene expression. LUAD DNA methylation datasets were downloaded on Feb 18. LUSC datasets were downloaded on Apr 4, 2014.
5. Clinical data which contain follow-up information were downloaded on March 19, 2014.
6. All these downloaded datasets were imported into relational database tables defined by expanding the columns defined in the downloaded tab-delimited files.

Genome Reference Data and Other Knowledge Data

The February 2009 human reference sequence (GRCh37) was downloaded from the UCSC Genome Browser. These data provided location information of genes to explore the genomic data such as CNVs and somatic mutations.

In the Gene Ontology (GO) term mapping module, we used the GO online database of the European Bioinformatics

Institute (EBI) to generate directly utilizable gene mapping files, term nodes and edge files. Specific GO term background rates in the genome were calculated and stored as local files. The relationships between GO terms were stored using term nodes and edge files to generate networks.

The EBI Molecular Interaction Database (IntAct) was downloaded on Jun 5, 2014. These data provided a related gene list of specific genes that will be used to identify molecular interaction relationships.

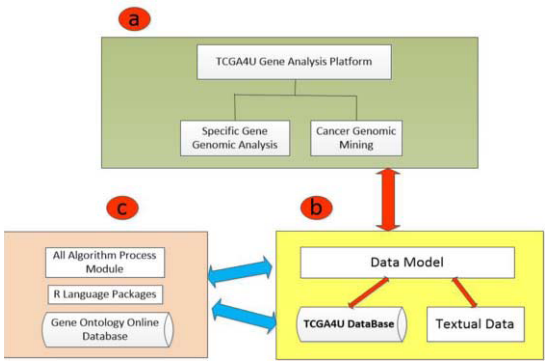

Figure 1 – TCGA4U System Schema

TCGA4U Platform

As shown in Figure 1, the TCGA4U platform provides two functions for the user. The first one is to provide a direct genomic query service that allows the user to query genomic characteristics of specific genes under different cancer types in the TCGA4U datasets. The second is a data mining result that allows the user to explore the driver genes for targeted cancer types in the GWAS level.

Genomic Analysis of Specific Gene

Four types of genomic characteristics with clinical data were available for genomic analysis. Clinical researchers only need to select the interested cancer type and input the gene symbol to obtain analysis results with four parts: CNVs, DNA Methylation, Somatic Mutations, Gene Expression.

Copy Number Variants Analysis

The CNVs datasets of tumor and matched normal were stored separately in two database tables. The gene location information obtained from the genome reference data will be used to obtain the CNVs (log_2-fold change) of this gene from these tables. A histogram of CNVs' values (as shown in Figure 2.A) will give the user an overview of this gene's CNVs under this cancer. Additionally, CNVs' mean, variance, and *p*-value (t-test) of tumor and normal samples can be calculated and shown to the user. Overall, these data can illustrate the amplification or deletion status of the gene copy number.

Integrating with clinical follow-up datasets, patient groups that are separated by CNVs results (level of amplication or deletion) will give four survival curves by Kaplan-Meier estimator (as shown in Figure 2.B).

DNA Methylation Analysis

The beta values of DNA methylation at each CpG site will be plotted as error bars as shown in Figure 2.C. More statistics including minimum, maximum and deviation will be also calculated to assist the user in assessing the DNA methylation rates in specific sites.

Furthermore, the DNA methylation rates at specific CpG sites can also separate patients into two groups (high or low beta value) which can be used to plot different survival curves for the user.

Somatic Mutations Analysis

The number of mutation samples of 11 somatic mutation types at different sites was plotted as a scatter diagram with 11 different colors and shapes (as shown in Figure 2.D). The user can easily identify the hotspot that has a high mutation rate in this mutation type of cancer. Some basic statistics, such as the number of mutation samples, total number of samples, and mutation rate were also calculated to reflect the mutation conditions of the gene in this cancer.

As we have done for other data types, mutation status of specific genes or sites were used to separate patients into different groups to show different survival curves to explore the influences of somatic mutations of specific genes on patients survival.

Gene Expression Analysis

Gene expression data (log_2-fold change) of specific genes were displayed in a histogram as shown in Figure 2.E. Using the IntAct data, a gene list related with query genes will be generated. An expression heat map of this gene list in different samples will be generated by using the R programming language (as shown in Figure 2.F). To make it more flexible, users are allowed to customize the gene list to generate a corresponding heat map. The visualized data and clusters will better illustrate the potential interactions in these genes.

As with other data types, levels of expression divide patients and generate survival curves, revealing the influences of different levels of expression on patients' survival.

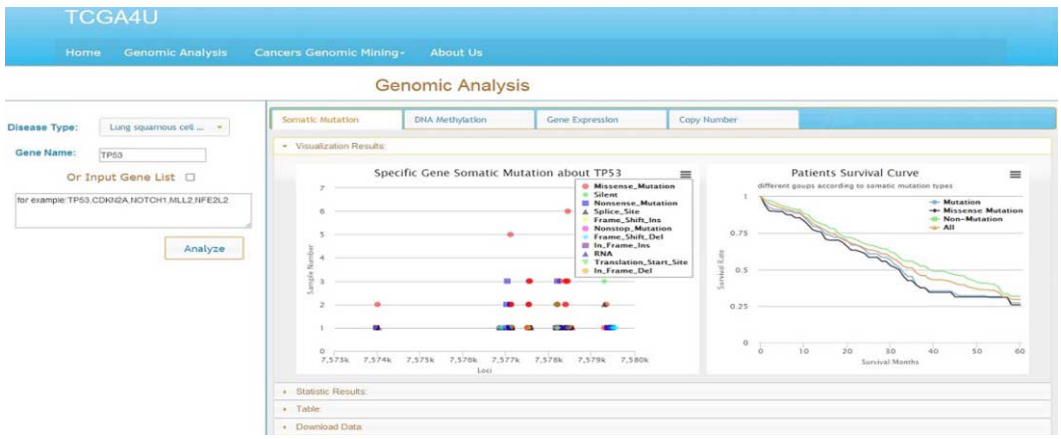

Figure 3 – Specific gene genomic data analysis page

Potential Driver Genes and Mutations Mining

The ability to identify driver genes or prioritize genes from TCGA datasets will help clinical investigators find these target genes for further research. An approach proposed by Trifonov named MutComFocal was used in a TCGA platform [12]. In brief, the MutComFocal algorithm is a Bayesian approach to identify candidate driver genes by integrating point mutation and copy number information in a large number of tumor samples. This method takes into account the recurrence of altered genes with the size of the lesions. Each gene will have calculated three basic and four composite score types: focality score, recurrence score, mutation score, amplification score, deletion score, amplification-mutation score (amp&mut), and deletion-mutation score (del&mut). Genes have separately calculated scores for copy number deletions and gains, with the assumption that high amplification scores will tend to be oncogenes and, conversely, high deletion scores will tend to be tumor suppressors. Finally, a mutation score separately combines with the amplification and deletion score to accomplish somatic mutations combining with CNVs. After that, genes can be tiered based on score distribution. In general, top tier genes are more concerning to us, and more likely to be driver genes. In TCGA4U, a mining tool based on this algorithm was developed. The LUAD and LUSC data was analyzed. A genome level visualization tool was developed to show the gene tiers, score and locations.

Gene Ontology Annotation analysis

The high priority genes in the first tier always contain more than several hundred genes. To further narrow-down the list, a GO annotation enrichment analysis was provided on the platform.

In this process, each gene in the list will be annotated with GO terms in three domains: Cellular Component, Molecular Function, and Biological Process [13]. The terms usage in the list will be compared with the genome background usage rate (the proportion of the number of gene products which mapped to a specific term on total number of gene products) to highlight some biological process that are involved in tumor development. Cytoscape.js – a large-scale network javascript library for graph analysis and visualization – was used to show the GO term networks. The interested terms will track back to the top level terms in the visualized network diagram with enrichment annotation to help the user understand the terms relationships [14].

Results

A publicly accessible website was developed based on these methods and published at http://www.tcga4u.org:8888.

Specific Gene Analysis: genomic alterations characteristics analysis

As previously mentioned, we developed a Specific Gene Genomic analysis module in TCGA4U platform as shown in Figure 3. The left panel was the user operating area that allows the user to choose specific cancer types and input a gene symbol as a query condition. The right part is the main display area. By switching between tab pages, different genomic data type results will be displayed for the user. Each tab page contains some accordion display modules (such as Visualization Results, Statistic Results, Original Table, or Download Data) to help the user locate interesting analysis results. In general, Visualization Results offered corresponding genomic type visualization results and survival curves. Statistic Results mainly provided some basic statistic results such as mean, variance, and the *p*-value of CNVs. Original Table and Download Data were for the convenience of the user to query and download raw data. Additionally, the Gene expression page also offered a heat map of related gene lists. Overall, this function module was designed to offer a simple and user-friendly operation and interface to help the user obtain meaningful analysis results about genomic alterations.

Offer Potential Driver Genes and Tiers Display

To offer researchers some valuable research objects, we developed the Potential Driver Genes Mining module. The same as the Genomic Analysis of Specific Gene module layout, the operating area made the user choose a specific disease and algorithm as query conditions. The right part contained three tab pages: Gene Tier Charts, Gene Score Tables, and Diverse Diseases Complex Heatmap. Gene Tiers Charts displayed Amplified and Deleted Gene Tiers and Amplified&Mutation and Deleted&Mutations Gene Tiers (as shown in Figure 4). The horizontal axis represented score value and vertical axis represented chromosomal location information. Genes were plotted as points with different colors meaning different tiers for the convenience of viewing the distribution of different tier genes on the chromosomes. Meanwhile, each chart marked the top 20 genes to facilitate the user viewing.

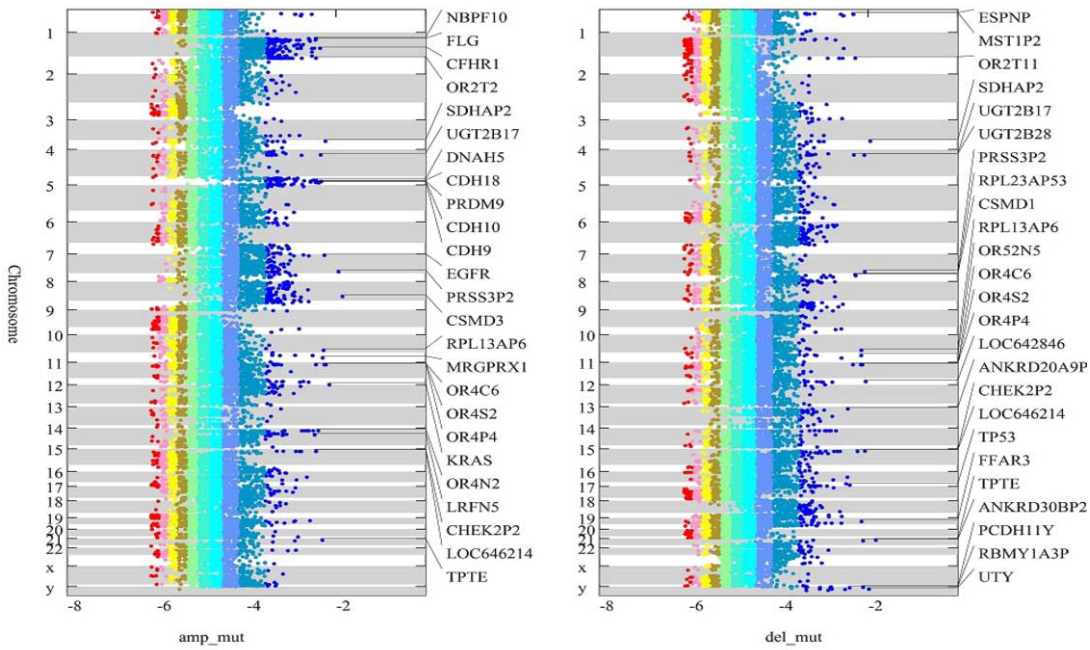

Figure 4– Amplified&Mutations and Deleted&Mutations Gene Tiers of LUAD

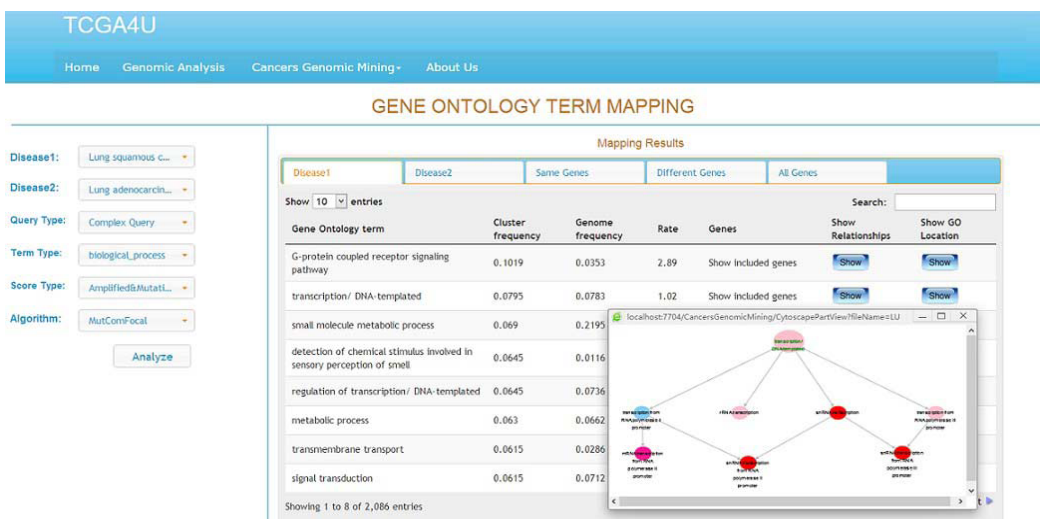

Figure 5– Gene Ontology Term Mapping Analysis Page

GO Term Mapping Analysis

A GO term mapping analysis page was developed as shown in Figure 5. In the query area, the user can choose one or two cancer types, algorithm type, query type, score type, and term type. In the diplay area, there is a GO term mapping table offering specific term mapping frequency, background mapping frequency and change ratio between them. Term cluster mapping frequency meant the percent of gene products in the input gene list mapped to the specific term. Background mapping frequency presented the percent of gene products in the whole genome gene list mapped to the specific term. Detailed gene lists mapping to a specific term in the input gene list were also available for the user. Meanwhile, the table also offered the relationship and location network diagram, if the user clicked the corresponding button. As shown at the lower right in Figure 5, the hierarchy network diagram contained term nodes (node color meant different change ratio values, node color was close to red if high value and blue if low value). Overall, the platform implemented a GO annotation enrichment analysis by simple operations, detailed term mapping information, relationship, and location information to assist the user to further narrow the scope of target genes.

Discussion

The strengths of our online analysis platform compared with other tools are its easiness to operate for biomedical researchers without bioinformatics training and directly provides potential driver genes as research objects. In general, this platform was designed to visualize genomic alterations of a single gene among tumor samples in TCGA and apply novel mining algorithms to ranking genes to offer further study for cancer researchers. In addition, we expanded to utilize gene lists to map to GO terms to narrow down the scope of target genes. The GO term relationships and locations were visualized for the user to help generate hypotheses to explain tumor development.

Although only two cancer types were used in this study, it is easy to extend the platform to more cancer types. We plan to incorporate more genomic data types (e.g., miRNA/mRNA sequencing) and more detailed query conditions according to different clinical data (such as age, sex, and smoking status) to help the user explore the TCGA in a different way. Furthermore, we will add more driver gene mining algorithms and more adaptive GO Annotation analyses.

Conclusion

We developed a web-based genomic analysis platform as a bridge between big data and biomedical researchers. Researchers could conveniently use the platform to query gene-related genomic alteration information in a user-friendly way. Through embedded driver gene mining algorithms and GO annotation analysis, cancer researchers with limited bioinformatics resources can easily explore the TCGA data. This publicly accessible platform will help cancer researchers generate and test their hypotheses on TCGA data more easily, better facilitating translational research.

Acknowledgments

[a] *Department of Biomedical Informatics, The Ohio State University, Columbus, OH, USA*

Abstract

*The worldwide incidence of melanoma is rising faster than any other cancer, and prognosis for patients with metastatic disease is poor. Current targeted therapies are limited in their durability and/or effect size in certain patient populations due to acquired mechanisms of resistance. Thus, the development of synergistic combinatorial treatment regimens holds great promise to improve patient outcomes. We have previously shown that a model for in-silico knowledge discovery, Translational Ontology-anchored Knowledge Discovery Engine (TOKEn), is able to generate valid relationships between bimolecular and clinical phenotypes. In this study, w*e have aggregated observational and canonical knowledge consisting of *melanoma-related biomolecular entities and targeted therapeutics in a computationally tractable model. We demonstrate here that the explicit linkage of therapeutic modalities with* biomolecular underpinnings of melanoma utilizing the TOKEn pipeline *yield a set of informed relationships that have the potential to generate combination therapy strategies.*

Keywords:

Malignant Melanoma; Knowledgebases; Combination Drug Therapy.

Introduction

Melanoma is the most deadly form of skin cancer, accounting for nearly 10,000 deaths in the United States in 2014. The incidence of melanoma is rising faster than any other cancer in the U.S., and there were over 76,000 new cases diagnosed in 2014 [1]. The death rate for melanoma patients in the U.S. has remained stagnant for the past 20 years, and less than 20% of patients have shown responses to traditional chemotherapeutic therapies [2, 3]. Cancer-driving *BRAF* mutations (V600E/K) are found in 40-60% of melanoma patient tumors, and BRAF-inhibitor agents, dabrafenib and vemurafenib, have extended median patient survival by 5-6 months [4]. Despite recent advances in targeted therapies, drug resistance remains a significant challenge for melanoma patients. Thus, further work to discover drugs that act synergistically with existing therapies and decrease drug resistance is desirable.

Traditional bench-based approaches for discovering synergistic drug combinations, including high-throughput drug screening, are costly and inefficient [5, 6]. It is estimated that an average of 1 billion dollars and 15-20 years is needed to bring a new drug from the bench to the bedside [7]. Further, 52% of drugs fail during development in phase 1 clinical trials, and only 25% of compounds that enter phase 2 proceed into full phase 3 clinical studies [8]. Biomedical informatics methods may offer more efficient and efficacious approaches for identifying synergistic drug combinations. Several computational approaches to optimize the drug discovery process have been proposed that involve modeling of structural, biochemical and biophysical properties [9].

In this study, we aim to computationally identify possible drug combinations to act synergistically with BRAF inhibitor therapies using a knowledge-anchored approach. The use of Conceptual Knowledge Discovery in Databases (CKDD) methods provides a potential means to accelerate hypothesis generation and recapitulation of known relationships between combinations of database entities. We have previously shown that a model for *in-silico* knowledge discovery, Translational Ontology-anchored Knowledge Discovery Engine (TOKEn), is able to generate valid relationships between bimolecular and clinical phenotypes in the context of large-scale, chronic lymphocytic leukemia datasets [10].

Knowledge discovery in databases represents a type of conceptual knowledge engineering method used to characterize relationships among distinct elements contained within a database [11]. Domain-specific knowledge collections, such as ontologies, are commonly used during knowledge discovery to augment meta-data contained in the targeted database schema. This overall approach is the basis for constructive induction, a type of knowledge discovery in databases (Figure 1). The constructive induction process generates conceptual knowledge constructs, otherwise referred to as induced "facts," that are defined by data elements and the semantic relationships that link them. Resulting conceptual knowledge constructs may be used to generate potential hypotheses about relationships between distinct data elements. Previous evaluation of the TOKEn method demonstrated its validity and "meaningfulness" according to domain experts [10]. Here we present the first application of TOKEn aimed at identifying drug combinations in malignant melanoma.

Methods

The TOKEn workflow has been previously described [10]. The overall workflow specifically applied in this study is shown in Figure 2. We obtained 42 FDA-approved and investigational "melanoma" drugs from DrugBank (version 4.1) [12]. DrugBank is a comprehensive database that includes chemical, pharmacological and pharmaceutical drug information as well as sequence, structure and pathway information regarding drug targets into more than 200 data fields per therapeutic agent. Relevant data fields pertaining to biomolecular foundations of drug action were selected, including "description," "mechanism of action," "pharmacodynamics" and "targets."

We developed an automated method to map selected DrugBank database fields containing free text to concepts within the Unified Medical Language System (UMLS), and selected those concepts belonging to the NCI, SNOMED-CT, MSH and GO ontologies due to their broad coverage,

including concepts related to drug features and actions. Similarly, a set of semantic types was heuristically defined to generate hypotheses targeted to drugs. Mapped entities were subsequently reviewed manually for accuracy and relevancy for mechanistic underpinnings of therapeutic agents. We obtained UMLS Metathesaurus associations from the previously curated set including parent, child and semantic relationships that were refined by subject matter experts to filter those relationships to be most meaningful for relating biomolecular and phenotypic concepts [10]. We determined that these heuristics generated in the original TOKEn study to be sufficiently generalizable for our purposes. We set search space optimization controls for the constructive induction method by calculating the shortest path depth-from-root of the ontology concepts selected and used them to annotate concepts as an indicator of concept granularity.

The UMLS MRHIER source file indexes all unique hierarchical paths determined by the source vocabulary as strings of distinct atoms from a particular concept to the UMLS root concept. Using this file, the minimum distance to the root was calculated for each UMLS concept corresponding to the source vocabularies. For each concept unique identifier (CUI), we set the 'minimum distance to the root' equal to the minimum number of elements in the corresponding path-to-root fields. The average depth of the ontology concepts that were mapped from the initial DrugBank data elements was found to be 4 "steps" from the UMLS root. We generated induced "facts" (Figure 1) using the graph-theoretic constructive induction algorithm previously described [10]. Traversal paths for drug combinations initiated at concepts associated with BRAF inhibitor drugs (vemurafenib, dabrafenib, PLX-4032) and terminated at those associated with the remaining 39 non-BRAF inhibitor drugs in the set. The algorithm avoids cycles by preventing the inclusion of duplicate concepts within a single traversal path. We constrained all concepts included in the induced "facts" to be at a depth equal to or greater than the minimum of the initial and terminal concepts. Pairs include direct relationships between drug-related concepts, while triples and quadruples include 1 and 2 intermediate concepts, respectively.

In order to prioritize drug relationships generated via the TOKEn method, we incorporated a novel ranking method according to their relatedness to melanoma pathogenesis. We obtained 663 "melanoma" concepts within the NCI Thesaurus (version 14.07d), and of those we used 221 concepts related to biomolecular properties of the disease. For example, we excluded tissue-level diagnoses or other high-level disease terms (uveal melanoma, acral melanoma, etc.). We further applied the TOKEn method to generate relationships that initiated with these NCI melanoma-associated concepts and terminated with concepts derived from the 42 DrugBank melanoma-associated therapies.

In order to rank BRAF inhibitor and non-BRAF inhibitor drug pairs generated via TOKEn, we calculated a Drug Combination Score (DCS) using the sum of two metrics for non-BRAF inhibitor drugs. Since BRAF inhibitors are expected to have the same degree of relatedness to melanoma pathogenesis, dabrafenib, vemurafenib and PLX-4032 were weighted equally. For each non-BRAF inhibitor drug, we summed: the Overlap score, the number of concept unique identifiers that mapped directly to drug concepts and those intermediate concepts derived from the induced facts between drugs that overlapped with the melanoma-associated set of CUIs; and the Distance score, the number of induced fact relationships between drug and melanoma concepts that were also weighted to the number of hops between initial and terminal concepts, where proximal relationships (i.e. fewer hops) were given a higher weight. Resulting Drug Combination Scores (DCS) were rank-ordered from highest to lowest for each non-BRAF inhibitor drug and final paths to concepts BRAF inhibitor. Log-2 transformed values for scores are reported.

Results

Concept identification and constructive induction

The 42 melanoma drugs indexed in DrugBank were mapped to UMLS concepts. Following manual review, a total of 495 drug-related UMLS concepts were identified for this study. The mean and median number of unique concepts per drug were 11.8 and 10.5, respectively. The BRAF inhibitor drugs (n=3) and non-BRAF inhibitor drugs (n=39) mapped to 23 and 300 unique concepts, respectively. The total numbers of induced facts in this study are listed in Table 1. For the total number of pairs, triples, quadruples and quintuplets, 28, 187, 6,469, and 196,284 concepts were anchored to a BRAF inhibitor. A total of 202,968 induced facts between BRAF inhibitor and non-BRAF inhibitor drugs were generated. In Table 2, examples of induced traversal paths between BRAF inhibitor drugs (vemurafenib, dabrafenib, PLX-4032) and non-BRAF inhibitor drugs are shown.

Drug combination scoring of induced facts

The FDA-approved anti-melanoma drug combination of trametinib and dabrafenib is evidenced here (Table 2) by the recognized relationship between the MAP2K1 and BRAF proteins in the MAPK signaling pathway and phosphorylation of its constituent proteins in melanoma tumors [13]. Furthermore, the combination regimen of trametinib and dabrafenib was recently approved by the FDA for use in melanoma patients with BRAF V600E or V600K mutations. Although PI-88 is an investigational drug not currently approved by the FDA, we show here evidence that it may support inhibition of tumor angiogenesis in combination with other BRAF inhibitors.

We implemented the DCS scoring metric to rank proposed BRAF inhibitor and non-BRAF inhibitor drug combination pairs predicted by the TOKEn algorithm (Table 3). The number of unique mapped concepts for the BRAF inhibitors dabrafenib, PLX-4032 and vemurafenib were 16, 3, and 14, respectively. Importantly, all three BRAF inhibitors shared the common set of concepts "BRAF gene," "Proto-Oncogene Proteins B-raf," and "Phosphotransferases" that were identified as initial concepts in all induced relationships that terminated with those associated with non-BRAF inhibitor drugs. Due to this congruency among concepts and the common therapeutic action of inhibiting BRAF protein activity, BRAF inhibitors were weighted equally in our scoring algorithm.

The Distance score component of the DCS was calculated over 69,856 induced facts between non-BRAF inhibitor and melanoma concepts. The values of non-zero log-2 transformed DCS ranged from 4.25 (AS1409) to 28.83 (AGRO100). In principle, the Overlap score emphasizes the direct relationships between drug and melanoma concepts (e.g. drug targets representing melanoma genes), with the tradeoff of possibly severely limiting potential drug-disease connections. Conversely, the Distance score emphasizes indirect relationships, or induced facts, between drug and melanoma concepts. Of note, the Overlap scores and Distance scores were significantly correlated among all non-BRAF inhibitor drugs (Pearson = 0.46, $p<0.0031$). Thus, these component metrics can be viewed as complementary when used to rank

drug combination predictions. Others have shown that distance-based metrics can be used to determine the similarity between drugs based on conceptual knowledge for drug repurposing applications [14-17]. Future work will assess the individual contributions of these metrics in validated drub combination relationships.

Discussion

In this study, we present the first application of the TOKEn method for *in-silico* knowledge discovery to database-derived melanoma drug-disease relationships. We developed a novel ranking metric for TOKEn-generated hypotheses for BRAF inhibitor (n=3) and non-BRAF inhibitor (n=39) drug combinations in melanoma. We found 202,968 unique relationships linking BRAF inhibitor drugs to 30 out of 39 non-BRAF inhibitor melanoma drugs that were indexed in DrugBank. AGRO100 was the highest ranked non-BRAF inhibitor drug for use in combination with BRAF inhibitors. AGRO100 is an experimental anticancer agent that acts as an aptamer and inhibits nucleolin, a protein that is uniquely expressed on the surface of tumors cells.Results from a phase I study of AGRO100 in patients with advanced cancers showed that half of the patients enrolled had stable disease with no toxic effects observed in any patient [18]. Further clinical development of AGRO100 resulted in the modified AS1411 agent, which has shown subsequent success in clinical applications [19, 20]. Interestingly, AS1411 was shown to reduce levels of a specific subset of miRNAs through its actions on nucleolin, including miR-21, miR-221, miR-222 and miR-103. These miRNAs are causally involved in breast cancer initiation, progression and drug resistance, and are also well known melanoma-associated miRNAs. Of note, all of the interferon-based therapies, with the exception of natural alpha interferon, were highly ranked according to their DCSs (rank 2-4).

Recently, combinations of BRAF inhibitors and immunotherapies have shown improved efficacy treating melanoma tumors and are being investigated in clinical trials [21]. Trametinib, a MEK inhibitor, is part of an FDA-approved combination with dabrafenib, and was ranked 7th according to DCS and 1st according to the overlap score alone. AZD-8330 is an experimental MEK inhibitor, and was ranked 5th according to DCS and 2nd according to the overlap score alone. This application of the TOKEn method has made improvements over the initial iteration by incorporating object-oriented programming and a system by which to prioritize induced facts.

Our study is currently limited by constraining the TOKEn method to canonical knowledge regarding melanoma concepts. The limited information contained within structured databases such as DrugBank may have prohibitively reduced our search space, and may have accounted for failing to recover relationships for 9 out of 39 non-BRAF inhibitor drugs. Furthermore, by limiting this study to known melanoma drugs indexed within DrugBank, we excluded possibilities to evaluate other existing drugs and small molecules that are not currently indicated or investigated in melanoma. Future work will include increasing our search space to other databases targeted to drug and melanoma information, as well as extracting data directly from the literature. We will also conduct future work to validate our findings and approach, including evaluating semantic similarity measures among mapped concepts, using graph-based network modeling methods and formal subject matter expert review.

Conclusion

We have demonstrated that a model for in-silico knowledge discovery, Translational Ontology-anchored Knowledge Discovery Engine (TOKEn), is able to generate valid relationships between drug and biomolecular phenotypes in the context of malignant melanoma.

Table 1– Summary of transitive paths generated at a search depth control of 5 and a distance from root of 4.

Number of concepts in induced "facts"	**2**	**3**	**4**	**5**
Number of unique relationships	5,940	103,540	4,789,356	100,289,621

Table 2– Examples of predicted "facts" connecting distinct drugs via triplets.

Relationship pattern	Conceptual knowledge constructs
Trametinib → Dabrafenib	MAP2K1 protein – [gene plays roles in biological process] – Serine/Threonine Phosphorylation – [process involves gene] – BRAF gene
PI-88 → Vemurafenib	FGF1 gene – [gene plays role in process] – Angiogenic process

Table 3– Top ten ranked non-BRAF inhibtor drugs hypothesized for use in combination with BRAF inhibitor drugs. DCS = Drug Combination Score. Reported DCS, Overlap and Distance scores are log-2 transformed values

Non-BRAF inhibitor drug	**DCS**	**Overlap score**	**Distance score**
AGRO100	*28.83*	*14.46*	*14.37*
Peginterferon-alfa-2a	*28.66*	*13.93*	*14.74*
Interferon_alfacon-1	*28.45*	*13.87*	*14.58*
Inteferon_Alfa-2b	*25.82*	*11.24*	*14.58*
AZD-8330	*25.77*	*14.68*	*11.10*
Trabectedin	*25.33*	*11.92*	*13.41*
Trametinib	*25.02*	*14.99*	*10.04*
ZEN-012	*23.09*	*11.40*	*11.70*
PI-88	*23.01*	*11.09*	*11.93*
ABT-510	*22.31*	*10.99*	*11.33*

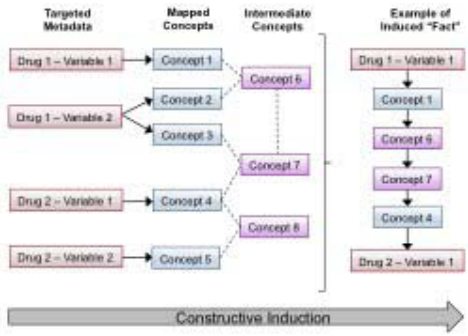

Figure 1 – Constructive induction of conceptual facts between distinct drugs. Mapping between database elements of targeted metadata to corresponding ontology concepts are utilized to induce "facts" among database elements, in this case, distinct drugs. Concepts 6 and 7 represent intermediate concepts not mapped to an original drug database element that define a higher-order transitive path that begins and terminates with drug database elements.

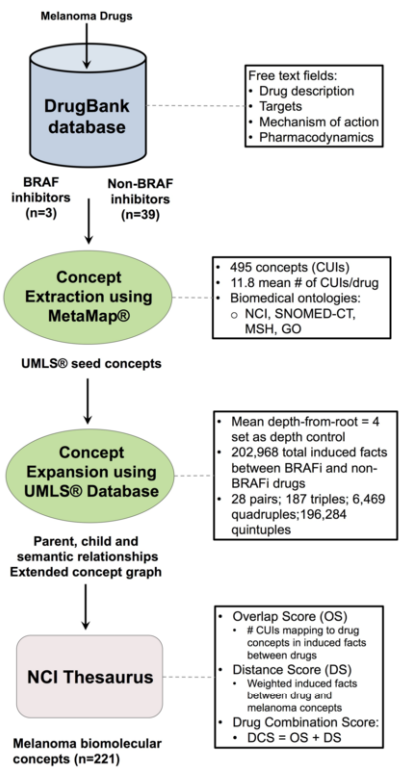

Figure 2 – Overview of TOKEn and DCS workflow.

Abstract

Biomarker-based translational research enables deep insight into cellular processes and human diseases. As a result, high-throughput technologies promulgating a fast and cost-effective generation of data are widely used to advance our understanding in the molecular background of individuals. However, the increasing volume and complexity of data increases the need for sustainable infrastructures and state-of-the-art tools allowing management, analysis, and integration of OMICS data. To address these challenges, we have performed site visits of core facilities with a focus on high-throughput technologies to explore their (IT) infrastructure, organizational aspects, and data management strategies. Different stakeholders were interviewed regarding requirements and needs for dealing with high-throughput data. We have identified four different fields of action: (1) the interface from biorepositories to service providers of high-throughput technologies, (2) aspects within services providers, (3) the interface from service providers to bioinformatical analysis, and (4) organizational and other aspects. For each field, recommendations and strategies were developed for implementation of a seamless pipeline from biorepositories to highly specialized high-throughput laboratories including the sustainable management and integration of OMICS data.

Keywords:

OMICS; clinical research infrastructure; metadata standards; data management.

Introduction

In personalized medicine, biomarker-based research is widely applied for translating biological knowledge into diagnostic, predictive, and therapeutic application (taking differences between individuals into account). Here, a variety of molecular high-throughput technologies are used to advance our understanding in cellular processes and human diseases. This includes analysis of the genome, transcriptome, epigenome, proteome, and metabolome. In colloquial language, these disciplines end with the suffix “omics”. Widely applied methods and technologies in the OMICS field are next-generation sequencing (NGS), microarrays, and liquid chromatography in combination with mass spectrometry. They all share a high degree in miniaturization, automatization, and parallelization.

Usually, high-throughput platforms are operated in centralized core facilities (CF) of scientific research institutions or health centers and have a focus on specialized disciplines (e.g., genomics or proteomics). Beside the efficient and effective provision of methodological skills, the operation of highly specialized equipment, and the bioinformatic data analysis; CF offer comprehensive consulting in project design, further development and maintenance of applications, and tutorials for the transfer of expert knowledge. In addition to CF, high-throughput platforms and profound knowledge can also be found in biomedical or natural sciences departments. In both cases, services are available to research groups affiliated to the institution and external cooperation partners, in compliance with dedicated concepts, rules, and conditions. Over the last years, technological improvements, significant cost reductions, and the faster analysis of biomolecules were the main impulses driving the field from research to clinical application. Here, the main focus is on the analysis of disease-related genes generally known as panels.

However, the growing popularity of OMICS also leads to big challenges [1-3]. The increasing volume of huge and highly complex data sets pose greater requirements on data management (including integration, analysis, archiving, and provision of data), server sizing, and computing power. The traceability and reproducibility of data also require comprehensive and standardized annotation of processes, equipment, and tools. Also, given the specific requirements on clinical data in terms of quality, priority, and validity, separate OMICS infrastructures are required for clinical context. In order to have a sustainable and long-lasting infrastructure, general concepts for data management and infrastructure organization are required. Here, we present strategies and recommendations for the design of a generic clinical research infrastructure for OMICS data; and an overview about tools for their management and analysis to accelerate translational research.

Materials and Methods

To address the current situation and needs of suppliers and users in terms of infrastructure organization and data management, and to develop strategies and recommendations for improved dealing with OMICS data; the following four steps were performed:

Design of the questionnaire

A structured interview guide was designed with the intention to address one issue per section and to analyze the current situation, challenges, and possible solutions. Identified topics were: (1) general questions concerning the CF and the local environment, (2) infrastructure organization, (3) offered services including their general regulations and conditions, (4) available equipment, (5) data management including concepts for data annotation, integration, archiving, and provision, and (6) bioinformatical issues. The interview guide was used as an

orientation guide for the interviews with experts in the field and for site visits of CF of biomedical and natural sciences departments with strong expertise in OMICS.

Identification of users and conduction of qualitative interviews

Four target groups were identified: (1) heads and managers of OMICS core facilities, (2) researchers and clinicians from the areas of human genetics, oncology / haematology, pathology, and pharmacology (users of OMICS technologies and data), (3) IT officers and computer scientists responsible for data management and IT infrastructure organization, and (4) bioinformaticians responsible for data analysis. In total, 15 interview partners were identified and contacted via E-Mail inviting them to participate in an interview. All interviews were conducted by the same two scientists to ensure standardized procedures. Interviews were recorded using a recording device and then transcribed. The transcription was restricted to the paraphrasing of statements made by the experts.

Identification of core facilities and conduction of site visits

In order to explore the processes, equipment with OMICS platforms and hardware, and organizational framework; site visits of CF were performed. Selection was based on two criteria: (1) focus on genomics, transcriptomics, proteomics, or metabolomics, and (2) affiliated with a scientific research institution or health center. Moreover, the selected facilities should represent a broad cross section of size, services, and equipment. In total, seven facilities were selected:

- the Microarray and Deep-Sequencing CF in Göttingen (Germany),
- the CF for Medical Biometry and Statistical Bioinformatics in Göttingen (Germany),
- the Institute for Clinical Molecular Biology in Kiel (Germany),
- the Functional Genomic Center in Zurich (Switzerland),
- the Interdisciplinary Center for Clinical Research in Leipzig (Germany),
- the Sequencing CF at the Max-Planck-Institute for Molecular Genetics in Berlin (Germany),
- the Institute of Experimental Genetics at the Helmholtz Zentrum in Munich (Germany),
- and the German Cancer Research Center and the University Hospital in Heidelberg (Germany).

Analysis of the results and conclusions drawn

Processes and results derived from the site visits were aggregated to a model infrastructure using Unified Modeling Language (UML) and Business Process Model and Notation (BPMN). Afterwards, requirements, needs, and challenges identified in expert's interviews were used to develop strategies and recommendations for improved management of OMICS data and infrastructure organization.

Results

As a result of our interviews, we find strong evidence, that due to today's high quality demands and the high degree of specialization we will see a consequential centralization of most biomarker service units towards high-throughput service providers. Considering the short model cycle and the high running expenses of sequencers only facilities with a high load factor and high quality interfaces from biobanks to the bioinformatic analysis groups will be sustainable.

Regarding the infrastructure, not only the measuring devices, but IT infrastructures are also cost drivers. A facility working to capacity will produce a similar amount of data as a Picture Archiving and Communication System (PACS) or a Pathology Information System in a hospital.

The service units mostly generate turnover from daily orders. As they are mostly only equipped with short-term storage, storing for longer time causes problems.

Therefore, the interfaces from the mostly vendor-specific file format from the measuring devices, the quality assurance in the primary analyses to the further steps outside the facility have to be taken into account.

Most relevant to our survey seems to be the pipeline from biorepositories and service providers of OMICS technologies as the data producing entities to the (secondary) bioinformatic analysis and data integration (Fig. 1). As the prognostic factor of OMICS data is very limited without further annotation, for example the phenotype data, structured anamnesis, and further clinical data have to be integrated prior to the overall analyses.

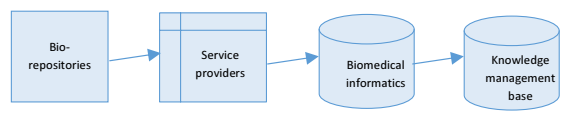

Figure 1 - Simplified pipeline from biorepositories to service providers of OMICS technologies (material logistics), transport of the resulting data to biomedical informatics units for integration of the corresponding data and further analyses. Furthermore, the results should contribute to a knowledge management base.

On the application level, we can distinguish four groups of software families along the high-throughput analysis pipeline.

While software for biorepositories has matured in recent years, the situation further down the pipeline seems to be much more complex. Within the service providers of OMICS technologies we find commercial software solutions with the corresponding analysis equipment [4]. Quite often this leads to vendor-specific file formats (e.g. bcl files for Illumina equipment) instead of standard formats like FASTQ [5, 6]. Unfortunately, there are still few standardized solutions for a workflow-supporting data management within most facilities from biorepositories to service providers of OMICS technologies and further down the pipeline to bioinformatic units. In consequence, this leads to individual solutions for the crucial transfer of analysis and result data from the sequencing facility to biostatisticians and bioinformaticians (iii).

For the integration of different data types (for example OMICS and clinical data) including the scripts for extracting, transforming, and loading the data (ETL), solutions are available [7] and discussed, evaluated, and further developed at many sites. As this is to be a larger scale problem, and initiatives like FAIRDOM[1] and research data alliance[2] are currently working on solutions. As a result, the openBIS [8] software seems promising to solve some workflow related problems.

In the last group we find some software packages that support the interface from data management to knowledge extraction

1 http://www.fair-dom.org
2 https://europe.rd-alliance.org/

and knowledge management (eTriks[3], bioxm[4] [9, 10], geneXplain[5]).

Discussion

In this paper, we identified four different fields of action: (1) the interface from biorepositories to providers of OMICS technologies, (2) aspects within providers of OMICS technologies, (3) the interface from providers of OMICS technologies to (bioinformatical) analytics, and (4) organizational and other aspects. The following guidance details each field of action:

Interface from biorepositories to providers of OMICS technologies

- While professional solutions documenting lab workflows, projects as well as management of biospecimens and their corresponding data are already widely spread and established in the domain of biobanking, there is a huge demand for the development and implementation of adequate IT solutions for managing OMICS labs.

Aspects within providers of OMICS technologies

- Adequate annotation schemes for the standardized and harmonized data acquisition from genomics, epigenomics, transcriptomics, proteomics, and metabolomics have to be developed and established.
- Already existing schemes for data annotation like the Minimum Information about a (Meta)Genome Sequence (MIGS) [11], the Sequence Read Archive (SRA) scheme of the European Nucleotide Archive, the Minimum Information About a Microarray Experiment (MIAME) [12], the Minimum Information About a Proteomics Experiment (MIAPE) [13, 14], and the Metabolomics Standards Initiative (MSI) have to be applied in practice, evaluated, and if needed, adopted.
- General overviews about existing laboratory equipment and a transparent (central-driven) procedure for the acquisition of new devices on a site are essential to achieve an efficient workload and to avoid unnecessary duplicate equipment acquisitions.
- For cost and quality reasons, it is to be expected over the medium term, that service providers in the OMICS field are becoming increasingly professionalized and centralized.
- Implementation and preservation of sustainable infrastructures cannot be done by project-related resources, but rather require the willingness of research institutions, institutions within the health system, and other national or international funding initiatives at the state level to make major investments and provide funds for operations.
- It has to be considered, that with falling prices for molecular high-throughput analysis, massive problems arise concerning long-term storage of data. To avoid the duplication of data at both providers' and customers' sites, processes and regulations are needed to clarify who has to preserve the data with respect to Good Scientific Practice (GSP) and Good Clinical Practice (GCP).
- Besides the raw data, long-term preservation has to contain quality scores, workload data from the labs and information about project design (including list of specimens and billing information). In the case of NGS analyses, raw data should be preserved as FASTQ, BAM or in vendor-specific formats from the laboratory devices (like bcl data format, which is generated by sequencers from Illumina). These vendor-specific formats allow for the deriving of all subsequent analysis data again.
- Many infrastructures for high-throughput data lack a standardized mechanism for data exchange between researchers, clinics, service providers, biomedical informaticians and biostatisticians. The definition and implementation of such interfaces are of major relevance. There is a need for action to achieve reproducibility and sustainable availability of data regarding GSP and GCP.

Interface from providers of OMICS technologies to analytics

- Integration, analysis, and interpretation of data require a profound knowledge about bioinformatic and biostatistic analysis as well as an understanding of the biological system context. However, the knowledge of researchers and physicians is oftentimes insufficient. To eliminate and avoid misunderstandings, the management, integration, and analysis of molecular high-throughput data have to be added to researchers' and physicians' curricula.
- A close collaboration between the OMICS fields and bioinformatics is necessary in the course of standardization, management, integration, and transfer of data and data models in systems biology.
- The lack of sustainable, site-independent solutions seems to be a widespread problem. International efforts are required in order to design such an infrastructure. Existing products like openBIS emerged from the Fairdom [8] project.

Organizational and other aspects

- For the sustainable operation of central service facilities, preservation and development of know-how as well as hands-on expertise are essential. Problems due to temporary mid-level academic positions have to be covered. To establish satisfactory expertise, these service facilities should also have a close connection to other related institutions.
- Existing infrastructure is predominantly research-oriented. Because of high requirements for patient care regarding quality, availability, and validity of high-throughput molecular data, separate structures are needed. Concrete and preferably generic concepts for the integration of OMICS analysis in clinical routine should be developed and implemented.
- Ethical and legal questions - especially for managing incidental findings and findings, which affect direct family members or derive from new scientific knowledge - have to be considered.

5 http://genexplain.com/genexplain-platform-1

Conclusions

From literature, interviews, site visits, we can infer that there are high-quality solutions established within the professional high-throughput labs. Mostly, the vendor-software corresponding to the lab equipment is embedded in individual solutions for accepting and integrating data from the clients, individual interfaces for transferring the data to further analysis or back to the client.

This severely hampers efficient workflows. Urgent action is needed for the design of standardized interfaces between service providers, biostatisticians and users in order to adequately integrate data and reach the goal of reproducible, GSP and GCP-conforming data management in the OMICS arena.

The increased need in personalized medicine for management and exploration of OMICS and clinical data poses a big challenge for data management. Available solutions [7] are discussed, prototypically implemented, and evaluated at many sites. The further development and dissemination of such tools in the OMICS community will be crucial for translational research.

As the conversion of the hitherto scattered measuring equipment to sustainable, highly specialized high-throughput labs will continue, the seamless pipeline from biomaterial to integration, analysis, and knowledge management will be a key factor for success.

Although site visits and interviews in this report covers only German and Swiss institutions, the findings and recommendations are consistent with OMICS facilities in the UK, Paris (France), Pavia (Italy), and in Boston (US) reported by our colleagues within the US and European i2b2 academic user group.

In addition to the rather technical findings, quite some ethical and legal challenges are discussed nationally and internationally.

Abstract

The aim of this work is to assess and analyze the discrepancies introduced in the reconstruction of an entire tumoral bone slice from multiple field acquisitions of a large microscopy slide. The reconstruction tends to preserve the original structural information and its error is estimated by comparing the reconstructed images of eight samples against single pictures of these samples. This comparison is held using the Structural Similarity index. The measurements show that smaller samples yield better results. The detected errors are introduced by the insufficiently corrected optical distortion caused by the camera lens, which tends to accumulate along the sample. Nevertheless, the maximum error encountered does not exceed 0.39 mm, which is smaller than the maximum tolerable error for the intended application, stated in 1mm.

Keywords:
Microscopy; Confocal; XY-table; Stitching; Bone tumor; Histological Techniques; Error evaluation.

Introduction

In a primary bone tumor resection surgery, a surgical specimen is obtained following the guidance of a preoperative plan based on Computed Tomography (CT) and Magnetic Resonance Imaging (MRI) studies [1,2,3]. In certain areas of the MRI images, however, the tumoral region limits cannot be well delineated by simple visual inspection.

Optical bright-field microscopy is a technique used in pathology to view samples and assess the classification of bone tumors [4,5]. The conventional practice in histopathology is to evaluate certain critical portions of the surgical specimen sample. Nevertheless, this practice does not enable establishing a direct correspondence between the microscopy images and preoperative MRI images, impeding the accurate classification of doubtful regions.

The main aim of this work is to enable the reconstruction of an entire bone slice sample from a surgical specimen, stitching together congruent microscopy pictures. Structural conservation is a major concern, due to the fact that the reconstructed image will be superimposed to its corresponding slice image in a volumetric magnetic resonance of the surgical specimen. Therefore an evaluation of the introduced error is addressed as well. The direct comparison between MRI image and microscopy images might lead to a new way of interpreting MRI images, and hence determine whether there exist tumoral tissues in the region under study.

Methods

Optical acquisition

In order to acquire the images, a Carl Zeiss microscope, Primo Star model (iLED Halogen/LED) was used, supplied with a Canon Powershot A640 camera, mounted through an array of coupling lenses. The total magnification rendered on the pictures corresponds to the objective magnification (40x) added to the camera analog zoom. This gives a total measured resolution of 1270 pixels per millimeter. The sample scanning is enabled by a XY-table designed with two step motors, providing a resolution of 200 steps per millimeter of movement (6.3 pixels per step). An 8-bits word UART serial communication between the controlling system, implemented in a PC running MATLAB® 2012b (The MathWorks, Inc., Natick, Massachusetts, United States), and the XY-table controller, implemented using a Texas Instruments® MSP430G2553 microcontroller completes the closed loop system.

Figure 1– Camera coupled to microscope, focusing a bone tissue sample disposed on the XY-table.

Sample scanning process

The scanning process is divided into two main steps:

- The control system, which takes consecutive pictures in the X axis direction of movement, generates a row

of the final image, and moves in the Y axis direction, leading to a new capture of pictures.

- The process of rows stitching.

Control system

Two consecutive pictures should have a transition region overlapping in a range from 40% to 60% of the capture area. Matching points between pictures are detected by searching common features with the Speeded-Up Robust Feature (SURF) algorithm [6]. Even though the movement is supposed to occur only in the X direction, there are displacements in Y due to the misalignment of the sample in the XY-table with the microscope-camera array. These displacements are compensated with consistent movements in the Y direction. During the search of features and execution of XY-table movements, a low-resolution video mode of the camera is used. Several high-resolution pictures are afterwards taken and their level of focus is measured using the Brenner gradient [7]. Once the best focused image is chosen, the process of stitching between consecutive images takes place. Afterwards, an optional blending step may be applied to match small differences in structure and luminescence in the transition zone between pictures.

Rows stitching

The rows previously obtained are then aligned one after the other, also using common features extracted with the SURF algorithm.

Optical compensations

Before starting the sampling process, luminescence compensation is performed: a sample-free RGB picture is taken (P), its mean is measured (μ), and the compensation RGB matrix (M) is calculated as follows:

$$Mij = \mu / Pij \quad (1)$$

Geometric compensation is also carried out, which attacks the fish-eye problem caused by the microscope-camera array lenses. This deformation consists on the stretching of the image increasing with the distance to its optical axes, and may cause image discontinuities after several pictures are attached together. In order to address this issue, an inverse deformation dependent on the square of the distance was applied [8]. This inverse deformation was estimated using pictures taken to a 0.1mm depth hemocytometer.

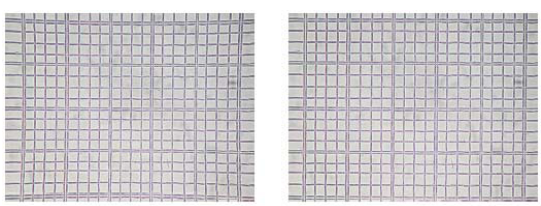

Figure 2– Fish-eye lens distortion geometrical correction applied to a 0.1mm depth hemocytometer picture.

Visualization

The software does not generate one final slide capture, but instead hundreds of small images, and a matrix that describes how to stitch them together. This design eases future work with higher magnification, since all that changes is the amount of pictures handled by the matrix.

Stitching error measurement protocol

Eight different samples were acquired, with sizes varying from 440 mm^2 to 1280 mm^2. In order to evaluate and determine the possible misalignments generated by the stitching process, a comparison between the final stitched image and a standard image must be performed. Thus, a not-amplified-by-the-microscope picture of the sample, taken using the same camera as in the stitching and corrected with the same geometrical factors, is used as a standard for comparison. Although it lacks the grade of definition of the stitched image, it serves as a pseudo ground truth to evaluate the level of preservation of image structure.

The method used for the quantification of this error uses the Structural Similarity (SSIM) index, combined with phase shifts between the images. The SSIM index ranks locally the similarity between portions of two images. The SSIM continuous range interval is -1 for worst case to 1 for perfect match. This index can be displayed as a gray level pixel map, giving a general idea of the amount of parity between images. The index per pixel is averaged to give an overall level of similarity, whose range limits are coincident with the previously mentioned.

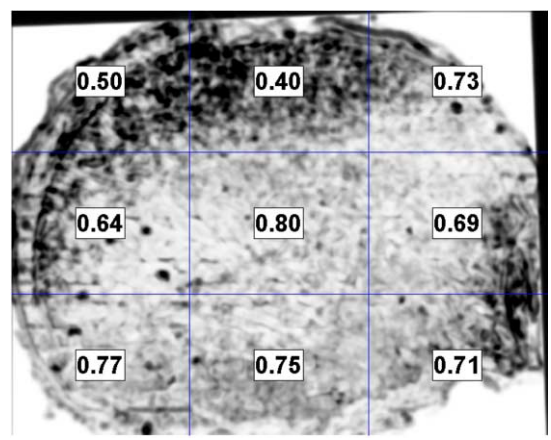

Figure 3– SSIM map displayed as (1+SSIM)/2 between the stitched image and the standard image, for Sample A. The map is divided in nine portions, where the corresponding index of each portion is labeled. Dark pixels mean bad correlation between images, while bright pixels correspond to good structural similarity.

The approach taken in this work to estimate the stitching error consists on registering the images, using rigid registration algorithms. Misalignment locations depend on registration process. If the correct registration and similarity congruency of a portion of the image leads to misalignments in other portions of the image, then a stitching error is identified. The stitching error in a part of an image may be compensated by adding translation offsets to the original registration. When moving one of the pictures a certain offset to the right, left, upwards, and downwards, SSIM map zones which originally appeared dark turn to white, meaning a good alignment in that part of the image, and vice versa.

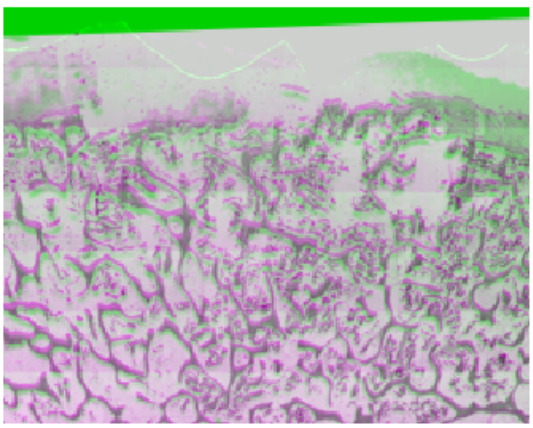

Figure 4– Portion of the image from Figure 3 (Sample A) with the lowest SSIM index (0.40), shown as the stitched image (magenta) superimposed in the standard image (green). As can be seen, a better registration can be achieved by moving the standard image upwards.

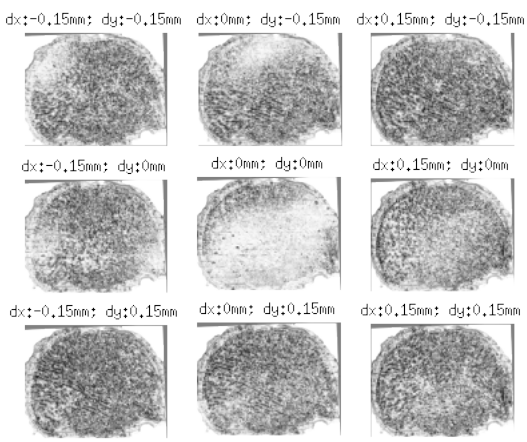

Figure 5– Gray level changes in the SSIM map representation of Sample A, as a function of offset. The center image represents the better registration found between images. Right (positive) and left (negative) shifts are labeled dx, while up (negative) and down (positive) are labeled dy.

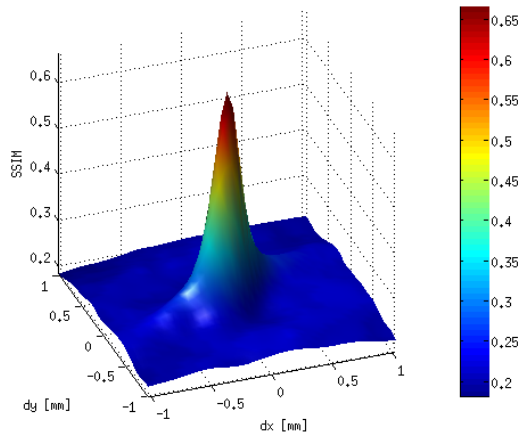
Calculating the SSIM index after every shift leads to the construction of surfaces like the one shown in Figure 6. In order to determine the error introduced by the stitching process, it is necessary to evaluate the final image misalignments produced all along the sample, compared to the standard image. This error will be quantified as the minimum radius of displacement required, in millimeters, to reach the denominated noise floor of the SSIM index in the sample. Knowing the bell-like shape of the SSIM index evolution as a function of space and being proven that it is not affected by local maximums phenomena, the SSIM map is evaluated in the initially dark areas for different shifts in X and Y directions. Strictly, the noise floor is considered reached after subsequent movements in one direction do not improve the SSIM index, but worsen it. It should be highlighted that due to its accumulative behavior, the stitching error tends to grow with the distance. Though, it is expected that the major discrepancies will appear around the edges of the image (see Figure 3 and Figure 5), assuming a rigid registration towards the center of both images.



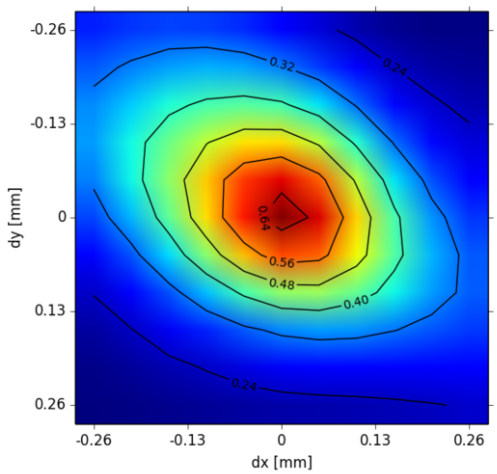


Figure 6– SSIM index as a function of image displacements (in X and Y) with respect to the better fixing registration employed in Sample A.

To evaluate an estimation of the general structural deviation of the stitched image proportions compared to the standard image ones, a Structural Deviation (SD) index is proposed for both X and Y maximun extensions (ΔX and ΔY correspondly):

$$SD_X = 100\ (\Delta Xstd - \Delta Xstitch) / \Delta Xstd \quad (2)$$

$$SD_Y = 100\ (\Delta Ystd - \Delta Ystitch) / \Delta Ystd \quad (3)$$

Results

The eight reconstructed samples (A to H) are displayed in Figure 7, and their error measurements are shown in Table 1.

Table 1– Error measurement of the samples stitched

S	Size [mm]	Total images	SD_X [%]	SD_Y [%]	SSIM index	Error [mm]
A	40 x 32	819	0.82	2.17	0.67	0.33
B	45 x 27	876	-3.27	-2.15	0.53	0.39
C	28 x 21	363	0.25	-2.08	0.64	0.28
D	20 x 22	266	-1.10	-1.44	0.73	0.10
E	26 x 22	364	-1.57	-0.13	0.67	0.26
F	29 x 24	392	-0.75	-2.77	0.65	0.22
G	23 x 23	326	-0.42	-1.45	0.75	0.16
H	32 x 22	378	-1.60	-0.35	0.63	0.20

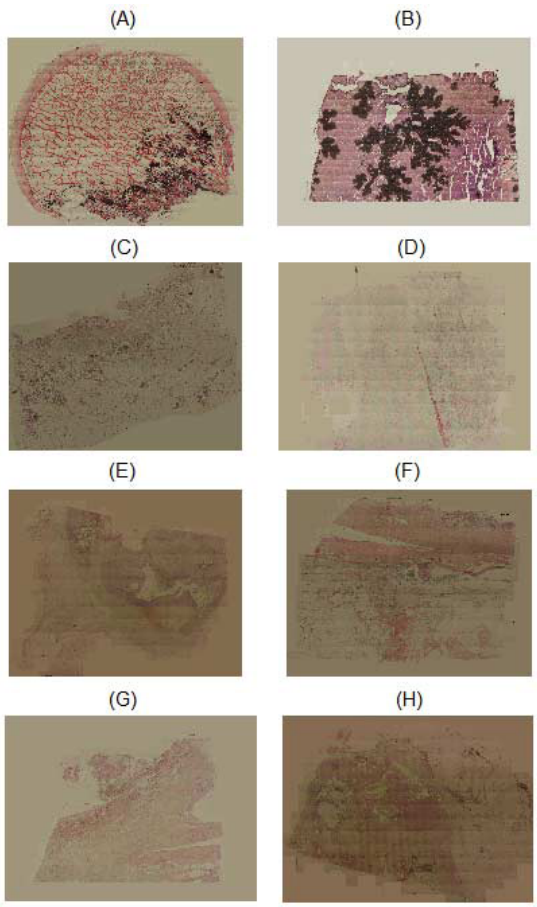

Figure 7– Images A to H showing the eight samples reconstructed using the stitching process.

Discussion

As it was shown in the results section, non-standard size (3 in x 1 in) samples could be reconstructed, with a 1270 pixels per millimeter resolution.

The results in Table 1 show an absolute maximum Structural Deviation of 3.27% in X and 2.77% in Y. In terms of stitching error, it can be seen that, in general, the higher the amount of pictures taken, the higher the error measured. Samples A and B appeared to be more deformed than the rest (0.33mm and 0.39mm), being both composed with more than three times as many images as Sample D (0.1 mm, minimum error). This deformation was caused by the accumulated stitching error along the entire sample, mostly due to the optical distortion produced by the camera lens used for acquisition, which is not perfectly corrected. In addition, this distortion was measured higher for thicker microscope slides (more than 4.5 mm thick), which were the ones used for Samples A and B. In order to lower the error caused by this effect, it is recommended to try to use thinner slides (1 mm thick) in all cases.

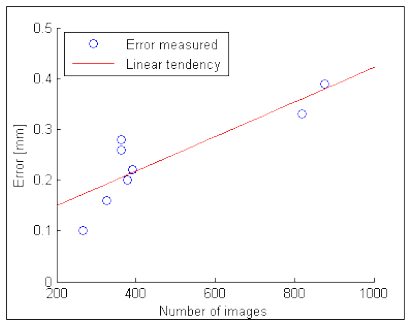

Figure 8– Error variation measured in the samples, as a function of the total number of images stitched.

Although the SSIM index is a relatively good index for assessing structural differences between images, in some cases it might perform poorly for the application presented in this work. Consider for example Figure 9. In spite of the fact that both images were taken with the same camera, the stitched image (B) presents much darker regions than the standard image (A), for the same tissue. This marked difference in the contrast of the images is interpreted by the SSIM index as a major structural difference, even though it is not.

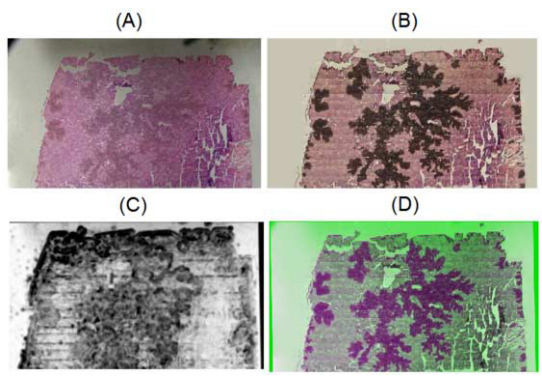

Figure 9– Although not a bone sample, this liver tissue sample clearly shows low rated areas due to contrast differences between images. (A) Standard image from sample B. (B) Stitched image from sample B. (C) SSIM map between standard image and stitched image from sample B. (D) Superposition of standard (green) and stitched (magenta) images from sample B. No significant structural differences can be seen.

Since the MRI resolution of the bone prior to becoming a surgical specimen is 1 mm, the same value will be taken as the maximum tolerable error in the complete stitched image.

It is considered essential the conservation of the original appearance of images. Although the blending between images

might lead to friendlier representations for the viewer, it could alter the specialist perception of the degree of cellular disorder appreciated, as shown in Figure 10. Hence, it is believed best to simply stitch the images one after the other, obviating any kind of image processing between them, both in the rows confection as in their alignments.

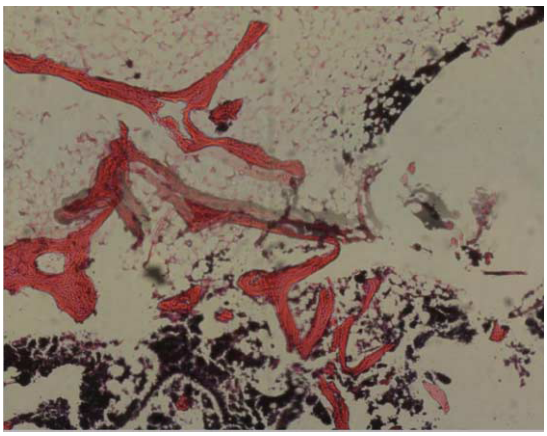

Figure 10– Stitching between two wrongly matched rows. The blending applied generates an unwanted ghost effect in the final image.

Conclusion

This work presents a new way to acquire histological images using a XY-table and a digital camera coupled to a microscope. Although being a relatively high time-demanding procedure (~30 seconds per image acquisition in average), it strongly lowers a Whole Slide Imaging Scanner budget. Measurement results presented show that the error committed is small enough for the suggested application, which aims, in the future, to help in the construction of a gold standard bone tumor samples repository.

Acknowledgments

We would like to acknowledge Luis H. Palacios for his collaboration in sample preparation and Horacio O. Milano for designing and building the XY-table hardware.

Abstract

Sub-Saharan Africa (SSA) bears the heaviest burden of the HIV epidemic. Health workers play a critical role in the scale-up of HIV programs. SSA also has the weakest information and communication technology (ICT) infrastructure globally. Implementing interoperable national health information systems (HIS) is a challenge, even in developed countries. Countries in resource-limited settings have yet to demonstrate that interoperable systems can be achieved, and can improve quality of healthcare through enhanced data availability and use in the deployment of the health workforce. We established interoperable HIS integrating a Master Facility List (MFL), District Health Information Software (DHIS2), and Human Resources Information Systems (HRIS) through application programmers interfaces (API). We abstracted data on HIV care, health workers deployment, and health facilities geo-coordinates. Over 95% of data elements were exchanged between the MFL-DHIS and HRIS-DHIS. The correlation between the number of HIV-positive clients and nurses and clinical officers in 2013 was $R^2 = 0.251$ and $R^2 = 0.261$ respectively. Wrong MFL codes, data type mis-match and hyphens in legacy data were key causes of data transmission errors. Lack of information exchange standards for aggregate data made programming time-consuming.

Keywords:

Information systems; Health information exchange; Interoperability; Health workforce; HIV.

Introduction

Sub-Saharan Africa (SSA) bears the heaviest burden of HIV. As of 2012, nearly two-thirds of the world's 34 million people infected with HIV lived in SSA [1]. Over the last ten years, there has been an unprecedented scale up of HIV prevention, care and treatment services. For example, UNAIDS reported a 40-fold increase in the number of HIV-infected persons receiving antiretroviral therapy (ART) from 2002 to 2012 [2]. A major obstacle to the scale-up of HIV care services in SSA is the chronic shortage of health workers [3, 4]. The health workforce density in the majority of countries in SSA fall below the World Health Organization (WHO) recommended minimum health worker per population [5].

In spite of support from multilateral and bilateral partnerships such as the Global Fund to fight AIDS, Tuberculosis and Malaria (GFATM) and US President's Emergency Plan for AIDS Relief (PEPFAR) as well as commitment from host-country governments, there is inadequate data to show that the number of deployed health workers, which include doctors, clinical officers, nurses and nurse-midwives, has increased with the scale up of HIV services. Studies from Zambia and Malawi show an increase in HIV-related workload against a relatively unchanged number of health workers [6, 7]. Data used in these studies were mainly health records and staff interviews from a few sampled health facilities. None of the studies used data from national health information systems such as the district health information systems (DHIS) or human resources information system (HRIS), and hence, had limited representativeness. A paper presented at the First Global Symposium on Health Systems Research, 2010 reported that low-income countries, which bear the heaviest disease burden, also have the weakest health workforce information systems [5].

Fully interoperable national health information systems are not yet common phenomena globally, and remain elusive in many countries due to a range of challenges including lack of standardization, lack of national unique identifiers, inadequate infrastructural capacity, lack of adequate skilled personnel, inadequate financial resources, and legal and organizational concerns [8-10]. Current initiatives focus on software development [11]. Published work also focuses on the software and on the exchange of health information at the individual patient level where interoperability has been shown to enhance continuity of care and efficiency [11, 12]. A few countries in SSA, including Kenya and South Africa, have developed national eHealth strategies prioritizing interoperable information systems as recommended by the WHO and the International Telecommunications Union [13]. However, the benefits of such systems is yet to be demonstrated. The need for high quality data from multiple interoperable sources for enhanced quality of care and to understand the correlations between scale-up of healthcare services and health workforce has never been greater, especially in resource-limited settings.

We conducted an observational study to assess the effect of interoperable national electronic health information systems on enhancing data availability to evaluate the effect of scale-up of HIV programs on human resources for health (HRH) in Kenya.

Methods

We created an environment of four interoperable systems that are part of the Kenyan eHealth architecture [14] as illustrated in Figure 1. The four systems were the district health information software-2 (DHIS2), regulatory human resource information system (rHRIS), integrated human resources information system (iHRIS), and the Master Facility List (MFL, a registry of health facilities in Kenya).

DHIS2: DHIS2 is a tool for the collection, validation, analysis and presentation of aggregate (not patient level) health statistics (https://hiskenya.org/). It is intended for, but not limited to, health information management activities. DHIS2 is a free and open source, web-based application. Kenya is among more than 30 countries in Africa, Asia, and Latin America, that have adopted DHIS2 as a part of their national health information system. Each month at the health facility level, aggregate health services statistics for all diseases, including HIV are entered into DHIS2. The automation of transmission of patient level data from electronic medical records (EMR) directly into DHIS2 is currently in progress. The aggregate data entered into DHIS2 include family planning, maternal child health, sexually trasmitted illneses, child health and nutrition, tuberculosis, and HIV services including HIV testing, prevention of mother to child transmission and antoretroviral therapy (ART). The data are stored in a central DHIS2 database hosted on a server at the Kenyan Ministry of Health (MOH) headquarters in Nairobi. DHIS2 implements application programming interfaces (APIs) which enable it to exchange information with other systems that implement similar or compatible APIs.

rHRIS and iHRIS: Human resources information systems (HRIS) collect and manage routine, national level, multi-cadre data on the health workforce including supply (i.e. training, exam, registration, licensure, intent to out-migrate, and continuing professional development) and deployment (i.e. health facility of deployment, date of appointment, work station in the facility, date of promotion, disciplinary actions, date of exit, and transfers). Regulatory human resources information system (rHRIS) collects and manages health workforce supply information while the integrated human resources information system (iHRIS) collects and manages deployment information. More information about the systems can be found at http://emorykenya.org/ and http://www.ihris.org/. A composite profile of a health worker can be created by linking the supply and deployment data detailing their educational, registration and employment credentials from both systems. rHRIS and iHRIS are web-based applications that allow updates to be made into secure databases by stakeholders in remote locations and for the generation of routine reports. The rHRIS and iHRIS have APIs that allow them to be interoperable with other systems such as DHIS2 and electronic medical record (EMR) systems.

MFL: WHO's guidelines for creating a master health facility list defines an MFL as a complete list of health facilities in a country, whether public or privately owned, and contains administrative information, identification information (signature domain) and service capacity (service domain) [15]. The set of identifiers in the signature domain uniquely identifies each health facility while information on service domain includes an inventory of services available and service capacity, which are essential for health systems planning and management. The MOH maintains an MFL that was created in 2008 by merging and reconciling several facility lists, which contained different, and sometimes conflicting, information about health facilities in the country. The MFL Code is a five digit number that uniquely identifies each health facility. Among the information contained in the MFL are ownership (Government of Kenya, private company or a faith-based organization), facility type (dispensary, health center, district hospital or referral hospital), administrative location (county, district, division, location), bed capacity, contact information (postal address and telephone number) and GIS coordinates (geo-coordinates). The MFL is updated regularly by the district health information and records officer whenever a new health facility is registered, an existing facility changes status, or if the information about it needs updating. As of November 2014, the MFL had 9,882 health facilities listed. The MFL database has an API that allows it to be interoperable with other systems such as the DHIS2, EMRs and HRIS.

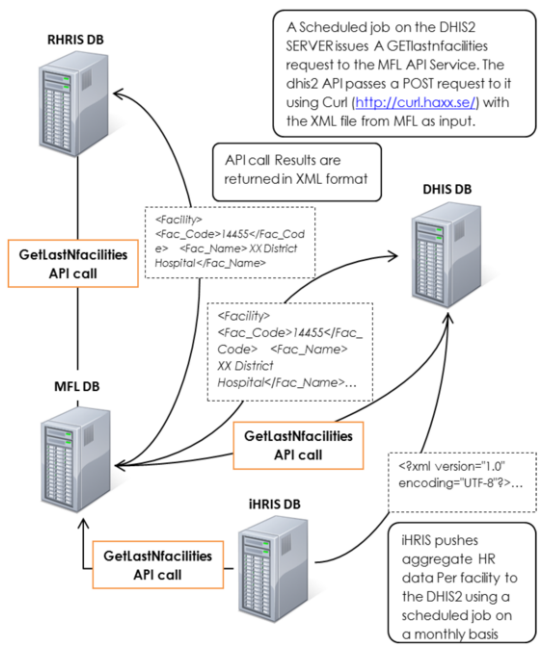

Figure 1: MFL-DHIS2; MFL-rHRIS; MFL-iHRIS; DHIS2-iHRIS Dynamic Interoperability

MFL-DHIS2-rHRIS-iHRIS Interoperability

The MFL API is currently implemented as a set of functions that accept defined parameters and generate details of facilities from the MFL in an eXtensible Markup Language (XML) that can be automatically parsed and read into a receiver database/system. More information on the exact implementation and usage of these functions is accessible at http://api.ehealth.or.ke. In order to make the MFL secure, a basic HTTP authentication has been implemented on the MFL API requiring a username and password to be passed into the MFL API for authentication purposes before any data is sent back to the receiver application.

In the MFL-DHIS2 implementation, an automated script that is scheduled to run daily at midnight using *cron* has been implemented to pull in the latest 100 facilities whose details are either new or have been added to the system. The ideal number to import from MFL depends on the nature of implementation and needs of the receiver system, however a random number of 100 was chosen initially and the basis of this selection was the fact that no more than 100 facilities have ever been added/modified in a day from across the country. This was determined by reviewing the facilities data based on date of addition and modification of records. It is however important to note that the higher the number of records selected, the slower the speed of import. To address the incompatibilites between legacy and current data, the legacy data were cleaned and data types modified to align with the programs and current data definitions.

iHRIS – DHIS2 integration: iHRIS-Manage system sends aggregate data on health workers per facility at the end of each month, disaggregated by county, cadre and gender, to DHIS2. This is done via scheduled *cron* jobs on the iHRIS-Manage server that automatically sends a preformatted file generated by the system using XLST (EXtensible Stylesheet Language).

An equivalent dataset was designed on DHIS2 with details of the data elements that hold the aggregated data values from iHRIS-Manage.

The rHRIS – DHIS2 integration is not yet fully automated. The DHIS team created a dataset for rHRIS to post aggregate training, registration, licensure and practice data. A data call to the rHRIS API pulls the selected data elements on health worker supply into the DHIS2 including the health-workers' registration status.

Error logs generated by scheduled batch jobs were used for tracking of exceptions that require attention.

Outcome Measures

To show the added value of interoperable systems in data availability and use, we created a flat file at the MOH's database populated with data abstracted from the interoperable data sources in order to understand the correlations between the national scale-up of HIV services and deployment of health workforce in Kenya. This data was hosted on the DHIS2 server and is accessible to key stakeholders in HRH, including the MOH and its partners and authorized users of DHIS2.

We used the following outcomes, (i) description of experiences implementing HRIS-MFL-DHIS2 interoperability (ii) correlation between scale-up of HIV care (measured through the number of HIV-positive individuals receiving HIV care) and deployment of health workers in Kenya, and (iii) trends in distribution of health worker per person living with HIV in Kenya. We also reviewed the data completeness as a component of data quality in the data sources.

Data Abstraction

After linking the MFL-DHIS2-rHRIS-iHRIS data, we abstracted the following data elements:

rHRIS/iHRIS	MFL	DHIS2
Cadre of health worker	MFL code	MFL code
MFL code	Facility name	Patients on care
Number of health workers	GIS coordinates	Patients on ART
Status of registration	County code	County code

From the above data elements, annual summaries by county were obtained, including the number of health workers deployed (nurses and clinical officers), number of patients enrolled on HIV care and number of patients currently receiving ART for 2012 and 2013. Additional data on the total number of people living with HIV per county were obtained from the national HIV estimates for Kenya based on mathematical modelling [16].

Due to low reporting rates in DHIS2 for the routine health statistics in 2011, we did not consider data for 2011 in the analysis.

Statistical and Spatial Data Analysis

We used scatter plots to assess the correlation between the number of patients receiving ART and the number of nurses in service. *Stata* was used to perform the analyses and calculate R^2 values. We used *ArcGIS*, a spatial analysis tool, for visual presentation of ratio of nurse to people living with HIV per county.

Ethical Considerations

We used aggregate data that did not contain any individually identifiable patient data. Additionally, the identifiable information of the health workers were removed by the MOH and regulatory boards/councils after linking the HRIS data to the DHIS2 and MFL. Dummy identifiers were assigned in order to conduct the analyses. There was no contact between the study team and patients or the health workers.

Results

Experiences implementing interoperable MFL-DHIS2-rHRIS-iHRIS

The synchronization mechanism described using the API has been largely successful; over 95% of data were successfully and accurately transmitted from the MFL to DHIS2 and from iHRIS to DHIS2. From the error logs, we were able to identify the most common causes of errors that prevented data from being imported into receiver systems (e.g. DHIS2). The common causes of errors include:

- Use of wrong MFL codes especially for older/legacy data that existed in the systems before automation of the data exchange process
- Data type mismatch that occurs when a system receives a request for a data type that is different from that of the stored variable (e.g. if a system received a request for a numeric variable when the stored variable is of type string)
- Presence of hyphen or an apostrophe in the data source.

The above sources of error were addressed through ongoing cleaning of legacy data and alignment of data types in the data files and programs.

Programming time for each system to ensure the APIs could exchange data was time consuming. It took nearly 10 months of programming, testing and documentation to achieve working solutions, and another month to get XML and XSLT transformations of facility list data between MFL and iHRIS right.

Data availability and use

Data was readily available in DHIS2 and was abstracted to support the analysis below:

(i) Nurses deployed vs. the number of HIV-positive persons: A total of 1,565,505 and 1,599,565 persons were HIV-positive in 2012 and 2013 respectively. Of these, 400,768 and 547,579 patients were receiving ART at the end of 2012 and 2013 respectively. The total number of nurses in service was 17,604 and 26,399 in 2012 and 2013 respectively. There was a weak, but positive, correlation between the number of the number of nurses deployed and the number of HIV-positive persons, R^2 = 0.281 (2012) and R^2 = 0.251 (2013). Figure 2 below shows the scatter plots for the periods under consideration. Each circle represents a county and the size is proportional to the number of HIV-positive persons.

(ii) Clinical officers deployed vs. HIV-positive clients: A total of 3,209 and 3,284 clinical officers were in service in 2012 and 2013 respectively. The correlation between the number of patients receiving ART and the number of clinical officers in service was positive but weak: R^2 = 0.380 (2012) and R^2 = 0.261 (2013).

(iii) Nursing workforce density (ratio of nurses to people living with HIV (PLHIV): The ratio of nurses to PLHIV improved from 1:89 to 1:61 from 2012 to 2013. The map in Figure 3 shows the change in the number of nurses per PLHIV by county.

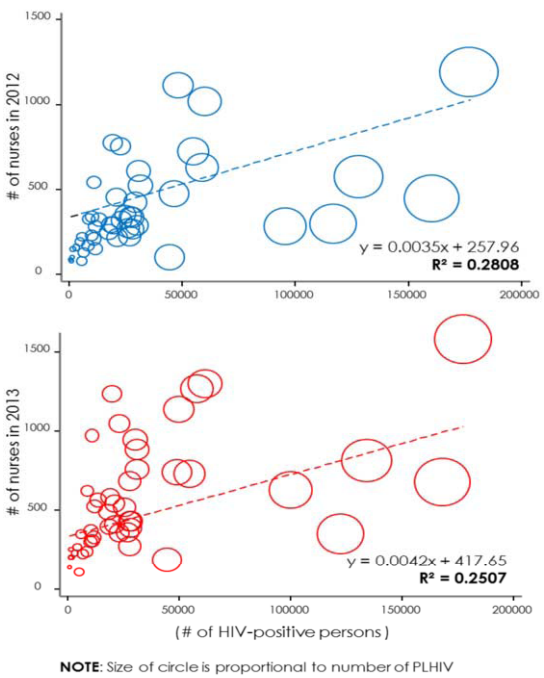

Figure 2: Correlation between number of HIV+ persons and no. of nurses by county in 2012 and 2013 in Kenya

Data Quality

Data quality varied based on the original source of data. Reporting rates for routine health service statistical summaries in DHIS2 improved tremendously from 2011 to 2012. In 2011, reporting rates to DHIS2 in a few counties were as low as 40% of the health facilities while in 2012, the majority of the counties had reporting rates above 80% of health facilities. Although coverage of the MFL data was high (>80% of health facilities in Kenya were listed in the MFL in 2012), a few facilities were missing from the MFL. There were no data losses during the transmission of data from the MFL to DHIS2 or the MFL to rHRIS/iHRIS.

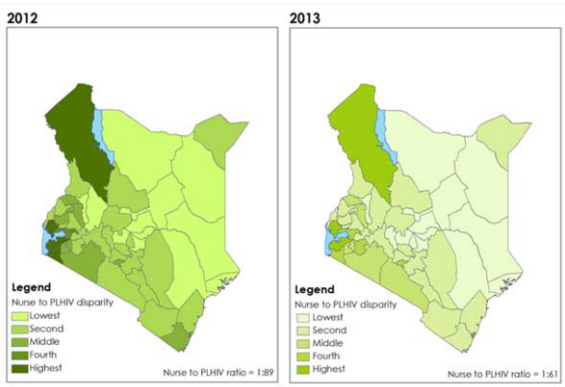

Figure 3: The ratio of nurse to person living with HIV by county in 2012 and 2013 in Kenya

Discussion

The implementation of interoperable MFL-DHIS2-iHRIS-rHRIS was successful. There was a weak, but positive, correlation between the number of people living with HIV and number of health workers in service, including nurses and clinical officers. Data quality varied by data source; the completeness of DHIS2 data was low in 2011 but improved in subsequent years. Over ninety-five percent of the data was transmitted from source systems (MFL and iHRIS) to the receiver system (DHIS2) making data readily available for analysis. The programming time and costs expended to achieve information exchange between the systems was high due to the lack of implementation of common standards and protocols that could be interpreted by the different systems.

The most common obstacles to the seamless synchronization of data between the different systems were identified as inconsistencies between legacy data and the current codes and data types. These findings are consistent with those reported by Alkaldi *et al* [17].To address these problems, we ensured that data cleaning and standardization of all legacy data was achieved before the automation of the data exchange using the API was done. In addition, appropriate validation rules or mechanisms were put in place to ensure that data from the source system is consistent with the type on the receiver system. The system administrators routinely reviewed the log files on the exchange process to ensure that data was exchanged as expected between the systems and took appropriate actions whenever errors were encountered. Although not implemented in this study, the use of data exchange schema and standards that enable *foundational, structural* and *semantic* interoperability defined by the Healthcare Information and Management Systems Society (HIMSS), such as XDS or the ADX data exchange protocol under development by the Integrated Healthcare Enterprise (IHE) - http://wiki.ihe.net/index.php?title=Quality,_Research_and_Public_Health, could further address the challenges encountered.

From the unweighted analysis, we found a weak but positive correlation between the number of patients receiving ART and the number of health workers (nurses and clinical officers) in service. This is similar to findings in Malawi and Zambia

which face similar human resource challenges as Kenya and other SSA countries [6, 7]. There was a marginal reduction in the ratio of health workers to the number of PLHIV, but with large variations geographically. Although we did not analyze the causes, mal-distribution of health workers could be informed by several factors including disease burden (HIV prevalence), urban/rural location and inadequate use of data to inform health workforce planning [18].

Our study had some limitations. We focused on the software component of interoperable systems, which is just one of the many factors that contribute to comprehensive information exchange of the national eHealth system. In order to implement these findings at scale, there is the need to tackle wider organizational, policy and infrastructural factors that affect the scale-up of interoperable health information systems [9, 10]. Low data quality, mainly due to low reporting rates by counties to the DHIS2, was identified as a key obstacle to data use. Although not presented with the results of this study, counties with fewer health workers were more likely to have incomplete data. It is worth noting that data completeness has significantly improved over time and currently reporting rates stand at over 80%. Finally, the data we presented in this study were not weighted or adjusted for factors that confound health workforce distribution such as population, disease burden and rural/urban locations.

The succcessful implementation of interoperable systems however provides an excellent opportunity for integrating data sources and enabling comprehensive analyses including health workforce and other health services data.

Conclusion

We demonstrated a successful implementation of interoperable MFL-DHIS2-iHRIS-rHRIS and showed added value in data availability and data use. There was a weak, but positive, correlation between the number of patients receiving ART and the number of health workers. More work needs to be done to assess the effect of use of information exchange standards on efficient achievement of interoperable systems as well as non-software factors associated with scaling up interoperable systems at a national level in resource-limited settings. Additionally, well designed studies are needed to understand correlations between the scale-up of HIV services and the health workforce in resource-limited settings.

Abstract

This work describes an integrated informatics system developed to collect and display clinically relevant data that can inform physicians and researchers about Type 2 Diabetes Mellitus (T2DM) patient clinical pathways and therapy adherence. The software we developed takes data coming from the electronic medical record (EMR) of the IRCCS Fondazione Maugeri (FSM) hospital of Pavia, Italy, and combines the data with administrative, pharmacy drugs (purchased from the local healthcare agency (ASL) of the Pavia area), and open environmental data of the same region. By using different use cases, we explain the importance of gathering and displaying the data types through a single informatics tool: the use of the tool as a calculator of risk factors and indicators to improve current detection of T2DM, a generator of clinical pathways and patients' behaviors from the point of view of the hospital care management, and a decision support tool for follow-up visits. The results of the performed data analysis report how the use of the dashboard displays meaningful clinical decisions in treating complex chronic diseases and might improve health outcomes.

Keywords:
Integrated Systems; Therapy Adherence; Clinical Pathways; Data Integration; Type 2 Diabetes.

Introduction

Treatment and management of chronic diseases often takes place outside clinical settings and impacts the daily life of patients. As a consequence, clinicians depend on patient reports of symptoms, side effects, functional status and treatment adherence. Patients typically report at clinical visits that are months apart, and recall accuracy can be highly fluctuating [1]. The possibility to gather and analyze accurate information at the right time from different sources, such as public healthcare systems, open data repositories, or hospital information systems is necessary to be able to perform correct clinical decisions [2]. The work presented in this paper aims to provide clinicians and researchers a software architecture based on data coming from heterogeneous data sources to support medical discovery and evidence-based practice about managing and controlling the evolution of chronic diseases. The system architecture relies on the open source i2b2 clinical data warehouse (CDW) [3] and the work done has been focused on expanding the basic functionalities of the framework by enhancing its visualization layer. A number of modules have been designed and developed to present the results through an intuitive and easy to use dashboard that shows results of process mining, temporal abstractions and similarity algorithms.

Materials and Methods

Type 2 Diabetes Mellitus (T2DM) is the most common form of diabetes. It accounts for at least 90% of all cases of diabetes. The World Health Organization (WHO) estimates that by 2030 there will be about 550 million people suffering from this disease [4]. This disease can remain undetected for many years because hyperglycemia (consequence of the insulin defects) develops gradually, and at earlier stages, the disease is not severe enough for the patient to notice any of the classic symptoms of diabetes. Despite the large number of models being developed and the increased interest and acknowledgement in the clinical field, only a small part of these models ends up being used in clinical practice [5]. One of the most important challenges of the MOSAIC European Union project is to combine the research activities related to the discovery of new risk factors, methods and models for diabetes onset, progression and evolution, with the development of software tools. The components and modules would incorporate innovations and make them usable by different end-users in a variety of settings. The biggest challenge of the project consists in translating innovations to achieve impact in the current clinical practice.

Data sources

To fill the gap resulting from infrequent clinical follow-ups of diabetic patients, the EMR used in FSM, a private hospital in Pavia, Italy, has been enhanced with data coming from the local public healthcare agency (ASL) of the Pavia area. This data contains administrative findings (e.g., prescription-based drug purchases), and data reporting environmental information (e.g., air temperature, air pollution, etc.) provided by the "Regione Lombardia" databases as open data.

Clinical usage

The main component of the software tool developed consists in a single page dashboard, where users can interact with a graphical presentation of clinical parameters. Dashboard users can analyze data though three different use cases:

- Use Case 1 (UC1): risk factors and indicators to improve current detection of T2DM

- Use Case 2 (UC2): hospital care management
- Use Case 3 (UC3): clinical decision support during follow-up visits

In this paper we will focus on use case 2 and 3, which are the ones that will be implemented for the management of already diagnosed T2DM patients at FSM. UC1 case is active in another research center participating in the MOSAIC project: the Hospital Universitari i Politècnic La Fe located in Valencia, Spain. UC1 will be integrated also in FSM by the end of the project, to allow a full evaluation of the system.

Architecture

We designed and developed a dashboard (Figure 1) to accomplish the goals described in UC2 and UC3. The dashboard communicates with the i2b2 DW where clinical, administrative and environmental data are integrated. A data mining module is responsible for running advanced temporal data mining algoritms on data queried from the CDW.

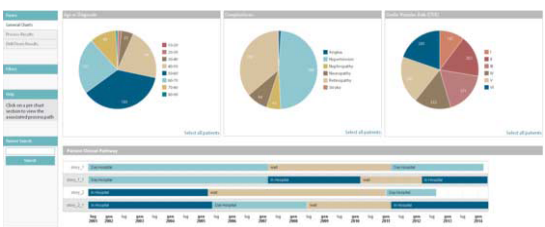

Figure 1 – starting page of the MOSAIC dashboard: charts show patients grouped by age at diagnosis, types of complications and cardio-vascular risk. The timeline displays four clinical pathways related to the selected patient set.

From this section, the user can either choose to select a subset of the population to use for further analyses or to search for an individual patient to examine his/her clinical charts. In the following paragraphs we will present some of the functionalities related to the two mentioned use cases.

Use Case 2.

UC2 is focused on the analysis of the clinical histories of a population of patients. This population could either be the whole patients' sample included in the data repository or a subset of patients conveniently selected by the user according to some clinical criteria available in the starting page of the dashboard. The models developed for data analysis rely on temporal and process mining techniques and are aimed at detecting the most frequent clinical patterns that are experienced by the patients' population [6, 7]. These models are focused on taking explicitly into account the temporal dimension, which strongly characterizes the evolution of chronic diseases. The ultimate goal of applying these techniques is to extract meaningful patients' stratifications that are based on the temporal evolution of some interesting clinical variables. For example, the most critical pathways in terms of severity that arise from complications and use of hospital resources could be highlighted. Temporal data mining is employed to understand which are the most interesting variables to use and to exploit the novel perspectives offered by temporal data integration.

Clinical histories are mined to extract behavioral patterns of prescription-related drug purchases, frequent clinical temporal patterns, cardio-vascular risk (CVR) profiles, level of complexity and evolution of complications. The extracted temporal patterns are presented to the user as timelines. The user can select a specific temporal pattern to drill down to the patients' population experiencing that behavior.

The target population of UC2 is of patients already diagnosed with T2DM. The data used to build and train UC2 models come from the FSM hospital EMR and are related to a cohort of T2DM patients followed up from 5 to 10 years. The EMR information related to these patients has been enhanced with public data coming from the Pavia ASL and with environmental information. This kind of data contains the history of all kind of therapies, hospitalizations, outpatient services, patient geo-localization, air temperature and degree of air pollution. To assess the complexity of care of the patients over time, a set of complexity stages, determined by the number of complications and hospitalizations patients undergo during the course of their disease, has been defined. The computation of these complexity stages is made possible by the availability of both clinical data related to the onset of complications and administrative information on hospitalizations and outpatient visits. Assuming that each patient starts with a stable state (it refers to pre-diabetic patients and type 2 diabetes patients who do not suffer any complications yet), when a complication arises the state shifts to “level 1.” If a second complication appears later than one year or if the second complication is a myocardial infarction, the state shifts to “level 2,” while if a second complication appears earlier than one year, the patient’s state shifts directly from “stable” to “level 2.” When an hospitalization, either due to the status of their diabetes-related complications or because of their metabolic instability occurs, the state change from “level 1” or “level 2” to "level 3.”

Use Case 3.

This use case refers to supporting clinicians to better manage T2DM chronic patients. Starting from patient’s EMR record, the system is able to project in a graphic way clinical information and behavioral patterns of prescription-related drug purchases. In this use case, clinicians are interested in having a better picture of what had happened to a single patient and what needs to be improved (e.g., changes in therapy, prescriptions of special examinations). Integrating information coming from the ASL and from the FSM EMR, analyzing and making them available in a unique tool, is a first step to achieve this goal. The part of the dashboard related to UC3 depicts data related to an individual patient, with a specific focus in the integration of data coming from different sources. Data integration is very important, as the clinical information related to the period that goes from the onset to the first follow-up at FSM is missing. The longer this period lasts, the more information becomes unobservable. This can be a limitation, especially if the objective of the analysis is to build predictive models (e.g. for complications prediction), as the events that occur in this not known time window might be the early determinant of a complication to arise. The data integration performed helps to mitigate this problem. In fact, it offers some additional information which comes from the public healthcare data. With this data, the information related to the not known time window becomes partially observable, given that the patient has been diagnosed after 2003.

The dashboard functionalities related to UC3 involve clinical and administrative data representation. Regarding clinical information, the dashboard reports temporal data related to (1) HbA1c values from laboratory exams performed within FSM hospital, (2) the evolution of the patient’s level of complexity and (3) the time course of the cardiovascular risk (Figure 2).

Figure 2 – MOSAIC dashboard example representing clinical valuesevolution over time.

One of the largest parts of information contained in the ASL data warehouse is related to prescription-based drug purchases by citizens at the pharmacy. Since this information is not directly available to the physician during clinical practice, it is very important to visualize it in a meaningful way in the dashboard. In particular, we have focused on drug purchase representation and on evaluation of the adherence to treatment behavior of the patient. Each drug purchase has been inserted in the i2b2 CDW using its Defined Daily Dose (DDD) that allows the expected number of therapy days related to that purchase to be computed. As the information about the actual drug dosages a patient should take is not available in our datasets, we use drug purchase as a proxy for estimating drug intake. Under this assumption, the DDD information represents the days supply for a specific purchase and we use DDDs to evaluate patients' behavioral patterns related to drug treatments. For each patient we retrieved the first prescription of a specific drug and divided the whole prescription period in semesters. For each semester we compute the sum of DDDs, which is an estimate of the total drug intake of the patient in that semester. We chose to use six months as an observation chunk, as in the current practice at FSM the average time between two consecutive follow-ups for chronic patients is one semester. Setting this temporal constraint gives the possibility of defining the granularity to observe modifications, adherence and continuity in drug treatments. As result a profile for each patient was constructed including the date of each purchase and the time period covered by the dispensed drugs, so to define the purchase pattern over time. In addition to the temporal profiles describing drug purchases, specific attention has been devoted to investigating the behavior of the patient in terms of treatment adherence. In recent years, several works studied the problem of harmonizing the integration of different healthcare information coming from heterogeneous sources while processing data coming from EHR or administrative databases [8]. One of the most common measures is the medication possession ratio (MPR) that indicates the percentage of received days supply divided by a period of time [9]. In our analyses, we have computed adherence to treatment using a validated index that corresponds to the MPR index for drug acquisition. The index is the Continuous, Single Interval Measure of Medication Acquisition (CSA). CSA index is calculated as the ratio: sum of DDDs over an observation period/length of the observation period (in our case one semester, 182 days). The CSA index indicates the percentage of days covered by the prescription. Besides DDDs, the information on CSA has also been included in the CDW. According to the CSA value, patients have been grouped into four clusters: no adherence (range of adherence between 0% and 40%), poor adherence (range between 40% and 80%), adherence (range between 80% and 100%), and over adherence (more than 100%). Patients belonging to the last group purchase, in a specific time window, more drugs than their prescription. The graphical representation of DDD values and therapy adherence percentage are shown in Figure 3.

Figure 3– MOSAIC dashboard example representing therapies DDD and adherence

Results

In this section we will present the results we obtained on a first sample of 433 patients using the methodologies described in the dashboard. Retrieving data from FSM EMR we had to deal with the fact that diabetic patients do not start to be followed at the hospital immediately after diabetes diagnosis. In Italy, this situation happens because this type of chronic patient is initially managed by the general practitioner (GP) who manages the patient until the GP believes it is more suitable for the patient to start being followed at the hospital outpatient service. Despite the wide variability of the period of time elapsed between onset of the first encounter, the majority of the patients start to be followed by FSM at a stable stage (73%). Analyzing the pattern of development of the first complication for our patients' sample and computing the time between the detection of the first complication and the first encounter at FSM, we observed how the diagnosis of the first complication occurs close to the first visit at the hospital. This is reasonable, if we consider that it is often the worsening of a patient's conditions that triggers a GP's decision to send a patient to the hospital outpatient service. As soon as the patient is managed by the hospital, the process that allows diagnosing possible complications is started, resulting in the recording of the complication in the EMR. Table 1 shows the distribution of the first complication for the patients who developed it after the first encounter at FSM.

Table 1 – Distribution of patients' first complication developed after first visit at FSM

Type of complication	% of development
Occlusion and stenosis of carotid artery	32.5 %
Fatty liver disease	25.8%
Nephropathy	12.8%
Retinopathy	9.7%
Neuropathy	8.2%
Peripheral vascular	6.9%
Chronic ischemic heart disease	4.1%

The administrative data related to drug purchases of about 433 patients considered in the analysis process consist in 244.190 records and a number of 21.055 distinct ATC codes. Classification of the purchased drugs on the basis of clinical relevance was the first type of analysis that we performed. In this way it was possible to reduce the variety in the data set to build simpler and meaningful scenarios based on treatment behaviors. To this end, the following ATC classes have been selected: A10 (drugs used in diabetes), B01 (antithrombotic agents), C02 (anti-hypertensives), C03 (diuretics), C10 (lipid modifying agents). The resulting codes have been further

grouped in 17 classes defined on the basis of medical knowledge and of the ATC-WHO system [10]. Table 2 details the number of patients and the number of box purchases per drug. Drugs that are not specific for the treatment of diabetes have been considered at a higher level of the ATC taxonomy, whereas drugs used to treat diabetes have been analyzed at a deeper level.

Table 2 – Knowledge-based classification of the ATC codes considered in our analysis (drugs not directly related to diabetes treatment)*

Drug	Patients	N° of Purchases
Alpha glucosidase inhibitors	85	331
Antihypertensive *	73	554
Antithrombotic *	338	3598
Phenformin_Sulfonamides	7	17
Diuretics *	157	1542
Gliptin	80	220
Incretin	23	79
Insulin	103	1381
LipidLowering *	303	3484
Metformin	352	3318
Metformin_Incretin	20	66
Metformin_Sulfonamides	73	709
Metformin_Thiazolidinediones	16	56
Repaglinide	98	638
Sulfonamides	150	1108
Sulfonamides_Thiazolidinediones	1	4
Thiazolidinediones	36	137

After computing the CSA values, we fixed a threshold (80%) to define if in a period, the patient purchased the appropriate dosage of the treatment, according to our assumptions. If the CSA is lower than 80% we associate a label to the semester indicating that there is Adherence = NO, otherwise we state Adherence = YES. We also represent the semesters during which there are no prescription as Adherence = INTERRUPTION and semesters where the purchases exceed the number of days in the time windows as Adherence = OVER. Table 3 summarizes the count of semesters on the basis of the CSA value.

Table 3 - Overall number of semesters classified as CSA >=80% (YES), CSA<80% (NO), CSA>100% (OVER), no prescription (INTERRUPTION)

Drug	YES	OVER	NO	INTERRUPTION
Alpha glucosidase inhibitors	39	34	253	5
Antihypertensive *	61	133	296	28
Antithrombotic *	875	555	1515	291
Biguanides_Sulfonamides	7	7	3	
Diuretics *	126	147	883	151
Gliptin			74	5
Incretin	58	66	92	6
Insulin	109	286	429	58
LipidLowering *	582	714	1587	228
Metformin	490	694	1932	202
Metformin_Incretin	21	23	21	1
Metformin_Sulfonamides	108	359	188	54
Metformin_Thiazolidinediones	18	10	28	1
Repaglinide	61	161	375	41
Sulfonamides	158	382	488	74
Sulfonamides_Thiazolidinediones	1	1	1	
Thiazolidinediones	32	23	80	2

Discussion

Despite the different values of CSA medians for different ATC groups, we analyzed the results in order to extract reliable and accurate patient's characterization on the basis of the general purchase behaviors. Our analysis has been focused on detecting main patterns of drug purchases. We identified the following subject classes:

- patients who purchase less drug boxes than the population taking the same drug class (CSAPatient<CSAPopulation)
- patients who purchase more drug boxes than the population taking the same drug and for whom the median CSA values stay below the 100%, not exceeding the recommended dosage (CSAPopulation <CSAPatient<100%)
- patients who purchase more drug boxes than the population taking the same drug but whose median CSA values stay above the 100%, exceeding the recommended dosage (100%<CSAPatient< CSAPopulation)

By identifying these groups it is possible to detect those patients who behave differently from the population of patients treated with the same drugs. A different purchase pattern could identify critical patients, independently from the CSA value. The developed procedure addresses the stratification challenge thanks to three consecutive steps, which are devoted to transform raw data into meaningful features and then using these features to in-depth tailoring specific patients' traits.

Step 1: Detection of subjects with statistically significant different purchase patterns from the population.

For each patient and each drug calculated, the median values of adherence for the whole prescription period were compared to the median value of the patient with the median value of the population has been performed (Wilcoxon Rank-Sum Test to asses is significant different, $p < 0.05$). If $p<0.05$, the patient was been assigned to one of two groups

Step2: Profiling of the $CSA_{Patient}$>$CSA_{Population}$ group.

For each patient belonging to this group and each drug check, if median values are <100% then classify as $CSA_{Population}$ <$CSA_{Patient}$<100% (ADHERENT) else if median values are >100% then classify as 100%<$CSA_{Patient}$< $CSA_{Population}$ (OVER ADHERENT)

Step3: Detect an overall purchase behavior

Each patient has the count of the number of drugs where the patient is UNDER - ADHERENT – OVER. If the behavior is detected for >50% over the total drug purchased then classify as: Under Adherent (LESS than POPULATION), Adherent (MORE than the population but less than 100%), Over Adherent (MORE than the population and more than 100%).

After we applied the process and retrieved the adherence stratification, we compared laboratory tests values and life style data in the different mined groups to understand if behavioral patterns of prescription-based drug purchases can be used as

biomarkers of specific clinical conditions of the patients who verify those patterns. The clinical variables (BMI, cholesterol and HbA1c), show significant differences ($p<0.01$, calculated with Kruskal-Wallis test) in the three groups. In particular, the patients identified as Adherent have better clinical values that the other groups. For BMI and Cholesterol, this difference becomes even more apparent ($p <0.01$, calculated with Wilcoxon test) when the Adherent group is highlighted and compared with the two Under or Over adherent groups considered together. This comparison emphasizes the clinical conviction that patients that not have a good adherence to therapy might suffer from metabolic disorders. Furthermore, considering other observations about patients diet, it is possible to detect better habits in adherent patients. During the whole observation period, adherent subjects have 118 observations of good diet habits, while they show bad habits only in 44 visits. The dashboard has been used to represent this information for UC3. Four data items are indicated: the median value of patient DDDs, the median value of group DDDs, the p-value resulted from Kruskal-Wallis test made to verify if there is difference between the patient and the group DDD median value, and an arrow used as visual indicator to display a positive or a negative difference between medians. Furthermore, we integrated from the ASL data warehouse, the cardiovascular risk index calculated as defined by the Italian Ministry of Health in the CUORE project [11] that takes into account values of gender, age, smoke habits, systolic pressure, cholesterol, HDL cholesterol, the diagnosis of diabetes and use of anti-of hypertensive drugs to produce the risk value.

Conclusion

In this paper, we presented an informatics approach that addresses the challenge of providing adequate clinical information such as therapy adherence, evolution of clinical pathways, and levels of complexity during inpatients encounters. The aim of our implementation is to improve the access to medical information through integrated informatics techniques necessary to gather data from different and heterogeneous sources such as hospital EMRs and public health or administrative records. By providing information in advance to physicians and not following the traditional approach based on questions to patients, we want to minimize the rise of bias and misunderstanding that can occur while patients report about medications and therapies they are following. With the introduction of the developed system into work practice and incorporating it into the hospital EMR, it will be easier to continually maintain the assessment of T2DM patients during their follow-up visits. Moreover, using the developed dashboard, clinicians are able to compare patient data they are visiting with a similar group on the basis of the variable they are interested. Analyzing data at the individual level and comparing them to similar group might have more impact in predicting how the clinical situation could evolve and might be useful for clinicians to perform correct clinical decisions.

Abstract

Translational medicine is becoming fundamental in promoting information flow between basic research and clinical practice, and in improving patients' health. The need for efficient systems to process and share information from multiple sources – including distinct areas of medicine – is a pressing need in biomedical research. Nevertheless, healthcare information systems are fragmented over different databases, medical institutions, and geographical locations.

There are already several approaches to tackle this problem based on centralized or distributed solutions. Nonetheless, mainly due to privacy reasons, these models only work for specific silos. In this paper, we present a new ecosystem for connecting database owners and researchers. Our approach consists of gathering, via a common fingerprint, an extensive characterization of dispersed databases. This fingerprint typically contains high-level aggregated information addressing questions at a population level and allowing, for instance, quick identification of databases with data that may help to answer a specific research question.

This work is being conducted in the context of EMIF (European Medical Information Framework), an IMI (The Innovative Medicines Initiative) joint undertaking funded project, wherein the Catalogue is being used to collect data from cohorts and Electronic Health Record systems of several European countries.

Keywords:

Translational Research; Real-World Evidence; Observational Studies; Cohorts.

Introduction

The quantity of clinical information and disease-specific data has steadily increased over the last decade. This information is fragmented over dispersed databases in different clinical silos around the world. However, as awareness about the potential of these data for clinical research increases, there is a growing need for solutions for secure sharing of information across different databases. This re-use of data will lead to many benefits, mainly for clinical and pharmacological researchers [1-3].

Several partial solutions have been proposed to solve the problem, from centralized to federated approaches with distinct security levels and different access roles. However, clinical researchers struggle to find datasets or clinical trial candidate subjects that fulfil their specific research questions. Moreover, this problem is not only due to privacy issues, but because most of the time appropriate datasets are not easy to locate, or their very existence is unknown [4].

In this paper, we propose a system that is able to summarize and aggregate databases' content, which is not dependent on the database type. While actual patient-level data are not shared and do not flow outside the healthcare institution's boundaries, clinical researchers are able to query high-level information and characteristics of the databases.

The system allows creating fingerprint templates, such as a set of questions that should adequately characterise each database type (e.g. observational data sources). Furthermore, researchers are able to search in the catalogue in any field. The integration of fingerprints from different databases and silos allows researchers to find databases suitable to their needs from a single access point.

This catalogue is being developed in the EMIF project (European Medical Information Framework), the broader main goal of which is to develop an information framework capable of integrating patient health information from different healthcare and research communities at a level that is currently not available.

Translational Research

The need for efficient systems to process and summarize information from multiple sources, including distinct areas of medicine, is a pressing need in biomedical research [3]. Translational medicine is fundamental to promote the flow of information between basic and clinical scientists, improve new biotechnologies, and increase patient health [5]. Biomedical informatics encompasses a set of methodologies to support knowledge transfer and integration across the major areas of translational medicine, from molecules to populations [2].

There are several questions that translational medicine will help to answer, starting by discovering which interventions might have an adequate benefit-risk profile in a given individual. Moreover, there are still many practices and protocols that are applied in clinical care based on intuition. Translational medicine can help researchers understand the reasons why some methods work, and how they can be developed in order to improve quality of healthcare. These results can be achieved through the contribution of different areas, including biomedical informatics.

Many areas may contribute to translational medicine, such as bioinformatics, imaging informatics, clinical informatics, and public health informatics. Bioinformatics seeks to improve the understanding of biological processes and therefore allow more targeted and efficient clinical interventions. Imaging informatics plays a significant role in understanding pathogenesis and identification of treatments at the molecular, cellular, organ, and tissue levels. New methods for visualising and analysing these data will be needed and are currently being developed [6]. Clinical informatics innovations are necessary to improve patients' care through the availability and integration of relevant information. Several methods are applied to medical report information, such as text mining and knowledge extraction. Public health informatics is the area

that intends to analyse and study new techniques to exploit data on a large scale. Translational medicine teams need to address many challenges, and it benefits from innovations in decision support, natural language processing, standards, information retrieval, and electronic health records, among other research areas.

There are efforts to integrate health data from multiple institutions, correlate it with genomic information, and incorporate knowledge from the scientific literature. Nevertheless, the integration of biomedical data is still largely not applied in practice, and significant obstacles pertaining to harmonisation challenges, ethical, legal and social issues around data sharing, the inherent complexity of the data, and difficulty in identifying appropriate datasets still hamper research and its translation to patient benefit.

Related Work

Many tools have been created to analyse clinical and genomic data, mainly for specific purposes, which allow researchers to extract knowledge from clinical databases. Consequently, several efforts have been made to combine biomedical data from different sources, with emphasis on clinical data integration.

REDCap (Research Electronic Data Capture) [7] provides a scientific research workspace for translational research. It allows users to quickly create and manage online surveys and databases. Users can insert data related to a research study and the forms are only available to users for whom access rights are granted. The software supports exporting the data to SPSS, R, SAS and Stata. It is a web-based application that has the ability to audit and log users' actions in the platform, and it can be used upon request. REDCap is being used in the production of more than 30,000 research studies, with over 92,000 users.

Mini-Sentinel [8,9] is a project aiming to create an active surveillance to monitor the safety of FDA-regulated medical products. It uses pre-existing electronic healthcare data from multiple sources. Several institutions provide access to data, as well as scientific and organizational expertise. The tools developed provide techniques to identify and validate medical products' exposure and potentially associated health outcomes. There are several isolated software tools to support specific research questions, allowing users to do research mainly inside the institution. However, there is still a great need for expertise to set up all these technologies.

ENCePP is a collaborative scientific network, launched by the European Medicines Agency (EMA), with the aim of strengthening the post-authorization monitoring of medicinal products, whilst bringing together relevant research centres, healthcare databases, electronic registries and existing networks covering certain rare diseases, therapeutic fields, and adverse drug events of interest across Europe. This project was completed in 2009 and provides a framework for improved pharmacoepidemiological research and post-authorization safety surveillance of medicinal products in Europe. This can be achieved by directly contacting the individual centres and networks registered in ENCePP or by submitting a request to the ENCePP secretariat to place an announcement in the ENCePP partners' forum. In the first phase of the project, it was possible to identify a number of suitable centres across Europe, leading to the establishment of a general inventory of research institutions following a survey at the level of EU Member States. In 2010, the ENCePP Database of Research Resources, which is part of ENCePP, was launched. The Resources Database is an electronic index of available EU research organizations and data sources in the field of pharmacoepidemiology and pharmacovigilance. It is available through the ENCePP web portal to the general public, and the information contained in this database is entered and maintained by the research organizations and/or data providers.

Bridge-To-Data [10] offers a tool that allows users to identify key features and compare database profiles. This resource also serves as an educational tool for public health research and as a template for health system planners to design or refine their healthcare data. BRIDGE provides a unique, searchable, and comprehensive compendium of information on population healthcare databases worldwide, allowing the healthcare professional to obtain profiles on various population datasets on a single website. The database profiles are updated with the most current data and verified by the respective database managers or representatives. Updated database profiles replace older versions to avoid duplicate reporting. BRIDGE subscribers can perform robust and advanced searches for a wide range of database profiles using the search page. Standardized data from each database allows subscribers to compare in-depth details from multiple databases. Informative resources are provided, such as a listing of recent publications using the relevant database and contact information for database managers. As part of its user-friendliness, BRIDGE also has a glossary, including coding systems to guide new subscribers with their search.

While these are already examples of solutions for database profiling, they do not apply deep summarization and there is still a gap in the clinical research communities, which are difficult to connect. A system for collecting detailed summarized views and asking high level questions regarding the databases is still needed.

Methods

A key idea behind the creation of the Catalogue is to allow researchers to find specific databases aligned with their research purposes. The main conception of the Catalogue was to have a summarized overview of a number of geographically scattered healthcare databases, with the aim of facilitating initial assessment and selection for specific research questions. Thus, a system that allows database owners to fill out a questionnaire and create their own database fingerprint was developed. Nevertheless, a process will be previously required to create a template schema of the fingerprint, which contains several questions with relevant information about the database and does not disclose person-sensitive information. The template schema of the fingerprint needs to be defined for each type of database, such as Observational Databases, Research Cohorts, or others. Thus, the Catalogue also allows system administrators to dynamically modify the questionnaires of each data source type.

Based on the appropriate template, database owners are able to fill in their database fingerprint, as shown in Figure 1 (i.e. answers to the questionnaire corresponding to their database type):

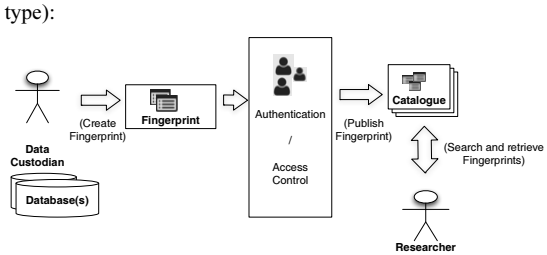

Figure 1: Workflow Description in the Catalogue

Fingerprinting a Database

While real data are not shared and do not flow out of healthcare institutions' boundaries, clinical researchers are able to query high-level information on the databases. We present the concept of the fingerprint, which is a questionnaire with a set of questions about a database type, such as database population, coding system, geographical distribution, and other relevant information.

Each template contains several groups of questions. Within these, each question can be individually defined, including the answer type (for instance, multiple-choice, plain-text, yes or no). Administrators can change each question or set of question and those entries are available in the administration panel (accessible for users with administration profile). Afterwards, the application will be automatically updated.

Users can create fingerprint templates using an online assisting tool, or a tabular textual schema (e.g. in Microsoft Excel). The process of building this kind of schema and allowing collaborative members to contribute without a steep learning curve was a priority when developing the Catalogue.

User Profiles

The definition of profiles and their role in the Catalogue is a really important issue. The user should have access to the features and interfaces of interest according to the research question, and therefore flexibility was a priority. We considered three types of users and defined their respective requirements: Researcher, Data custodian and System administrator.

The researcher is able to search over a set of fingerprints. A free-text search feature is provided, so that regular users can access all content provided by database owners. Comparison of search results, tabular views, and searching for 'similar' databases are also provided. This requires the definition and agreement of similarity measurements for specific property matches or various other properties, such as location proximity.

Data custodians have full control over their workspace. They are able to manage and access the databases they maintain on the system, and navigate through the corresponding fingerprint data. Due to the complexity of the database information, the user is also able to save the database fingerprint at any point and edit it over time.

The administrator is able to create and edit fingerprints schemas, create group questions in the templates, define questions, validate user registrations, and several other management tasks.

Architecture

The Catalogue is built in three distinct layers (Figure 2). The top layer is open for interactions with both end users, through the user interface, by third party applications, and through direct data exchanges with the Catalogue Web services. At this level, four main modules were developed: Browse Catalogue, Fingerprint Template, Administration Management, and API Web services.

The idea of the Browse Catalogue module was to create a workspace where the user is able to browse the fingerprints and also search for researchers' questions. Furthermore, the system allows the user to search in the Catalogue (search engine) and also compare results (e.g. compare two databases and return the similarity for each field in the fingerprint).

Fingerprint Templates is a module to create and edit the templates. Furthermore, an Excel template was defined to allow specific types of databases to easily define suitable new fingerprint templates so that they could be easily imported into the system. Also, data custodians can submit information about their database to the Catalogue. After the database fingerprint is submitted to the system, it should be searchable in the Catalogue.

Administration Management is available to administer the accounts and roles in the Catalogue. It also controls the user's access and registration in the system.

The API Web Services provide a set of programmatic endpoints that can be consulted by third party applications and by the Catalogue presentation layer. The main idea is that other applications can send data to the Catalogue in the format of key-value pairs, containing, for instance, population characteristics.

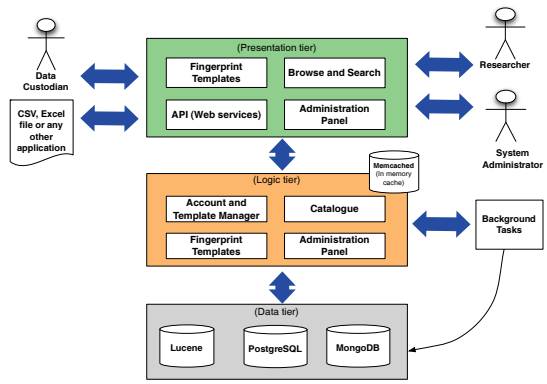

Figure 2: Catalogue - Software Architecture

There is also the logic layer containing the models that define the Catalogue's entities, such as users with different profiles and permissions, definition of the template schemas, fingerprint instances, and many others. The business logic is also defined in this layer. Finally, the data layer is where the information is stored. For example, the information regarding the catalogue templates and the dynamic groups of questions, as well as users' accounts, are stored in a PostgreSQL database. Furthermore, each database is indexed in an Apache Solr instance. This open source search engine framework allows full-text search and is used in large-scale information retrieval projects. Moreover, specific aggregated views of the database, such as population characteristics, are uploaded to a MongoDB instance, which allows greater flexibility in the stored values while maintaining good filtering features over stored data.

The Catalogue was developed in Python using Django[1], a web framework that encourages rapid development and clean programmatic design. However, a considerable part of the development was implemented in HTML5, CSS, and Javascript; namely, the interface and the end-user interaction. Furthermore, in order to improve the web design quality, we have adopted the Bootstrap[2] framework, a front-end aesthetic framework for web development.

Due to the high number of tasks the Catalogue is subject to, we realized that several processes could slow down the system when dealing with numerous concurrent interactions. Accordingly, we adopted several strategies to improve its performance. One of those is to have a cache based on the memcached[3] system. Several tasks, such as indexing the fingerprint in Solr, take too much time, making users wait for the opera-

[1] https://www.djangoproject.com
[2] http://getbootstrap.com
[3] www.memcached.org

tion to complete. All of these heavy tasks are added to a queue message (Rabbit MQ[4]) and the Celery backend executes them in the background.

Results and Discussion

EMIF (European Medical Information Framework) is a joint IMI project supported by the EU and the European pharmaceutical industry (through EPFIA), which has the overall ambition of enabling efficient re-use of health data for research purposes. It will allow the creation of new features to re-shape the way researchers answer key questions, and it will also determine possible future research directions [11]. The framework being developed (EMIF-Platform) supports two important research topics that serve as exemplars and test cases: 1) obesity and its metabolic complications (EMIF-Metabolic), and 2) markers for the development of Alzheimer's disease and other forms of dementia (EMIF-AD). Through the participating data sources, the project also aims to explore how the massive data available in pan-European Electronic Healthcare Record systems (EHR) and research cohorts can be optimally leveraged to improve biomedical research.

In this context, there is a need to integrate medical records, clinical and other omics information from different sources. Aiming to tackle this problem, a system that should be able to provide the first step towards answering questions from clinical researchers, in terms of knowing and comparing data sources' capacities, was created.

The current version of the EMIF Catalogue is accessible at http://bioinformatics.ua.pt/emif, but is only for registered users until a full governance model is set up in the project, which is expected to be completed by the end of 2017. Two distinct communities are already using the EMIF Catalogue:

- Observational Data sources: the fingerprint schema has 12 groups of questions, and in total 212 questions.
- Alzheimer Cohorts: the fingerprint schema has 27 groups of questions, with a total of 558 questions.

The EMIF Catalogue has already collected 46 fingerprints of different Alzheimer's Cohort databases and 15 from Electronic Healthcare records (EHR) data sources, corresponding to a total of around of 30 million patients. Overall, the Catalogue has more than 100 users registered, including both database owners and researchers.

Conclusion

Biomedical researchers have faced several difficulties in finding databases or information that fulfil their requirements.

In this paper, a software architecture able to fingerprint any kind of healthcare and research database was presented. The goal is to facilitate the initial assessment and selection of appropriate data sources for studies intending to answer a research question. The system is already being used to collect fingerprints from a wide collection of cohort and EHR databases, allowing faster identification of databases and resources.

A Cloud-Based Infrastructure for Feedback-Driven Training and Image Recognition

Mani Abedini[a], Stefan von Cavallar[a], Rajib Chakravorty[a], Matthew Davis[a], Rahil Garnavi[a1]

[a] *IBM Research – Australia, Carlton, VIC, Australia*

Abstract

Advanced techniques in machine learning combined with scalable "cloud" computing infrastructure are driving the creation of new and innovative health diagnostic applications. We describe a service and application for performing image training and recognition, tailored to dermatology and melanoma identification. The system implements new machine learning approaches to provide a feedback-driven training loop. This training sequence enhances classification performance by incrementally retraining the classifier model from expert responses. To easily provide this application and associated web service to clinical practices, we also describe a scalable cloud infrastructure, deployable in public cloud infrastructure and private, on-premise systems.

Keywords:

Machine Learning; Information Processing; Information Storage and Retrieval; Cloud Computing; Dermoscopy; Melanoma.

Introduction

New and inexpensive computational and communication capabilities continue to drive growth in the amount of healthcare data generated. For example, the number of mammograms in the US has increased from 26 million in 2003 [1] to over 48 million today, resulting annually in many petabytes of new image data alone. With the growth of other heterogeneous types of data (text, images, video, genetic sequences), in a broad range of clinical domains, the need for new techniques and applications to store, process, and utilise these data continues to evolve.

Making sense of these large amounts of data is a complex but essential task. Algorithmic machine learning techniques are essential to extracting useful information or modelling large data sets [2-4]. In the context of clinical diagnosis – two major classes of machine learning algorithms exist: Fully automated algorithms for diagnosis and algorithms that assist an expert clinician to perform the diagnosis, or computer assisted diagnosis (CAD). The purpose of computer-based systems is to support clinicians in their decision making, not to replace them. Therefore, CADs have better synergy in clinical environment, by providing a suggestive diagnosis or "second opinion" to assist a clinician [5] and are already used in many routine clinical tasks [6,7].

Modern communication technologies permit access to computing resources (processing, data storage, etc.) remotely. This has significant benefit for clinical applications, making data collection, analysis, and reporting more flexible and reliable [8]. Application of machine learning algorithms on a large amount of data require massive computational infrastructure. "Cloud" computing provides a suitable model to access such computational systems in different levels – infrastructure, platform, software, and data. Despite some challenges, such as patient data privacy and associated regulatory concerns, cloud technologies are being adopted by organisations at an increasing rate [9,10]. For health care providers, it presents a cost-effective way to get access to advanced technologies [9]. Cloud computing platforms hide the complexity of multiple tools, operating platforms, and frameworks from the end user [11,12]. Moreover, care providers in remote regions can obtain access to specialized resources (human experts, databases, digital models etc.) in real time [13].

In the health domain, machine learning algorithms require large volumes of training data in order to draw useful conclusions. Designing these algorithms to run efficiently on cloud-provided infrastructure is an effective strategy. There have been efforts to develop frameworks, such as MapReduce [14] and GraphLab [15], which parallelize the execution of processing algorithms on the kinds of distributed infrastructure found in cloud environments. While these frameworks are more suitable for machine learning researchers than non-technical end-users, hosted software applications, built on the same compute infrastructure and tailored for clinical users, are becoming available [16,17].

In this paper, we introduce a new, feedback-driven application for performing image training and recognition, targeting dermoscopy image recognition and melanoma identification. This application provides a web application and web service to clinical practices, potentially scaling to thousands of users, while hiding the complexities of a modern machine learning system from medical domain experts.

Methods

The system is composed of two high-level components, a machine learning and analytics pipeline for performing training and recognition and a scalable, cloud-based infrastructure for storing models and media and for executing tasks against the analytics pipeline.

Image analytics and feature extraction

A "supervised" machine learning work flow (described in previous section) uses "features" or "properties" of images from various classes to build a model [18]. These features are collected from the image by applying a number of image processing algorithms.

1 Author order is alphabetical

The collected features can roughly be divided in three broad categories: Low, mid, and high-level features.

Low-level features are directly extracted from image pixel data. Histogram of pixel values or other empirical modelling of pixel intensity distribution is one such low level feature.

Mid-level features try to abstract some properties of the object of interest, collected from an image annotation. Typically, operations or processes take place on raw pixel intensities that result in higher-level features. One such example is "edge" [19], roughly a gradient operation on raw pixel intensities. Horizontal, vertical or diagonal edges or any combination of these edges can be easily obtained. Similarly, operators to detect corners, textures, and shapes are also available [20].

High-level features represent domain specific properties of a given image. For example, in a cardiac MRI image, an enlarged myocardium, or an infarct scar, can be a high-level feature.

Based on the expert opinion (e.g. annotation from domain experts), features are extracted either from an entire image, partial image, or both. This ensures that local and/or global features are captured from a single image.

The system allows the user to choose from a number of pre-defined features to be extracted from the image. The choice can be made available from the user interface or via a configuration file.

Analytics Pipeline

The analytics pipeline contains four subcomponents, as shown in Figure 1. Three of these stages are derived from steps in a traditional machine learning pipeline; namely, annotation, training, and classification. The pipeline also incorporates a fourth stage, which takes user feedback from a classification result to refine the classifier through incremental training.

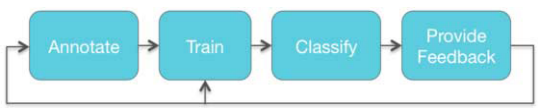

Figure 1 - Stages of the analytics pipeline

Annotate

For automated analysis and recognition of images of a certain class/type, annotation is an important step and prerequisite to training. In the annotation phase, a domain expert generates ground truth and training samples for the training module. In other words, annotation is the process of attaching metadata to images to facilitate development of classification models. In a computer-assisted system for melanoma recognition, for instance, the annotation can include:

- clinical diagnosis or histopathology of the given image (i.e. melanoma vs. benign)
- spatial boundary of the lesion, separating the lesion from surrounding normal skin
- number and types of colours (e.g. light brown, dark brown, black, etc.) observed in the lesion
- identified dermoscopy patterns (e.g. reticular pattern, globular pattern, pigment network, etc.) observed in the lesion

Clinical approaches, such as pattern analysis [21], ABCD rule of dermoscopy [22], CASH algorithm [23], and others, can be used as a basis for defining an "annotation template" and applied by the domain expert (clinician) in the annotation phase.

Our system provides an annotation image tool, as shown in Figure 2, to simplify the process of defining annotations for an image. The annotation tool enables a clinician to label features in an image from one or more templates provided through configuration. Labels are applied to the full image or spatial regions of interest, such as the lesion border. In addition to feature labelling, the clinician also specifies the clinical diagnosis for each image (melanoma or benign).

Train

After attaching annotations to training samples in the annotation phase, the clinician can train and build a classification model. First, the user creates a new training dataset by selecting from one or more pre-annotated images. A training set will contain images of mixed diagnosis, for example images with benign lesions and those diagnosed as melanoma. After creating the training set, the user launches the training algorithms by selecting "Train New Model". While the system defaults to a pre-configured set of parameters, advanced users

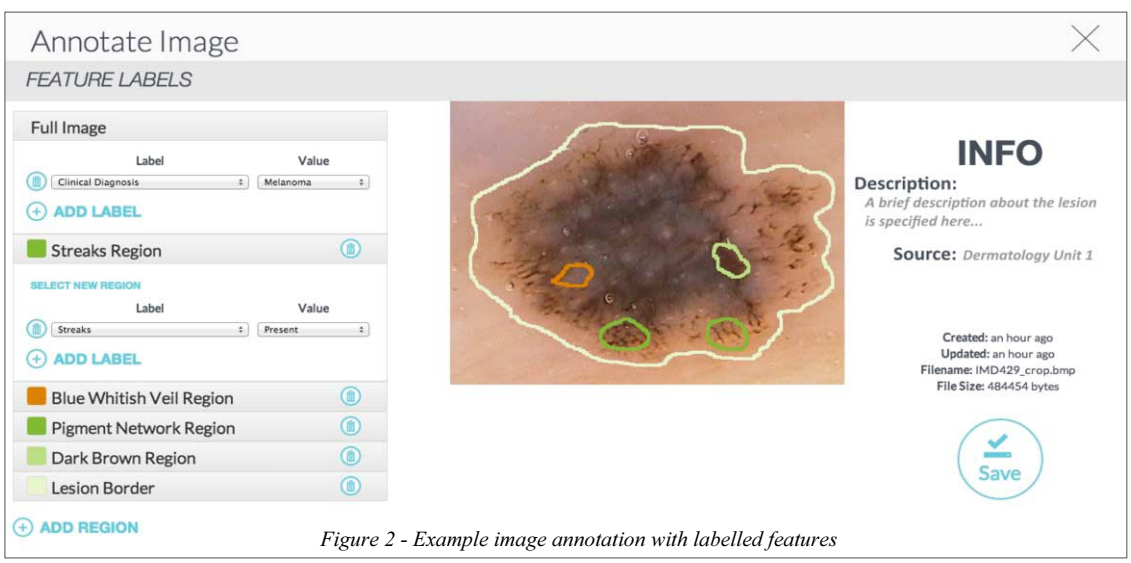

Figure 2 - Example image annotation with labelled features

can optionally fine-tune the analytic pipeline kernel and parameters provided to the training algorithms.

One feature of the system enables the domain expert to improve previously built models. After adding and annotating new samples to a previously trained dataset and model, the user can select "Update Model". This will trigger an incremental learning mechanism, which updates the existing classifier and builds an enhanced classification model without retraining the entire training set.

Classify

After building the model in the training phase, the clinician can now test the model on unseen images. Our system enables a fast classification (Figure 3) by uploading a dermoscopy image from the application. Using one or more classification models developed in the training stage, the system provides a diagnosis (e.g. melanoma vs. normal) and a confidence score on the classification result.

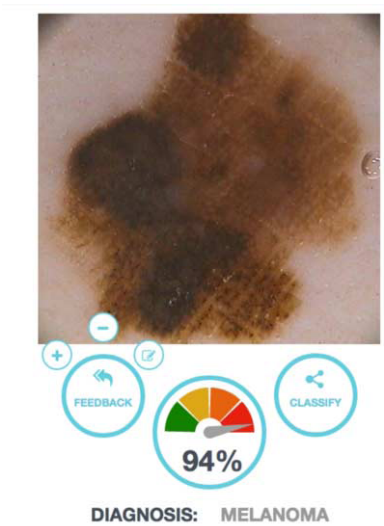

Figure 3 - Classify operation results and feedback controls

Feedback

To continually improve classifier performance, the system provides a mechanism to gather classification result feedback from expert users. As shown in Figure 3, after a classification is complete, the clinician can choose to provide feedback to the classifier score. Feedback can be provided in two ways. The simplest is with a binary answer, either agree or disagree with the diagnosis or score. The system also provides a third, structured feedback option. These feedback results are stored in the database and can be reviewed by an expert to help refine the classifier. The second option enables the user to "mark up" the classified image by providing a new annotation. In this process, the image annotation tool, shown in Figure 2, is used to define the annotation structure, including a clinical diagnosis. The previously untrained image, along with the new annotation, is then appended to the classifier model's existing training dataset and the classifier is incrementally retrained. We use stochastic gradient descent SVM [26, 27] as backend incremental learning method. When the feedback is available from expert, the already trained SVM is updated using gradient descent mechanism. Eventually, as more feedback is provided (more training examples), the SVM accuracy improves.

System and Infrastructure

The infrastructure component is implemented using cloud-computing principals of elastic scaling and deployment platform flexibility. The system architecture (Figure 4) is made up of four subcomponents, an application middleware providing consumable web services, a collection of worker processes for executing tasks on the analytics pipeline, a priority job broker for queuing and distributing tasks to workers, and an extensible document and media storage platform. Each component in the system is built to operate asynchronously and uses technologies, such as Web Sockets, to receive requests and provide an asynchronous response.

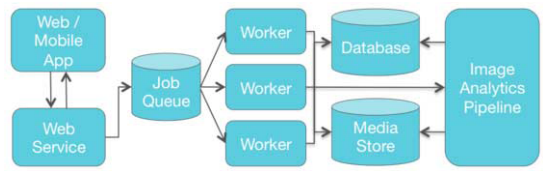

Figure 4 - Overview of system architecture

Web Service Interface

Access to the system is through web service application programming interfaces (APIs) using a representational state transfer (REST) methodology, JavaScript Object Notation (JSON) data format, and implemented in JavaScript using Node.js[2]. These APIs provide an authenticated web service to submit jobs for execution on the analytics pipeline. The system also provides a media management web service for uploading new media files for classification and training.

As many of the tasks are "long-running", in that they take more than three seconds to complete, the web services are designed to execute asynchronously. When a long-running request is submitted, the service will provide an immediate synchronous response with a task identifier then close the channel. The application has two options for receiving the acquiring response. First, the application can on-demand poll a result web service by providing the task identifier. Additionally, the application can subscribe to an asynchronous messaging channel using Web Sockets. In this situation, the web service will push a response to the application as soon as it becomes available.

Compute and Storage Infrastructure

Execution of tasks on the analytics pipeline is handled by a set of worker processes, implemented in Python, calling machine learning runtimes built on C, Java™, and Python code libraries. These workers provide an interface layer for accessing the analytics pipeline in a scalable and predictable manner. Individual workers subscribe and listen for waiting tasks from a job broker. When a worker process receives a job from the broker, it downloads required models and data from a media store, executes the analytic pipeline for a set of parameters (default or specified), and provides an asynchronous response back. The worker processes are pooled and stateless execution routines can be created and destroyed as needed.

The job broker monitors system load and provisions or de-provisions virtual machine (VM) instances as needed. For each instance, a set of worker processes are spawned to fill available capacity, taking into account available CPU, memory, and network capacity. We implement the job broker

2 http://nodejs.org/

process using Redis[3], to exclusively block and distribute waiting jobs, and Celery[4] for managing distributed workers on a set of VMs.

The system supports several storage options. For metadata storage and management, the system uses a document store, such as MongoDB[5]. For large, opaque binary data, including media (images) and classifier models, the system supports multiple data stores. In addition to a MongoDB-based storage backend, the system also supports distributed object stores, such as Amazon Simple Storage Service (S3)[6] and OpenStack Swift[7].

While the system can operate in public cloud service platforms, such as IBM BlueMix[8] or Amazon Elastic Compute Cloud (EC2)[5], it is designed to support a hybrid of public and private infrastructure. As many countries require personal health data to remain onshore [24], this separates web service APIs and applications from data storage and computation, simplifying security and monitoring requirements. In addition to the regulatory considerations, this offers other advantages. In some situations, it may be inefficient or cost prohibitive to transfer and store certain types of media in cloud object or block stores [25]. By keeping data on-site or by providing a "bring your own" storage environment, data storage as well as billing and payment is outsourced to other services or local infrastructure, further reducing security and latency concerns.

Results and Discussion

Annotation

Traditionally, annotating images for input into training modules is done using a spreadsheet tool such as Excel [28]. In tests, the time to annotate a series of images using our system's annotate image tool is significantly faster, especially for images that require drawn annotations. Despite these enhancements, we found the process to still be extremely time consuming. Future versions of the annotation tool will improve the annotation process with contextually aware user interface enhancements along with a feedback-trained "smart" annotation tool. The smart annotator will suggest an annotation structure for a previously untrained image and allow the clinician to accept or amend the suggestion. These modifications provide further feedback to future annotate and train operations.

Training and Feedback

The feedback mechanism of the system enables incremental updates to the classification model as updates arrive over time. Figure 5 demonstrates an example of the accuracy of the classification model as new user-provided feedback responses (either accepting the prediction or rejecting it) are received over time. The example set contains both "agreement" and "disagreement" from the experts. The graph suggests that the classifier struggles to predict correctly for the first few samples, but, as the system receives more feedback responses, the overall accuracy of the model improves. The initial classification model is trained using one example, then gradually updated by receiving more training samples. In this example, the classification accuracy for the first ten feedback responses is 56% but quickly improves to 75% over the next fifteen. The accuracy continues to improve with some fluctuation before converging at approximately 90% after 150 responses.

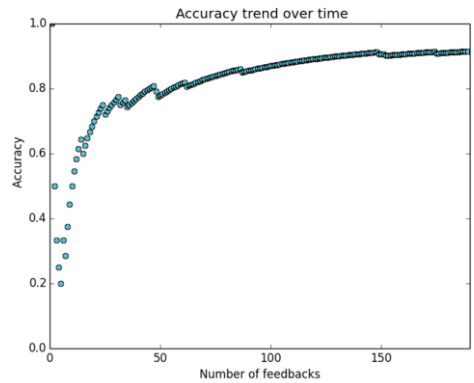

Figure 5 - Accuracy of classify operations as number of feedback results increases

Classification and Scalability

To test classifier performance and response time, we built a new classifier model from a corpus of approximately 100 images. We selected five images of similar size and resolution for classifier testing. Three images were of positive diagnosis (melanoma), two negative (normal skin). The five images were randomly selected and submitted in variable time increments to the web service, which submitted the images as jobs to the job broker. The job broker and worker processes were provisioned onto three virtual machines (VMs), each providing eight compute cores and 16 gigabytes of memory.

For each classification operation, the baseline response time was approximately 6.5 seconds per task (no additional system load), with an image upload time of 0.5 - 0.75s and classifier runtime of 5.7 - 6.0s. As expected, by varying the number of concurrent worker processes per VM, we found the classifier jobs scale with the number of compute cores linearly, indicating efficient CPU utilization by the classifier. Increasing the number of concurrent jobs beyond the number of compute cores for the VM resulted in an increase in classification and queue time. Additional work is needed to model and optimise total wait time and classification time against the costs associated with available but unused compute resources.

Conclusions

In this paper, we have described an innovative feedback-driven system for performing melanoma recognition in dermoscopy images. This system provides domain experts (clinicians) easy access to the complexities of a machine learning system, including annotation, training, and classification, through a simple user interface. Additionally, the system is built on top of a cloud-enabled infrastructure that can scale to thousands of users. Next steps involve further work to refine the training annotation workflow and a public deployment with one or more clinical partners.

A Two-stage Dynamic Model to Enable Updating of Clinical Risk Prediction from Longitudinal Health Record Data: Illustrated with Kidney Function

Abstract

We demonstrate the use of electronic records and repeated measures of risk factors therein, to enable deeper understanding of the relationship between the full longitudinal trajectory of risk factors and outcomes. To illustrate, dynamic mixed effect modelling is used to summarise the level, trend and monitoring intensity of kidney function. The output from this model then forms covariates for a recurrent event Cox proportional hazards model for predicting adverse events (AE). Using data from Salford, UK, our multivariate model finds that steeper declines in kidney function raise the hazard of AE (HR: 1.13, 95% CI (1.05, 1.22)). There is a non-proportional relationship between the hazard of AE and the monitoring intensity of kidney function. Neither of these variables would be present in a classical risk prediction model.. This work illustrates the potential of using the full longitudinal profile of risk factors, rather than just their level. There is an opportunity for deep statistical learning leading to rich clinical insight using longitudinal signals in electronic data.

Keywords:

Biomarkers; Clinical Prediction; Estimated Glomerular Filtration Rate; Longitudinal Analysis; Model Calibration.

Introduction

Most risk prediction models incorporate only the most recently measured value of a biomarker or risk factor. This is often inadequate as risk may be driven by decline, variability, or other complex aspects of the longitudinal trajectory. Electronic medical records contain rich longitudinal data from which risk factor trajectories can be estimated, and therefore used to enrich prediction models. In this paper we present an example of a two-stage model that first estimates the longitudinal trajectory of a risk factor, then uses predictors derived from this in a risk prediction model.

We illustrate the model using the example risk factor of estimated glomerular filtration rate (eGFR), which is a measure of kidney function. Deteriorating kidney function is an important risk factor for adverse events. Chronic heart failure (CHF) and type 2 diabetes (T2DM) both damage the kidneys. CHF reduces blood flow through the kidneys due to weaker heart pumping; the factors causing it also affect the kidney blood vessels; and some CHF treatments may damage the kidney. T2DM damages the blood vessels and other parts of the kidney directly. So, patients with these conditions require particularly diligent monitoring of their regular laboratory test results.

Kidney disease in patients with T2DM is well documented in the literature. A recent study in the US showed that as many as 43.5% of patients with T2DM have chronic kidney disease (CKD) [1]; CKD is strongly associated with increased mortality and accelerated cardiovascular disease [2]. Patients with T2DM are also more likely to experience acute renal failure than patients without diabetes (adjusted hazard ratio: 2.5, 95% CI 2.2 – 2.7) [3]. Like CKD, acute renal failure is also associated with high mortality rate, around 50% [4].

Data from the EuroHeart Failure survey suggest that patients with T2DM and impaired kidney function have amongst the worst short and long-term outcomes [5]. A recent study [6], showed that the combination of poor heart and kidney function is a particularly strong and discrete risk factor for death. Another study [7] found that T2DM was a statistically significant predictor of all-cause mortality in patients with CHF, but only those who had eGFR between 30 and 90 ml/min*1.73m^2. Heart and kidney dysfunction are closely linked [8] and diabetes worsens the situation, whether measured by hospital admissions or death rates [9].

In addition to slowly progressing disease, the kidneys can suffer acute injury leading to emergency hospitalisation and death, especially among patients with CHF and T2DM. Most reported studies in this area have focused on measuring kidney function at the time of endpoints such as death or admission. This study shifts the focus to the *process* of deteriorating kidney function itself. The aim is to examine in detail the trajectory of eGFR prior to endpoints being observed. In particular we will consider the effects of eGFR level, rate of decline and intensity of monitoring on adverse events such as emergency hospitalisation rates and all-cause mortality in patients with CHF and T2DM.

Methods

The data used in this study were obtained from the Salford Integrated Record (SIR) – a medical data store in Salford, Greater Manchester, UK. The population of Salford is around 234 thousand with 53 general practices and a single hospital. SIR contains linked data from both primary and secondary care for the population that engage with health services.

The cohort was restricted to patients who had both CHF and T2DM. Patients with congenital heart disease and those with cor pulmonale were excluded from the study, as were patients who had renal replacement therapy during the study period, where eGFR has a different interpretation. The study period spanned from January 2008 to August 2012.

The main outcome of interest was adverse events (AE), which comprise emergency hospital admissions and all-cause mortality. The covariates of primary interest were eGFR level, rate of decline and intensity of monitoring. Models were corrected for patient's age at the time of follow-up start, gender, and index of multiple deprivation (IMD) 2010. All covariates related to

eGFR are time dependent and as such require estimation of the longitudinal process for each patient. Therefore we take a two stage modelling approach. In Stage 1, the eGFR process is estimated. Stage 2 then models AEs as a function of the eGFR process.

For Stage 1, a simple approach to estimating the eGFR level at any time, t, is to use either the most recent eGFR value or some summary of a collection of recent eGFR values like the median or the mean. The eGFR decline can be calculated as the difference between the last and the penultimate eGFR values. In both cases, one needs to make several, rather arbitrary, decisions, for example, decide how far apart the two eGFR values should be in the case of calculating the eGFR decline. Also, as eGFR values can be 'noisy', this approach can be affected by variations in eGFR values. In order to smooth the variation in eGFR values and use all of the information about the degradation process of the kidney function in this particular population, we used dynamic mixed effects regression [10-11]. The eGFR level and decline for each patient at any given point in time t, was derived from a mixed effects model fitted to all of the eGFR data prior to t. The generic model was formulated as follows: dependent variable – the logarithm of eGFR, predictors (fixed effects) – age, gender, IMD, time since diagnosis (TSD) and time since study start (TSS), and random effects – variance of random effects on the intercept and coefficient of TSS.

For each patient at each endpoint at time t, eGFR level was measured by the predicted eGFR value at time t and eGFR decline was measured as $(a - b) / (t - t_a)$, where a is the predicted eGFR value at the start of the study, t_a, and b is the predicted eGFR value at time t. Since the kidney function for the cohort considered in this study is in progressive decline, for all $t > t_a$ the eGFR slope is a positive number, where higher values indicate steeper decline.

The eGFR intensity of monitoring was measured as the proximity of the most recent eGFR record: within 180 days, between 180 and 365 days and more than 365 days.

For Stage 2, modelling the risk of AE, we used a repeated measures Cox proportional hazards (CPH) model with gamma shared frailty – i.e. patient level random effects were modelled using a gamma distribution [12]. CPH model is a popular method used to model survival data [13-14]. It is a semi-parametric method with an advantage over parametric methods in that it focuses on hazard ratios only, thus, bypassing the need to specify a parametric distribution for the baseline hazard. This allows direct comparison of the risk between subjects with different characteristics, where a hazard ratio of one indicates that there is no difference in risk; ratios above one indicate higher risk; and below one lower risk.

Results

The process of deriving the cohort is illustrated in Figure 1.

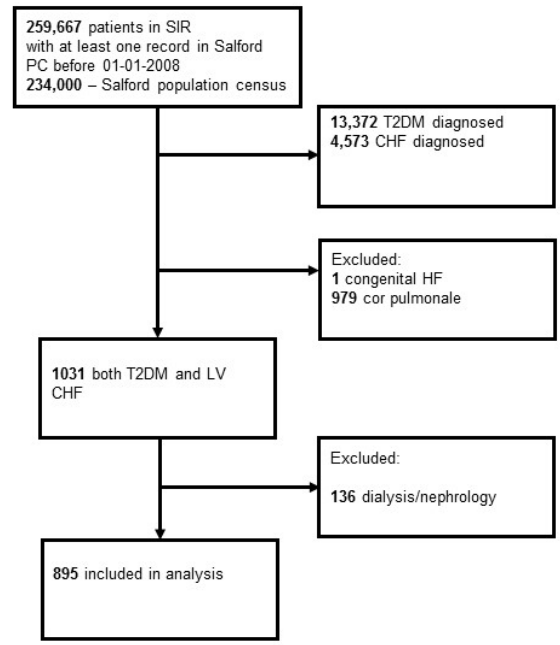

Figure 1 – Exclusion flowchart.

Stage 1

Table 1 shows exponentiated fixed effects of two log eGFR mixed effects models. The first model is the model fitted for the first AE during the study period. It is the model that used the smallest number of eGFR records for estimating the kidney function decline process. For each subsequent event, this model was updated with more data until the last model, which was fitted at the end of the study. Time is measured in years. From Table 1 we can note that older patients tend to have lower eGFR, female patients have lower eGFR than male patients, patients who have had both CHF and T2DM for longer have lower eGFR, and the eGFR is in decline with time.

Figure 2 shows the random effects of each patient on the intercept and the coefficient of the TSS for the last model. For the intercept, patients with negative random effects have lower than average eGFR. For the slope, patients with negative random effects have steeper than average decline in eGFR. We can see from Figure 2 that most of the steeper decline in eGFR is associated with patients with below average eGFR. The predicted eGFR levels and declines where carried forward to Stage 2.

Table 1 – Exponentiated parameter estimates of log eGFR models. Interpretation example: male coefficient is greater than one, meaning male eGFR is predicted to be higher.

	First model	**Last model**
Intercept	139.5 (119.72, 162.56)[a]	146.01 (126.47, 168.56)[a]
Age	0.99 (0.99, 0.99)[a]	0.99 (0.99, 0.99)[a]
Gender:		
Female	1	1
Male	1.07 (1.03, 1.11)[a]	1.05 (1.01, 1.1)[a]
Time since diagnosis	0.98 (0.98, 0.99)[a]	0.98 (0.98, 0.99)[a]
Time since study start	0.96 (0.95, 0.98)[a]	0.97 (0.97, 0.98)[a]

Key: a – statistically significant at 5%

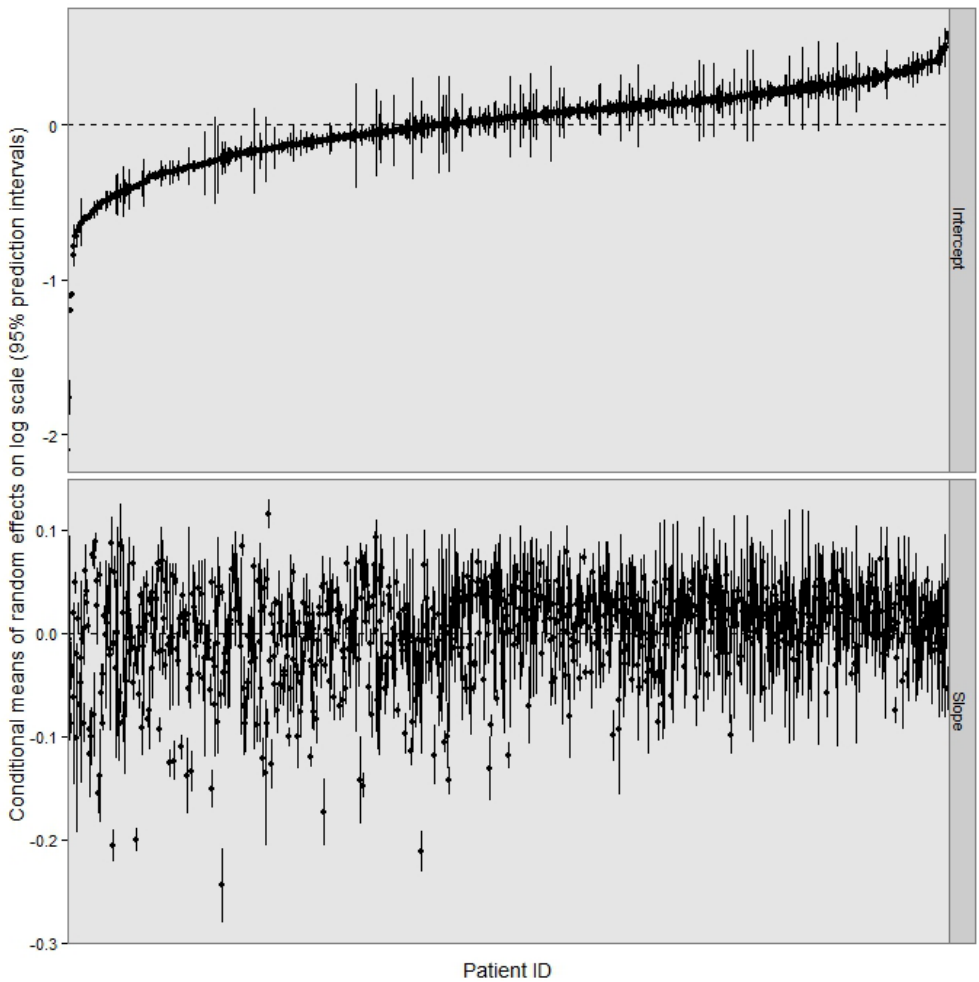

Figure 2 – Patient random effects on the intercept and on the slope of time since study start [15].

Stage 2

Table 2 shows covariate details and hazard ratios for univariate and multivariate models for AE. We can note the following from the table. Older patients are at higher risk of AE. Gender, IMD and eGFR level were not statistically significant, whereas the eGFR decline was. The hazard ratio for the eGFR decline indicates that a one unit decrease in eGFR per year increases the hazard of AE by 10-11%. The hazard ratios for the eGFR monitoring indicate that patients with more recent eGFR records are more likely to have AE. The multivariate model was selected on the basis of significance of the parameter estimates. The eGFR monitoring covariate failed to adhere to the proportional hazards assumption, so the multivariate model is stratified on this. Kaplan-Meier plots of the eGFR monitoring strata are presented in Figure 3.

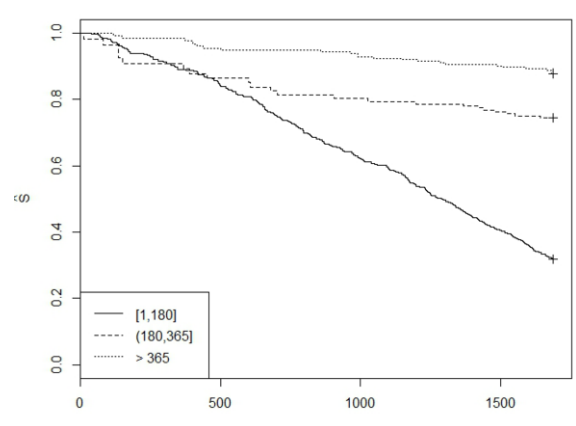

Figure 3 – Kaplan Meier plot of AE-free survival stratified by time since most recent eGFR measurement.

Table 2 – Hazard ratios for emergency hospital admissions models. Hazard ratios greater than one represent higher risk.

Covariates	**Mean (SD), count or proportion**	**Hazard ratio (95% CI)**	
		Univariate	**Multivariate**
Age	73.03 (10.43)	1.02 (1.01, 1.04)[a]	1.03 (1.01, 1.05)[a]
Gender:			
Female	42%	1 (reference)	-
Male	58%	1.2 (0.857, 1.68)	-
IMD 2010	37.16 (18.20)	1 (0.993, 1.01)	-
eGFR level	59.03 (18.18)	0.996 (0.988, 1)	-
eGFR decline	2.27 (2.05)	1.11 (1.03, 1.19)[a]	1.13 (1.05, 1.22)[a]
Last eGFR	58.58 (21.37)	0.993 (0.986, 1)[a]	-

> 365	190	0.13 (0.08, 0.20)[a]	-

Key: a – statistically significant at 5%

Discussion

We have presented a proof-of-concept study of a two-stage framework for modelling the full longitudinal profile of a risk factor and its impact on risk, using the example of eGFR decline in T2DM and CHF patients. We found that eGFR decline, modelled as patient-specific slope from a mixed effects model, was a strong predictor for adverse events (AE), and eGFR level was not a significant predictor either in a univariate or multivariate model. In a standard predictive modelling framework, only the most recent eGFR measurement would have been taken, so eGFR decline would not have been captured. We additionally considered the intensity of eGFR measurement as a predictor, and found a complex relationship between this and AE.

The main strength of this study is the incorporation of longitudinal information from routine care-records into risk prediction, a feature absent from standard models. We considered one risk factor but the method is easily extended to multiple risk factors. The main weakness is that uncertainty in eGFR predictions is not propagated to the estimates of the hazard ratios across the two stages of the method. Future work will investigate joint modelling approaches to overcome this.

We considered only mixed effects regression to model the trajectory of eGFR. Other methods such as random forests, neural networks and support vector regression could be used for this purpose. These machine-learning techniques might better cope with additional covariates, particularly treatments for T2DM and CHF that could influence kidney function. In our data, there were over a thousand different medications prescribed among our patient cohort in the month preceding the first eGFR measurement. Future work will compare alternative dynamic modelling strategies capable of incorporating complex covariate structures.

The ability to monitor and predict longitudinal processes using dynamic models, integrated with medical records, provides an opportunity to develop optimal monitoring polices for these risk factors. Linking the predictions of the kidney function decline to the effectiveness of its monitoring, aimed at averting adverse events, is a hard problem and the subject of ongoing research. This requires investigating the mechanism behind how the decline in eGFR leads to adverse events. For example, it may be that the decline in eGFR first leads to changes in treatment that in turn precipitate adverse events.

As with most routine care-records, the data in our study had limitations. In particular, the linkage of emergency hospital admissions to the SIR database required general practitioners to enter or accept data on admission episodes. In addition, we did not have data on the duration of hospital admissions, which could have been used to refine our endpoint definitions.

Despite limitations in the data and methodology this study has clearly demonstrated that clinical predictive models can improve their predictive abilities by taking account of the longitudinal information in electronic health records.

Consider EU Directive 2007/47 that considers algorithms used for prognostic purposes to be “medical devices.” The usual validation methods for such algorithms certify the encoding into software of models, but rarely question the fact that published model parameters will drift in calibration as risk-factor environments change. In addition, the structure of models may need reconsidering as populations, contexts of healthcare/observation and data-quality evolve.

Conclusion

Sophisticated statistical modelling with electronic health records allows for complex relationships between risk factor trajectories and outcomes to be captured, thereby improving predictions. Most current predictive models do not exploit longitudinal health record information in this way – neither is the regulatory framework for clinical algorithms set up to cope with this dynamic modelling approach. Research is urgently needed into statistical methods and computational frameworks for optimising clinical prediction from the continuously evolving risk information across heterogeneous populations, healthcare environments and information systems.

Abstract

Laboratory test results in primary care are flagged as 'abnormal' when they fall outside a population-based Reference Interval (RI), typically generating many alerts with a low specificity. In order to decrease alert frequency while retaining clinical relevance, we developed a method to assess dynamic, patient-tailored RIs based on mixed-effects linear regression models. Potassium test results from primary care were used as proof-of-concept test bed. Clinical relevance was assessed via a survey administered to general practitioners (GPs). Overall, the dynamic, patient-tailored method and the combination of both methods flagged 20% and 36% fewer values as abnormal than the population-based method. Nineteen out of 43 invited GPs (44%) completed the survey. The population-based method yielded a better sensitivity than the patient-tailored and the combined methods (0.51 vs 0.41 and 0.38, respectively) but a lower PPV (0.66 vs 0.67 and 0.76, respectively). We conclude that a combination of population-based and patient-tailored RIs can improve the detection of abnormal laboratory results. We suggest that lab values outside both RIs be flagged with high priority in clinical practice.

Introduction

Failure to follow up laboratory test results is a major concern in primary care [1]. Missed test results can lead to delayed interventions or to decisions made on the basis of incomplete information with potential compromise of patient safety [2]. For patients, poor test handling may generate increased number of visits, repeated laboratory examinations, and unnecessary stress or harm [3]. Callen *et al.* [1] showed that the extent of the failure to follow up test results in primary care ranges from 7% to 62% of results and can cause delayed diagnosis, preventable hospitalisation and adverse drug reactions.

Electronic Health Records (EHRs) can improve test result follow-up and management [4]. However, general practicioners' (GPs) satisfaction of informatics systems in place to manage tests is low [5]. One of the main barriers for timely follow-up is the high number of often unecessary alerts that physicians are presented with on a daily basis [6, 7]. It is estimated that each general practitioner spends almost an hour per day processing alerts generated by primary care information systems, the majority of which are composed of test result alerts [5, 6]. As a consequence, physicians may not have the necessary time to focus on the most important alerts [8]. This information overload contributes to alert fatigue [9] and can potentially generate patient safety issues [1].

The high number of alerts produced is directly related to the lack of specificity of current threshold-based methods for detecting abnormal values. The majority of EHRs use population-based Reference Intervals (RIs), which are defined as "intervals that, when applied to the population serviced by the laboratory correctly include most of the subjects with characteristics similar to the reference group and exclude the others" [10]. RIs are usually calculated by assuming a Gaussian distribution of test results for the given physiological measure (e.g. potassium, creatinine, heamoglobin), and estimating population mean and variance to calculate the RI as the 95% reference range. By definition a value outside the RI is flagged as abnormal [11]. As this approach is based on population estimates, it may flag values as abnormal that may be considered normal in the context of a specific patient's medical history. For instance, some patients have persistently high or low levels of certain physiological parameters, and this is dealt with via the clinician's knowledge of the patient. Conversely, some patients may experience sudden changes in critical parameters that need prompt medical action, but these changes are not flagged as abnormal because measured values are still within the population-based RI. In this regard, the adoption of more personalised methods that adapt to the patient's history could reveal key patterns and insights the interpretation based on population thresholds would not [12].

The aim of the paper is to develop a dynamic patient-tailored method for detecting abnormal laboratory test results in primary care, and assess the incidence of abnormal test results when using this method alone and in combination with the population-based method. Furthermore, we aimed to assess the potential clinical relevance through a survey administred to experienced practicioners in UK primary care.

Methods

Model

Mixed-effects modelling allows the analysis of data with complex patterns of variability and hierarchical structure [13]. Specifically, when estimating RI for laboratory tests, mixed-effects modelling can take into account both the population variability and the intra-patient variability. Consider a patient i and its corresponding test result set $Y_i=y_{i1}..$, by applying the introduced hierarchical structure and calculating the maximum likelihood estimate:

If $y_{ij} \sim N(\alpha_i, \sigma^2)$, $\alpha_i \sim N(\mu,\omega^2)$, then $\alpha_i \mid \bar{y}_{ij}, \sigma^2, \mu,\omega^2 \sim N(\tilde{\mu}_{ij}, V_{ij})$ where

$$\tilde{\mu}_{ij} = \frac{\mu\omega^{-2} + \bar{y}_{ij}\frac{n_{ij}}{\sigma^2}}{\omega^{-2} + \frac{n_{ij}}{\sigma^2}} \quad \text{and} \quad V_{ij} = (\omega^{-2} + \frac{n_{ij}}{\sigma^2})^{-1}$$

Equivalently,

$$\tilde{\mu}_{ij} = \mu\lambda_{ij} + (1 - \lambda_{ij})\bar{y}_{ij} \qquad (1)$$

$$\lambda_{ij} = \frac{\omega^{-2}}{\omega^{-2} + \frac{n_{ij}}{\sigma^2}} = \frac{\frac{\sigma^2}{n_{ij}}}{\omega^2 + \frac{\sigma^2}{n_{ij}}} = \frac{V_{ij}}{V_{ij} + \omega^2} \qquad (2)$$

Here, μ and ω^2 are population mean and variance, y_{ij} is the jth observation of patient i, α_i is the mean of patient i, σ^2 is the intra-patient variance. Moreover, $\bar{y}_{ij}$ and n_{ij} are the sample mean and number of observations for patient i after j observations. Finally, $\tilde{\mu}_{ij}$ and V_{ij} are the maximum likelihood estimates of α_i and σ^2, and λ_{ij} is a shrinkage factor, that as soon as there are more observations for patient i, increases the weight of the sample mean $\bar{y}_{ij}$ compared to the population mean μ. Accordingly, by using $\tilde{\mu}_{ij}$ and V_{ij} it is possible calculate an adaptive patient-tailored RI for patient i (defined as in the standard method as the 95% reference range), which is dynamically updated at each new test result and tells us what is normal/abnormal in a specific patient's context. Figure 1 shows an example of the application of the population-based and patient-tailored RIs to a patient's potassium results time series to detect abnormal values. As it is possible to notice at the first observation (on the left), with no previous information about the spefic patient, the population-based and patient tailored RIs coincide. Conversely, with new observations coming the patient-tailored RI is updated and adapts to the the patient's context. For example, the third value, that is similar to the previous ones but slighlty outside the population-based RI, is not flagged as abnormal according the patient-tailored method but it is according to the population-based ones. Finally, the last value, that is inside the RI but "unusual" for the patient, is flagged as abnormal by following the patient-tailored RI and it would be missed with the population-based one.

Data

The Salford Integrated Record (SIR) database was used to test our method. SIR is an anonymized electronic health record database from the City of Salford (population 234k, UK), which collects data from 49 primary care providers and one secondary care provider. Records are stored using Read codes v2 and CTV3 standards [14].

We focused our analysis on potassium results and we extracted data from SIR for patients aged 18 to 85 during the period 1/1/1990–31/12/2012. Potassium results are influenced by medications and chronic conditions, and in case of hypokalemia (<2.5 mmol/l) or hyperkalemia (>6 mmol/l) it can result in significant cardiac dysrhythmias. In addition, some patients can have levels persistently outside the RI without any effect on heart ryhthm. Accordingly, a patient-tailored alerting system would be particularly helpful for this laboratory parameter. As a consensus RI across UK laboratories, we implemented in our study a potassium RI of 3.5 to 5 mmol/l [15].

Parameter estimation

From SIR data extraction, after outliers exclusion in order to reproduce the implemented potassium RI, we derived two datasets: 1) a test set made by 500 patients randomly exracted, with all their potassium results; 2) a training set composed by all the remaining data extract used for fitting the mixed-effects model and estimate its parameters to implement the abovementioned adaptive patient-tailored RI.

Potassium results in the test set were flagged as abnormal if out of the RI range according either to the standard threshold-based method using our UK consensus RI (referred from now on as *standard method*) or the adaptive patient-tailored RI *(patient-tailored method)*.

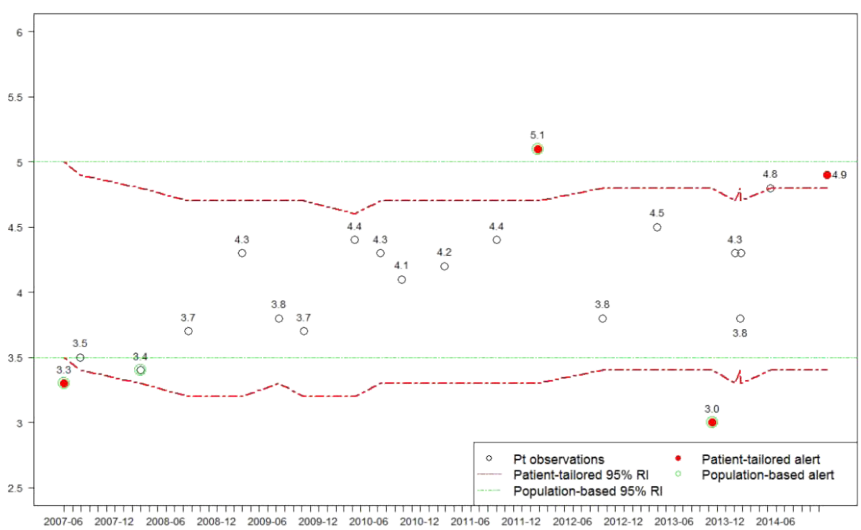

Figure 1 – Example of application of the patient-tailored and population-based RIs to a patient's potassium results time series to detect abnormal values.

Evaluation

Survey design

In order to test the clinical relevance of flagged values by the patient-tailored method as well as the standard method, we defined a gold standard as the GPs' clinical judgement, which we obtained through a survey, designed as follows. From the analysed testing dataset, we randomly selected 15 values for each possible combination of the two methods, i.e. values alerted by: 1) only the standard method; 2) only the patient-tailored method; 3) the standard AND patient-tailored methods at the same time (referred in the text as *combined method*); 4) none. From these values, we randomly included 2 per combination (for a total of 8) in a survey. GPs were asked to rate on a colour-based scale how abnormal each value was in the context of the specific patient:

- *Green* (normal value; i.e. no actions required);
- *Yellow* (probably abnormal; i.e. repeat in more than a week, do further test, change medication);
- *Red* (definitely abnormal; i.e. repeat urgently / hospital admission).

For each value GPs were provided with patient characteristics (i.e. age and gender), a graph showing the patient's previous potassium results, brief summary of past medical history (i.e. comorbidities and time since diagnosis), and medications from the last four months. In order to avoid any possible priming, no information about the standard and patient-tailored RIs were provided. Since values were randomly selected each time from the 15 values per combination included, it is noteworthy that: all surveys administered to participants were different between each other, while maintaining the proportion between the different combination of the two methods; each value could be assessed by more than one general practitioner.

The survey also contained three questions about respondent's working days (1-3 days, 4-5 days), years of experience (1-10 years, 10-20 years, >20 years), and opinion about abnormal test results alerts ("not enough", "about right", "too much")

Participants and survey setting

We administered the survey to a group of 43 GPs taking part in a 5 days Continuing Professional Development course for leadership development held in the city of Manchester (UK) in Octorber 2014.

Data analysis

We considered as clinically relevant, a value that was judged by GPs as at least probably abnormal (i.e. yellow and red in the coloured scale in the survey). In order to test performance, we calculated sensitivity and PPV for the standard, patient-tailored and combined methods by taking the prevalence of the different type of flagged values (i.e. flagged only by the standard method, only by the patient-tailored or by both methods at the same time) in the original dataset into account.

In order to assess variable importance, possible intra-assessor and intra-value correlation, a mixed-effects logistic regression was employed, using the flags by standard and patient-tailored methods as well as respondent characteristics as independent variables and the values clinical relevance as binary outcome.

All analyses were performed using the R software (http://www.r-project.org/).

Results

Data analysis

We extracted 1,411,757 unique potassium results from the SIR database, for a total of 151,681 patients. Mean age at first potassium record was 45.4 (17), female accounted for 49.8% and the mean follow-up time was 4.7 (4). The training dataset was composed of 500 patients and 4,144 potassium results. Of these, 470 (11.3%) values were flagged as abnormal by the standard method, 372 (9%) by the patient-tailored method and 301 (7.3%) by the combined one. The patient-tailored and combined methods registered a 20% (98 values) and 36% (169 values) reduction of the number of abnormal flagged values compared to the standard method.

Evaluation

Of the 43 GPs that received the survey, 19 completed it (response rate of 44%). Each value was assessed by a median of 3 GPs. Table 1 reports respondents' characteristics. The majority of GPs had more than 20 years of experience in general practice (63.2%) and worked 1-3 days in general practice. Furthermore, 42.1% thought that there are too many test results alerts in general practice.

Table 1 – Baseline characteristics of general practitioners.

Question	Reply	N (%)
Days per week in practice	1-3 days	10 (52.6%)
	4-5 days	9 (47.4%)
Years of experience	<10 years	2 (10.5%)
	10-20 years	5 (26.3%)
	>20 years	12 (63.2%)
Opinion about tests alerts in general practice	Not enough	4 (21.1%)
	About right	7 (36.8%)
	Too much	8 (42.1%)

Out of the 152 values assessed by GPs, 92 values were cosidered normal (green), 54 as probably abnormal (yellow), and 6 values as definitely abnormal (red). On average, each general practitioner identified 4.8 normal values (minimum: 1, maximum: 8), 2.8 probably abnormal values (minimum: 0; maximum: 7), and 0.3 definitely abnormal values (minimum: 0; maximum: 1).

Table 2 reports cross tabulation of values flagged as abnormal by all methods and whatever values were considered clinically relevant by GPs.

Table 2– Cross tabulation between standard, patient-tailored and combined methods and general practitioners judgement as clinically relevant.

		Clinically relevant		
		Neg	*Pos*	*Total*
Standard method	*Neg*	63	13	76
	Pos	29	47	76
	Total	92	60	152
		Clinically relevant		
		Neg	*Pos*	*Total*
Patient-tailored method	*Neg*	55	21	76
	Pos	37	39	76
	Total	92	60	152
		Clinically relevant		
		Neg	*Pos*	*Total*
Combined method	*Neg*	83	31	114
	Pos	9	29	38
	Total	92	60	152

Table 3 reports sensitivity and PPV of all three methods, calculated by taking the prevalence in the original dataset into account. The standard and combined methods had the best performance in terms of sensitiviy and PPV respectively.

Table 3– PPVs and sensitivities based on general practitioners judgements as clinically relevant.

Parameter	Standard method	Patient-tailored method	Combined method
Prevalence in testing dataset (n=4144)	11.3%	9%	7.3%
Prevalence in values assessed by GPs	50%	50%	25%
Sensitivity	0.51	0.41	0.38
PPV	0.66	0.67	0.76

Table 4 shows the adjusted ORs for the fixed effects in the mixed-effects logistic regression of values identified as clinically relevant by GPs. The estimated variance of the random effects for assessor and value were 1.5 (SD:1.2) and 0.4 (SD: 0.6) respectively. The only two significant variables were the flags by the standard and patient-tailored methods.

Table 4– Adjusted ORs for values identified as clinically relevant by general practitioners.(GP: General Practice)

Parameter	Adjusted OR [95% CI]
Standard method pos. vs neg.	24.5 [5.3,113.7]
Patient tailored method pos. vs. neg.	6.2 [2.0,19.1]
Weekly working days in GP: 4-5 days vs 1-3 days	2.2 [0.4,11.3]
Years of experience in GP: 10-20 years vs <10 years	3.5 [0.4,11.3]
Years of experience in GP: >20 years vs <10 years	6.0 [0.3,103.1]
Opinion about tests alerts in GP: not enough vs about right	0.5 [0.7,3.7]
Opinion about tests alerts in GP: too much vs about right	0.2 [0,1.3]

Discussion

This paper describes the development and preliminary evaluation of a method to produce dynamic, patient-tailored alerts for abnormal test results. The evaluation was focused on potassium results and clinical relevance was assessed via a survey administred to a group of experienced GPs in Manchester (UK).

Looking at performance of the standard and patient-tailored method, overall the standard method yielded a better trade-off between sensitivity and PPV. Although the dynamic, patient-tailored method achieved a reduction in the number of flagged abnormal values and a slightly better PPV, the standard method was significantly more sensitive.

The combined method showed poor sensitivity (similar in absolute numbers to the patient-tailored method). However, PPV was the best by far. This result suggests that combining population RI with patient-specific contextual information, improves the clinical relevance of flagged values. This finding is not unexpected: values flagged by the combined method are potassium results that are abnormal for the healthy population as well as in the context of a particular patient. The importance of the additional information provided by the patient-tailored method is also confirmed by the mixed-effects logistic regression modelling.

To decrease the number of not relevant test results alerts, some investigators have suggested alerting physicians only about those values that have a high deviance from the RI [16, 17]. We performed a sensitivity analysis by adopting a threshold-based approach with potassium RI of 2.5-6 mmol/l (previously proposed in [17]) that confirmed our main analysis. In detail, weighted sensitivity and PPV were 0.1 and 0.89 respectively. Although values outside the adopted RI had a very high deviance from the UK potassium RI, not all flagged values were considered clinically relevant and just a small proportion were considered definitely abnormal. This confirms the importance of the context and the bluntness of using fixed-thresholds when looking at individual patients.

Our main focus was on PPV, which is key to avoiding alert fatigue. However, we note that low sensitivities obtained by the patient-tailored and combined methods would lead to clinically relevant abnormal values being missed, with possible consequences for patient safety. It is noteworthy that in absolute numbers, even the sensitivity by the standard method (0.51) cannot be considered satisfactory and would lead to miss many values that are abnormal in the context of a specific patient but lay within the population RI. In addition to the lack of sensitivity, the patient-tailored and stardard methods have further drawbacks directly related to how they are defined. On one side, because of his adaptative nature, the patient-tailored method in presence of patients that are not stable but worsen over time (i.e. the value for a specific parameter keeps increasing or decreasing) would slowly adapt to the abnormal values and produce a biased patient-tailored RI. On the other side, the standard method, which uses fixed thresholds, would keep flagging tests results as abnormal when patients' values are stable but consistently outside the population RI. Improvements are needed in these regards for all methods.

Our analysis has several limitations. First, we focused on only one biochemical factor (potassium). Second, we carried out our evaluation within a relatively small panel of GPs in one geographical area. Third, the UK potassium RI adopted might have been slightly different than the one used in other laboratories that the clinicians may be used to; furthermore there might have been GPs that slavishly applied the abovementioned RI when replying to the survey.

Conclusion

This study demonstrates that the combined adoption of a patient-tailored method and a the standard threshold-based method for assessing potassium levels can improve the PPV of results flagged as abnormal. This could be particularly important to prioritise alerts by making the values flagged by both methods more prominent.

We plan to extend our experiments to a wider panel of laboratory tests (e.g. creatinine, eGFR, calcium, heamoglobin) and to a larger number of GPs, as well as investigating alternative statistical approaches (including Bayesian inference). We also plan to relate the alerting performance to adverse health outcomes.

This study represents a first step towards a next generation of context-aware alerting systems that in future may enhance patient safety.

Abstract

The National Surgical Quality Improvement Project (NSQIP) is widely recognized as "the best in the nation" surgical quality improvement resource in the United States. In particular, it rigorously defines postoperative morbidity outcomes, including surgical adverse events occurring within 30 days of surgery. Due to its manual yet expensive construction process, the NSQIP registry is of exceptionally high quality, but its high cost remains a significant bottleneck to NSQIP's wider dissemination. In this work, we propose an automated surgical adverse events detection tool, aimed at accelerating the process of extracting postoperative outcomes from medical charts. As a prototype system, we combined local EHR data with the NSQIP gold standard outcomes and developed machine learned models to retrospectively detect Surgical Site Infections (SSI), a particular family of adverse events that NSQIP extracts. The built models have high specificity (from 0.788 to 0.988) as well as very high negative predictive values (>0.98), reliably eliminating the vast majority of patients without SSI, thereby significantly reducing the NSQIP extractors' burden.

Introduction

The American College of Surgeons (ACS) National Surgical Quality Improvement Project (NSQIP) is widely recognized as "the best in the nation" surgical quality improvement resource in the United States [1]. NSQIP helps member hospitals to track outcomes associated with surgical patients, by collecting data on over 150 variables, including preoperative characteristics, intraoperative factors, and postoperative morbidity occurrences. In particular, postoperative morbidity outcomes are rigorously defined surgical adverse events occurring within 30 days of surgery, such as surgical site infection (SSI), urinary tract infection (UTI), and acute renal failure (ARF). NSQIP uses collected data elements to calculate relative performance regarding postoperative morbidity and mortality and to compare each member hospital's performance with benchmarking, which is risk stratified, including providing an observed to expected (O/E ratio) for every surgical adverse event [2]. With this feedback, member hospitals are able to focus attention and resources to areas of opportunity for improving the care of patients, which may also result in achieving reduced length of stay and readmission rates [3].

Unfortunately, less than 20% of hospitals in the United States currently participate in NSQIP, in large part due to its associated costs to implement. In addition to the participation fee, hospitals must employ a formally trained surgical clinical reviewer (SCR). An SCR ensures the reliability of clinical data abstraction, selects operation cases following NSQIP inclusion criteria, manually reviews and extracts data elements, and documents surgical postoperative occurrence outcomes. This manual yet expensive approach leads to high-quality clinical data, but the associated cost remains a significant bottleneck to NSQIP's wider dissemination.

An SSI is an infection occurring after surgery in the part of the body where surgery took place. While most surgical patients do not experience an SSI [4], SSIs are very expensive and morbid. According to the depth and severity of infection, SSIs are categorized into superficial, deep, and organ/space. Definitions for SSIs have been standardized by the Centers for Disease Control and Prevention (CDC) and are used by NSQIP SCR to identify and document each SSI category [5-6].

Previous work has explored risk factors associated with SSI, but few studies have focused on the detection of SSI. Most papers examining detection have relied heavily on administrative data or claims databases (such as age, gender, principal diagnosis, and billing information about medications and procedures) [7-8]. Since EHR data contains more detailed and richer clinical data (e.g. vital signs, lab results, and social history), compared with claims data it would provide additional significant indicators and signals to SSI and thus enhance the detection performance. In addition, most studies are procedure-specific, only processing SSIs following certain types of operation, such as hip and knee arthroplasty [9-10], instead of the current approach which is broadly inclusive of different types of surgery. To help reduce the labor and cost in reviewing patient records for postoperative surgical occurrences, we hypothesized that we could leverage both electronic health record (EHR) data and historic NSQIP registry data to develop and validate an automated approach with supervised machine learning algorithms to detect NSQIP occurrence outcomes. In particular, we focused on the postoperative SSI occurrences to develop a classifier of three SSI categories (superficial, deep, and organ/space) and the total SSI, and to reduce the SCR's burden by eliminating the vast majority of patients associated with surgeries that did not result in SSI.

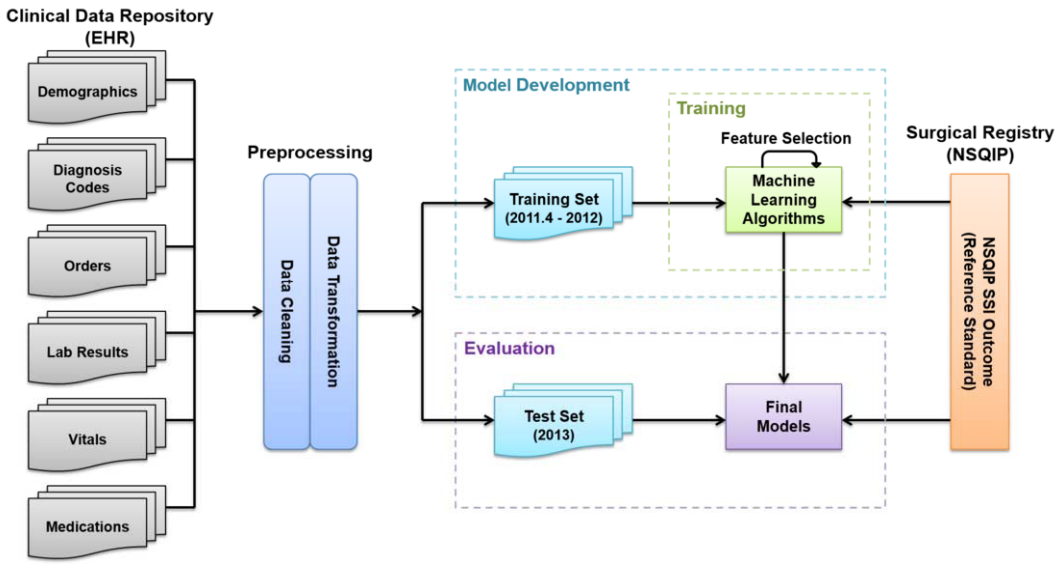

Figure 1 - Overview of Materials and Methods

Materials and Methods

Our overall methodological approach for this study included four steps as outlined in Figure 1: (1) identification of the patient cohort and associated patient EHR data, (2) data preprocessing, (3) iterative supervised learning model development, and (4) evaluation of the final models using gold standard outcome data from the NSQIP registry. Institutional review board approval was obtained and informed consent waived for this minimal risk study.

Data Collection and Patient Cohort Identification

The University of Minnesota Academic Health Center Information Exchange platform includes access to the clinical data repository (CDR) which contains University of Minnesota Medical Center (UMMC) clinical data. UMMC has been a member of NSQIP since 2007 and has used the inpatient instance of Epic since April 2011. CDR and NSQIP registry, two different data sources, were linked through the patient medical record number and the date of surgery. Subjects with no records in the EHR were eliminated. The patient cohort was divided into two datasets: data of patients with surgery from April 2011 to the end of 2012 (model development set) and data of patients with surgery in 2013 (evaluation set). The former dataset was used as the training set for model development. The evaluation dataset was held out fully for the overall evaluation of the developed models. Table 1 describes the detailed demographic information. From April 1, 2011, through December 31, 2013, a total of 6258 procedures with 405 SSIs were collected. The period of April 2011 to the end of 2012 comprised 3996 procedures and 278 SSIs (6.95% rate). About 79% procedures were patients no more than 65 years old, and 21% were patients more than 65 years old. Approximately 83.8% were white, 8.6% were black, and 7.6% were other race/ethnicity and unknown. The year of 2013 comprised 2262 procedures and 127 SSIs (5.6% rate), with similar patient characteristics, as shown in Table 1.

The clinical data utilized included six data types: demographics, diagnosis codes, orders, lab results, vital signs, and medications. Demographics included each patient's gender, race, and age at the time of surgery. Diagnosis codes consisted of related ICD-9 codes generated during the encounter and hospital stay at the time of surgery from coding, as well as the diagnoses from the past medical history and problem list. Orders related with SSI diagnosis and treatment were also gathered from the EHR, including imaging orders, infectious disease consultation orders, and procedures with incision and drainage. The most recent lab values and vitals results before surgery and those during the postoperative 30-day window (since surgical adverse events defined as occurring within 30 days after surgery) were collected. Medications utilized for this analysis included antibiotics from the third day after surgery onwards.

Another two important data measures included were American Society of Anesthesiologists (ASA) physical status classification and surgical wound classification. ASA classification from 1 to 6 indicates a patient's status from normal healthy to declared brain-dead; the surgical wound classification is used for postoperatively grading of the extent of microbial contamination, indicating the chance a patient will develop an infection at the surgical site. We dichotomized the wound classification as the bottom two (no or mild disturbance) versus the remaining levels (significant disturbance).

Data Preprocessing

EHR data of interest were collected, cleaned, and analyzed next. Identifying and removing outliers, and correcting inconsistent data were the very first tasks of data preprocessing. How to transform clinical data into meaningful features was our main interest. Most clinical data, such as lab test results and vitals, tended to be longitudinal with repeated measures. Traditional methods to summarize those variables by calculating the moments (mean and standard deviation) or extremes tended not to be sufficient to describe the temporal behavior of such variables. To better summarize individual tests, we explored other features like the change of values

Table 1 - Characteristics of patients and cases of surgical site infection (SSI) from cohorts

Characteristic	4/2011-2012					2013				
	No. of procedure	No. of SSI	Superficial SSI	Deep SSI	Organ/Space SSI	No. of procedure	No. of SSI	Superficial SSI	Deep SSI	Organ/Space SSI

Other	361	29	15	2	9	239	9	5	3	1

during an "elevating period". An elevating period is a time period during which the measurement in question is near-monotonously increasing from a low level (trough point) to a high level (peak point). For patients with SSI, some lab results, like serum glucose (GLC), platelet count (PLT), and white blood cells (WBC), have significant increases in the measurement from the third day after operation.

As shown in Figure 2, GLC increased in three time periods: (I) day 3~7, GLC increased from 116 to 128; (II) day 7~9, from 104 to 140; and (III) day 15~28, from 87 to 148. Such elevation may indicate the onset of SSI. To capture the elevating period, a feature defined as the postoperative increase from a trough to its nearest peak was included in our tentative model. In the case of multiple elevating periods, the feature was computed by using the period with the highest peak. For measures where low values could indicate SSI, a "descending period" can be defined analogously.

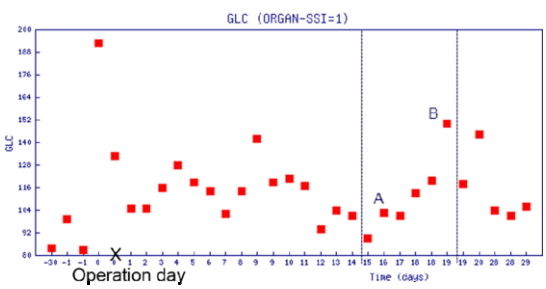

Figure 2 - GLC values within 30 days before and after surgery

Figure 3 depicts the flowchart of the algorithm to compute this feature. The algorithm first searches for the maximum value (p_m) from all results at least two days after the operation ($\{p_i, i=0, \ldots,n\}$), (e.g., in Figure 2, point B is the maximum GLC value, which was measured nineteen days after the operation). Then the algorithm proceeds by searching for the trough point backward from point B. The algorithm is robust in its filtering of the abnormal point that temporarily breaks the rule of monotone. For example, in Figure 2, the elevating period is

from day 15 to 19, however, there is an abnormal point A which breaks the monotone increasing trend between day 15 and 17; to overcome the problem and identify the real trough, the algorithm further compares day 15 and day 17 in order to determine whether the criterion of monotone increasing is satisfied.

For other data like antibiotic use and specific orders, we created binary variables to indicate whether a relevant element was observed. For example, a value of 1 for Interventional Radiology signifies that an abscess drainage order was placed for a patient; while a value of 0 signifies that no such test was ordered.

Model Development

To build our SSI detection model, we utilized multivariate logistic regression models. We constructed one model for total SSI and one model for each of the three SSI subtypes. Binary variables were entered as dummy indicator variables and continuous variables were entered unmodified. We used stepwise construction to select significant features and Akaike Information Criterion (AIC) for model selection.

Evaluation

In assessing detection of surgical adverse event outcomes like SSI, since these events are relatively rare, overall detection accuracy percentage is not an optimal criterion for evaluating model validity. Instead, we report specificity, as well as the the area under the curve (AUC), in evaluation of our automated detection system. Our aim was to maximize the specificity under the constraint that the negative predictive value remains above 98%. This aim is reflective of our original expectation of actual use of the detection models: to assist a NSQIP chart extractor to eliminate patients who clearly did not suffer the adverse event and then to accelerate the process of data abstraction from clinical charts.

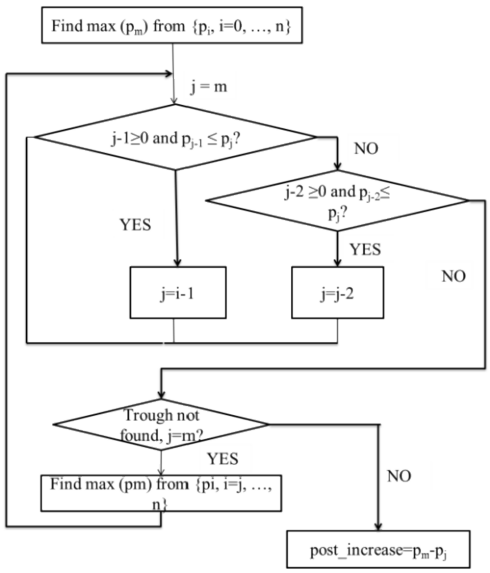

Figure 3 - Finding the postoperative increase in GLC

Results

Significant Variables Selected

Tables 2 through 5 show the results for the multivariate detection models for the three kinds of SSI and the total SSI, selected by AIC. The two most common variables included were diagnosis codes (the ICD-9 codes of SSI is 998.xx) and antibiotic use. Superficial SSI occurs just at the skin incision and thus relatively easily diagnosed. Therefore, imaging diagnostic orders tend to be unnecessary. Infection is sometimes diagnosed with microbiology cultures, however, frequently this diagnosis is based on the physical examination only. Actually only cultures ordered or not is a signal of SSI. According to table 3 and table 4, we can find that abscess culture, fluid culture and wound culture are significant factors for detecting deep and organ/space SSI. Since these two kinds of SSIs occur deep within or under the wound, imaging orders for both diagnosis and treatment are frequently required.

We also found the postoperative elevating period of GLC, for superficial and PLT for organ/space, to be indicative of clinical suspicion. Clinically these lab values can be altered in the setting of infection. For a unit increase in postoperative increase of GLC, we expect to see approximately a 0.0112 increase in log-odds of superficial SSI. Similarly, for a unit postoperative increase of PLT, approximately a 0.0115 increase in the log-odds of organ/space SSI is expected.

Table 2 - Significant indicators for detecting superficial SSI

Significant variables	Estimate	P-value
Diagnosis codes	2.1126	<0.0001
Wound culture ordered	2.1941	<0.0001
Antibiotic use	1.1321	<0.0001
Encounter type (inpatient)	1.6007	0.0010
ASA Classification (significant disturbance)	0.4342	0.0058
Abscess culture ordered	1.5020	0.0050
Postoperative increase of GLC	0.0112	0.0687

Table 3 - Significant indicators for detecting deep SSI

Significant Variables	Estimate	p-value
Diagnosis codes	3.1959	<0.0001
Antibiotic Use	2.2276	<0.0001
Abscess culture ordered	1.2880	0.0868
Gram stain ordered	0.8040	0.0427
Imaging treatment ordered	1.5445	0.1107
Imaging diagnosis ordered	0.6254	0.0981
Tissue culture ordered	1.6516	0.1010

Table 4 - Significant indicators for detecting organ/space SSI

Significant Variables	Estimate	p-value
Imaging treatment	1.3999	<0.0001
Imaging diagnosis	1.2090	<0.0001
Antibiotic Use	1.1662	<0.0001
Abscess culture ordered	2.3041	<0.0001
Fluid culture ordered	1.4204	0.0003
Preoperative PLT	0.00332	0.0135
Drainage culture ordered	1.3760	0.0711
Diagnosis code	0.8259	0.0667
Postoperative increase of PLT	0.0115	0.0606

Table 5 - Significant indicators for detecting total SSI

Significant Variables	Estimate	p-value
Diagnosis codes	5.3940	<0.0001
Antibiotic use	1.3672	<0.0001
Abscess culture ordered	3.2565	<0.0001
Wound culture ordered	2.2926	<0.0001
Imaging diagnosis ordered	0.8741	<0.0001
Fluid culture ordered	1.2909	<0.0001
Encounter type (inpatient)	1.0185	0.0037
ASA Classification (significant disturbance)	0.4258	0.0031
Preoperative PLT	0.00214	0.0440
Post maximum pain	0.0775	0.0957

Model Performance

Four detection models exhibited excellent specificity to eliminate the majority of non-SSI patients, which greatly accelerate the process of extracting postoperative SSI occurrences. Table 6 presents the negative predictive value (NPV) for each of the SSI identification models. The highest specificity 0.988 was for detecting deep SSI at NPV equals to 0.99, and the lowest 0.787 was for detecting total SSI at NPV equals to 0.99. AUC values for the four models were 0.820, 0.898, 0.886 and 0.896, respectively.

Table 6 - Negative predictive value and specificity for four SSI models

	NPV	Specificity
Superficial SSI	0.980	1.000
	0.985	0.987
	0.990	0.900
Deep SSI	0.980	1.000
	0.985	1.000
	0.990	0.988
Organ/space SSI	0.980	1.000
	0.985	0.999
	0.990	0.974
Total SSI	0.980	0.935
	0.985	0.888
	0.990	0.787

Discussion

The current research is a pilot study to examine the feasibility of automatically detecting postoperative SSI occurrences based on EHR data. The aim of this study is to assist a NSQIP SCR to eliminate patients who clearly did not suffer the adverse event. Therefore, a very high NPV is desired, which could assist in the reliable identification of patients without postoperative SSI. From the modeling results, we can see that all four models perform very well (with specificity ranging from 0.788 to 0.988) in eliminating the majority of patients without SSI based on the NPV equals to 0.99. Considering the nature of NSQIP SCR's work, SCRs still need to review all clinical charts, even if the positive predictive value for a patient is 0.9 or higher, since they need to extract the clinical characteristics of patients with SSI. Therefore, achieving high NPV, and thus allowing SCRs to eliminate patients, rather than achieving a high positive predictive value, is the main focus of this research.

Among selected potential indicators, a few of them were found to be quite significant with very small p-values. Only the indicators that had p-value less than 0.0001 were employed in the logistic regression modeling, however, this did not improve the detection performance. Other modeling methods, like Random Forest and Support Vector Machine, were employed; however, logistic regression models were found to outperform these methods for detection of all types of postoperative SSI events.

The current study was limited by the fact that it was conducted with only complete cases over three years. This may have limited our ability to fully refine and optimize the automated detection model. In the future, more procedures will be included, and the treatment of missing data will be studied.

Large quantities of meaningful information are stored at the clinical notes, such as imaging reports and culture results, which we did not utilize in this study. For example, a positive abscess culture result could be recorded as "On day 2, isolated in broth only: Bacteroides fragilis group". However, we merely considered whether the diagnostic and therapeutic imaging orders or cultures were placed, we did not use the actual results. Natural language processing (NLP) has played an important role in detecting adverse events [11-12]. In our future research, we will apply NLP techniques to extract additional important information from clinical notes.

Conclusion

In this study, to accelerate the process of extracting postoperative SSI outcomes from medical charts and reduce the workload of NSIQP SCR, an automated postoperative SSI detection model based on supervised learning was proposed and validated. The models exhibited good performance, they reduced the SCR's burden by reliably eliminating the vast majority of patients with no SSI. The significant factors of detecting SSI identified by our models are in line with clinical knowledge. In addition, some useful patterns, (e.g. postoperative increase of PLT and GLC), were extracted from the longitudinal lab results.

Mining Temporal and Data Constraints Associated with Outcomes for Care Pathways

Abstract

A care/clinical pathway defines a standardized care process for a specific patient group, which consists of clinical goals, activities, data attributes, and constraints describing temporal dependencies and data preconditions of the activities. The constraints, which are the key elements to represent the best practices, are difficult to define due to the variations in different regions and populations. In this paper, we propose an approach to discover temporal and data constraints that are correlated with clinical outcomes for care pathways. For each activity of interest, we extract a set of associated event-condition-action (ECA) rules from electronic medical records (EMR) to represent the temporal and data preconditions of the activity, by using our modified association rule mining algorithm. Then the best ECA rule that is significantly more likely to lead to a positive outcome is translated into the constraint on the activity. The approach has been applied to real-world EMR, and discovered meaningful constraints for different groups of type 2 diabetes patients, which can be used to provide decision support during individual patient care.

Clinical Pathways; Data Mining; Association Learning; Electronic Medical Record.

Introduction

A care/clinical pathway defines a standardized care process for a well-defined patient group, aimed at improving patient outcomes and promoting patient safety [1]. Generally, a care pathway consists of clinical goals (e.g., controlling glucose of diabetes patients), activities such as laboratory tests and medications, data attributes such as problem histories and test items, as well as constraints on the activities. The constraints, which describe temporal dependencies (e.g., check renal function (RFT) before using biguanides (BG)) and data preconditions (e.g., BG can be used only if the patient does not have ketoacidosis (KA) and creatinine (CR) ≤ 2.0 mg/dL) of the activities, play the most important role in achieving the clinical goals and reducing medical errors.

Real-world care processes, however, are dynamic, complex and ad-hoc [2]. For a certain disease, the care practices may vary in different regions, different periods and different patient populations. Therefore, if only guided by general medical knowledge such as clinical guidelines, it is usually difficult to define the pathway constraints that can represent the best practices for a specific patient group. However, because real clinical activities and patient outcomes are tracked in electronic medical records (EMR), a potential improvement for care pathway modeling is to discover the constraints from EMR using data mining and process mining techniques.

It is a challenging problem, however, to discover the complex constraints for a pathway. Firstly, both temporal dependencies and data preconditions should be extracted to build the care pathway. These temporal and data preconditions are usually associated with each other and cannot be mined independently. Secondly, to summarize the best practices for a specific patient group, the discovered constraints should be correlated with positive clinical outcomes. Previous works on clinical process mining [2-5] mainly focused on mining temporal dependencies of activities, and did not consider data conditions. Moreover, most of these methods [2-4] focused on the extraction of frequently satisfied dependencies. These frequent practices are not always the best practices. Although an existing solution [5] can highlight the mined temporal dependencies that have high correlation with patient outcomes, it can neither distinguish positive dependencies from negative ones, nor discover the data conditions associated with the outcomes. Several process mining methods for general purposes [6,7] can discover data preconditions that discriminate between satisfaction and violation of a temporal constraint, but these methods cannot obtain constraints that are correlated with outcomes.

In this paper, we address these issues by proposing an approach to discover constraints that are associated with positive clinical outcomes for care pathways. The constraints are defined using event-condition-action (ECA) rules, where temporal dependencies and data preconditions of an activity can be represented as events and conditions respectively. We discover the ECA rules from EMR by providing a modified association rule mining algorithm, which uses the metrics of support and valid rate to measure the frequency of a rule, as well as the relative risk and Fisher's exact test to quantify its correlation with a clinical outcome. For each activity of interest, the best ECA rule, which is significantly more likely to cause a positive outcome, is translated into the constraint of the activity. The proposed approach has been applied to real-world EMR to extract constraints for different groups of type 2 diabetes patients. The discovered constraints are reasonable and meaningful, which can be integrated into a care pathway management system to help clinicians refine the pathways and provide decision support during individual patient care.

Methods

Our method takes as input, a set of patient traces from the EMR and a draft care pathway, and the output is a complete care pathway with discovered constraints that are significantly associated with positive outcomes. The method includes two main steps. Firstly, we construct an activity dataset from the patient traces to represent the execution situation of the care pathway during each activity of interest. Secondly, a set of ECA-based constraints are mined from the activity dataset.

Materials

A variety of representations have been proposed for care pathway modeling, such as computer-interpretable guideline

languages [8], business process models [5], and the case management modeling and notation (CMMN) standard [9]. Generally, the key elements, such as stages, goals, activities, data attributes, and constraints on the activities are normally defined in a care pathway model. Actually, using our previous approach [10], every patient trace can be aligned with a multistage care pathway, where each record is mapped onto a corresponding stage according to a hidden Markov model. In this work, we focus on the constraint discovery within each stage of the pathway. Formally, a stage of a pathway model can be represented as $M = (g, A, B, \Phi)$, where g is the clinical goal (e.g., Glycated hemoglobin (A1c) < 7.0% and Fasting plasma glucose (FPG) ≥ 3.9 mmol/L), A is a set of clinical activities, B is a set of data attributes and Φ is a set of constraints on the activities of interest $A_I \subseteq A$. A constraint $\varphi \in \Phi$ can be defined in the form of an ECA rule:

on *events*(A) **if** *conditions*(B) **do** *action*(a_I),

where the event (on) part represents the temporal dependency of the activity $a_I \in A_I$ on other activities in A, and the condition (if) part represents the data preconditions of the activity a_I. We treat each event, condition or action as a rule item $c = (f, \omega_f, x_f)$, where $f \in A \cup B$ is the feature to represent an activity or an attribute, $\omega_f \in \Omega_f$ is the possible operator on f (e.g., =, ≥, ≤), and x_f is the reference value that can be boolean, categorical or numeric depending on the feature type. A ECA rule contains a set of rule items $C = C_A \cup C_B \cup C_I$, where C_A, C_B and C_I are respectively the item sets in the event, condition and action parts of an ECA rule. For instance, the above example about biguanides can be formally represented as:

on *Renal_function_test*.completed = true
if *Ketoacidosis* = *false* ∧ *Creatinine* ≤ 2.0
do *Biguanides*.enabled = true.

Figure 1 shows the graphical representation of this constraint in a CMMN-based care pathway model [9,11].

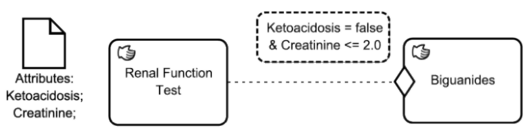

Figure 1 – A fragment of an example care pathway model

In EMR, a patient record can be formally represented as $r = (p, e, v, t)$, where $p \in P$ is the patient identifier from a cohort P, $e \in E$ is the code from a standard terminology to represent a care event such as a diagnosis, a medication or a lab test, v is the value (e.g., the value of a test item), and t is the occurring time of the event. For a specific patient p, his/her records can be sorted by t to generate a patient trace $\sigma = \langle r_1, r_2, \ldots, r_k \rangle$. Figure 2 illustrates an example patient trace, where "CR (1.0)" is a record whose code e represents CR and $v = 1.0$.

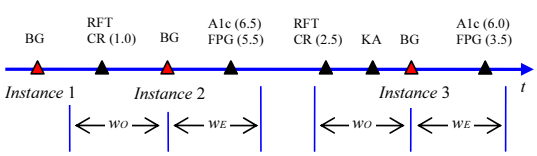

Figure 2 – An example patient trace

In a draft pathway model, the goal g, activities A and attributes B are pre-defined by users, while the constraint set Φ is empty. For constraint mining, a many-to-one terminology mapping Δ_A: $E_A \rightarrow A$ between a subset of event codes $E_A \subset E$ and the activities A in the pathway should be pre-defined, as well as a mapping Δ_B: $E_B \rightarrow B$ between a subset of codes $E_B \subset E$ and the attributes B. With these mappings, every relevant patient record can be mapped onto an activity and/or an attribute. Then the objective of our approach is to discover a set of constraints Φ for the activities of interest A_I, from the given set of patient traces Σ. The mined constraints should be frequently fulfilled in Σ and associated with achievement of the goal g.

Activity Dataset Construction

To discover the desired constraints, we first derive an activity dataset D from patient traces Σ, where each instance $d \in D$ can represent the execution situation of the care pathway at the time point of a patient record r. An instance $d = (a_d, \boldsymbol{x}_A, \boldsymbol{x}_B, y)$ contains the current activated action a_d for an activity of interest, the event feature vector $\boldsymbol{x}_A$, the condition feature vector $\boldsymbol{x}_B$ and the outcome y after the action. Each event feature x_a in $\boldsymbol{x}_A$ is a boolean attribute to represent whether the corresponding activity $a \in A$ was executed within an observation time window w_O (e.g., 1 year) before the current action. Each condition feature x_b in $\boldsymbol{x}_B$ contains the most recent value of an attribute $b \in B$ within the observation window w_O. The outcome y is a boolean label to represent the achievement result of the goal g within an evaluation window w_E (e.g., 3 months) after the action a_d.

Table 1 shows an example activity dataset where the three instances are derived from the patient trace shown in Figure 2. In this example, BG is taken as the activity of interest. For each record that can be mapped onto BG (highlighted in Figure 2), we create a new instance to record at the time of that action, whether renal function test (RFT) and other activities had been executed within w_O, whether ketoacidosis (KA) and other problems had occurred, the most recent values of creatinine (CR) and other test items within w_O, and the outcome (the truth value of A1c < 7.0 ∧ FPG ≥ 3.9) after the action within w_E. Note that the condition features and the outcome can have null values, when they cannot be validly evaluated within the time windows.

Table 1 – An example activity dataset derived from Figure 2

Ins.	Action	Event features			Condition features			Outcome
	a_d	x_{a1} (RFT)		…	x_{b1} (KA)	x_{b2} (CR)	…	y
1	BG	false		…	false	null	…	null
2	BG	true		…	false	1.0	…	true
3	BG	true		…	true	2.5	…	false
…	…	…			…			…

Constraint Mining

Based on the activity dataset D, we then discover the desired constraints Φ. For each activity of interest $a_I \in A_I$, the objective is to mine an ECA rule $C \rightarrow O$ that is composed of a set of associated rule items $C = C_A \cup C_B \cup C_I$ and prone to result in a positive outcome O. Existing association rule mining methods [12, 13] can find a rule that satisfies *support* and *confidence* constraints based on the *Apriori* algorithm. Let $D(C) = \{d \mid d \in D, C(d) = \text{true}\}$ denote the set of instances satisfying all rule items of C, and $|D(C)|$ is the number of the instances, then the support of the rule is the proportion of instances satisfying the rule in the instances where the action a_d equals a_I:

$$Sup(C) = |D(C)| / |D(C_I)|,$$

where $D(C_I) = \{d \mid d \in D,\ d.a_d = a_I\}$. The support measures the applicability of the rule, and the confidence measures the association level with the outcome, which is the proportion of instances causing a desired outcome in the satisfying instances:

$$Conf(C \rightarrow O) = |D(C) \cap D(O)| / |D(C)|,$$

where $D(O) = \{d \mid d \in D,\ d.y = \text{true}\}$. Notice that the confidence only measures the outcome of the satisfaction cases, and the consequence of violating the constraint is not considered, which is also critical to evaluate the effectiveness of the constraint. Furthermore, the significance of the mined rules, which is very important for clinical evidence to be accepted, cannot be ensured just using support and confidence.

To address these problems, we use relative risk (RR) and Fisher's exact test to evaluate a constraint. Relative risk is the ratio of the probability of developing positive outcomes in an satisfaction group to the probability of developing positive outcomes in a comparison, violation group:

$$RR(C \rightarrow O) = \frac{Conf(C \rightarrow O)}{Conf((\neg C \cap C_I) \rightarrow O)}.$$

Relative risk has been widely used to quantify how strongly the presence or absence of a condition is associated with an outcome in clinical trials and risk analysis [14], which also has a clear interpretation in our scenario: "satisfaction cases of the constraint would be *RR* times as likely as violation cases to develop a positive outcome." A higher *RR* (> 1) means that the positive outcome is more likely to occur in the satisfaction group than in the violation group. Right-tailed Fisher's exact test can be performed to test if *RR* is significantly greater than 1. Fisher's exact test is valid for small and highly unbalanced dataset, which can therefore be applied to the rules with high support and few violation cases.

Another issue is that in real-world EMR, some of the data can be highly censored. The features with too many null values may cause an inaccurate calculation of support and relative risk. To tackle this problem, we replace the instance set $D(C_I)$ with $D(\hat{C}_I) = D(C_I) \cap \{d \mid d \in D, c \in C, d.x_c \neq \text{null}\}$ in the above formulas to obtain an unbiased evaluation of a rule. We also measure the valid rate of a rule, which is the proportion of instances without null value features:

$$VR(C) = |D(\hat{C}_I)| / |D(C_I)|.$$

Algorithm 1. Care Pathway Constraint Mining

Input: A draft care pathway (g, A, B) and a set of activities of interest A_I
The activity dataset D
Pre-defined thresholds: $\Theta = (\theta_V, \theta_S, \theta_R, \theta_P)$
Output: A set of constraints Φ

1: $\Phi = \emptyset$
2: **for each** $a_I \in A_I$ **do**
3: $L_1 = \emptyset$, $C_I = \{a_d = a_I\}$
4: **for each** $f \in A \cup B$ **do**
5: L_f = genCandidate1Rules(f)
6: **for each** $C_f \in L_f$ **do**
7: **if** evalRule(C_f, C_I, D, Θ) = true **then** $L_1 = L_1 \cup \{C_f\}$
8: **end for**
9: **end for**
10: **for** $k = 2$; $L_{k-1} = \emptyset$; $k = k + 1$ **do**
11: $L_k = \emptyset$, L_T = genCandidateRules(L_{k-1})
12: **for each** $C_T \in L_T$ **do**
13: **if** evalRule(C_T, C_I, D, Θ) = true **then** $L_k = L_k \cup \{C_T\}$
14: **end for**
15: **end for**
16: $\Phi = \Phi \cup$ {getBestRule($\cup_k L_k$, C_I, Θ)}
17: **end for**

As shown in Algorithm 1, our constraint mining algorithm takes as input the draft pathway model, the activity dataset derived from the EMR, as well as a set of pre-defined thresholds $\Theta = (\theta_V, \theta_S, \theta_R, \theta_P)$, where θ_V is the minimum valid rate θ_V, θ_S is the minimum support, θ_R is the minimum relative risk, and θ_P is the maximum p-value.

For each $a_I \in A_I$, the algorithm first builds a set of 1-rules L_1, where each rule has only one item (line 3-9). The function *genCandidate1Rules* (line 5) generates a set of candidate 1-rules for a feature *f*. If *f* is a categorical or Boolean feature, we create a set of candidate rules $L_f = \{C_f \mid C_f = \{(f, \omega_f, x_f)\},\ \omega_f \in \Omega_f,\ x_f \in X_f\}$, where X_f is the set of possible categories of *f*, and Ω_f is the possible operators (e.g., $\{KA = \text{false}\}$). If *f* is a numeric feature, we first discretize the attribute [12] and then build an item set similarly (e.g., $\{CR \leq 2.0\}$). Notice that $|X_f| \times |\Omega_f|$ candidate 1-rules are created for *f*, and not all of them are valid, frequently satisfied and correlated with the outcome. Therefore, we use the function *evalRule* to evaluate every rule $C_f \in L_f$ using the above metrics, and prune the uninteresting rules (line 7). For an event feature $f \in A$, if $VR(C_f \cup C_I) \geq \theta_V$ and $Sup(C_f \cup C_I) \geq \theta_S$, then C_f can be added to L_1. And for an condition feature $f \in B$, besides *VR* and *Sup*, we also check whether $RR(C_f \cup C_I \rightarrow O)$ is greater than θ_R to further remove the rules that are not very likely to cause positive outcomes.

In each subsequent pass *k*, the algorithm builds a set of *k*-rules L_k, where each rule has *k* items (line 10-15). The function *genCandidateRules* is similar to the Apriori algorithm [13], which uses L_{k-1} found in the pass *k*-1 to generate the candidate rules L_T by joining and pruning (line 11). Because one feature may have multiple candidate rule items with different operators and/or different reference values, the function also ensures that in each rule there is no implied items (e.g., $CR \leq 2$ and $CR \leq 3$) or conflicted items (e.g., $CR \leq 2$ and $CR > 3$). Then *evalRule* is performed to evaluate every rule $C_T \in L_T$ and remove the invalid, infrequent or negative rules (line 13).

After generating all the rules for a_I, the algorithm selects the best rule (line 16) that has as many items as possible and is significantly more likely to lead to a positive outcome. The function *getBestRule* first ranks the rules $C \in \cup_k L_k$ by *k* and *RR* orderly, and removes the rules whose p-values from Fisher's exact test is less than θ_P. Then the top-one rule in the rank list is selected as the constraint of a_I and added to the constraint set Φ. After all the iterations (line 2-17), the set Φ contains the discovered constraints for all the activities of interest in A_I.

Results and Discussion

We performed a case study using our method on real-world EMR collected from a China hospital. The EMR data contains 729,027 events (including 163,654 diagnoses, 178,019 medications and 387,354 lab tests) that occurred over 4 years, from a cohort of 2,693 patients with type 2 diabetes, where 1,454 patients also had cardiovascular diseases (CVD).

Two different care pathways were focused on in this study: (I) care pathway for the management of general type 2 diabetes; (II) care pathway for managing diabetes patients with CVD. The draft pathways are derived from a clinical guideline of type 2 diabetes mellitus [15] and recommendations from diabetes experts. In the care pathways, we defined clinical activities including 9 classes of medications and 7 panels of laboratory and vital sign tests, as well as attributes including 6 categories of problems and 12 test items. Some of the activities and attributes are shown in Table 2.

Table 2 – Abbreviations of activities and attributes

Abbr.	Clinical activity	Abbr.	Attribute
	Medications:		**Problems:**
BG	Biguanides	HG	hypoglycemia
SU	sulfonylureas	KA	ketoacidosis
αGI	α-glucosidase inhibitors		**Test Items:**
TCM	traditional Chinese meds	TG	triglyceride
ST	Statins	LDL	low density lipoprotein cholesterol
FI	Fibrates	HDL	high density lipoprotein cholesterol
	Laboratory tests:	ALT	alanine transaminase
MFT	metabolic function test	TB	total bilirubin
LFT	liver function test	CR	serum creatinine
RFT	renal function test	ACR	urine albumin/creatinine ratio

We first mined constraints for the general diabetes pathway (I). Its goal is controlling glucose levels (A1c < 7.0 %) while avoiding hypoglycemia (FPG < 3.9 mmol/L). The activities of interest are three classes of most widely used oral hypoglycemic drugs, as well as traditional Chinese antidiabetic medicines which are also used in China hospitals. The observation window and evaluation window were set to w_O = 1 year and w_E = 3 months, and the thresholds in Algorithm 1 were set to $\theta_V = 0.6$, $\theta_S = 0.75$, $\theta_R = 0.85$ and $\theta_P = 0.05$. The attributes used to evaluate outcomes were removed from the feature set to avoid the obvious correlation. Table 3 shows the number of instances for each activity, the mined constraint with temporal (on) and data (if) conditions, as well as its support and relative risk. All the constraints are statistically significant (p-value < 0.05). The CMMN representation of the first constraint in Table 3 is shown in Figure 3, which means that "use biguanides only after checking metabolic function, renal function and liver function, and only if hypoglycemia and ketoacidosis did not occur before, as well as CR ≤ 2.0 mg/dL, ACR ≤ 400 μg/mg and ALT ≤ 50 IU/L".

Table 3– Constraints mined for (I) (θ_V=0.6, θ_S=0.75, θ_R=0.85)

Act.	#Ins.	Constraint	Sup	RR
BG	4364	**on** *MFT*∧*RFT*∧*LFT* **if** ¬*HG*∧¬*KA*∧*CR*≤2∧*ACR*≤400∧*ALT*≤50	0.76	1.21
SU	2338	**on** *MFT* ∧*RFT*∧*LFT* **if** ¬*HG*∧¬*KA*∧*CR*≤3∧*ACR*≤400∧*ALT*≤70∧*TB*≤30	0.92	1.39
αGI	2825	**on** *MFT*∧*RFT*∧*LFT* **if** ¬*HG*∧¬*KA*∧*CR*≤3∧*ACR*≤500∧*ALT*≤50	0.93	1.57
TCM	201	**on** *MFT*∧*LFT* **if** ¬*HG*∧¬*KA*∧*ALT*≤50	0.94	1.63

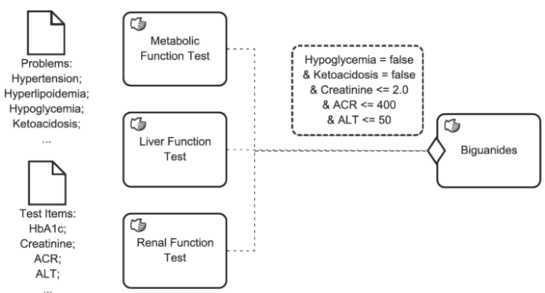

Figure 3 – Graphical representation of the constraint on BG

The discovered constraints are reasonable and meaningful, which indicate that all these medicines cannot be given to hypoglycemia or ketoacidosis patients, which is consistent with the clinical guideline [15]. Moreover, it is commonly accepted that severe hepatopathy and nephropathy are contraindications to the use of most oral antidiabetic drugs. Our study not only revealed that renal function and liver function should be checked prior to oral hypoglycemic medications, but also found the reference thresholds of the relevant test indicators for each pharmacy class, which are not always explicitly given in guidelines. For example, a very high CR and ACR usually denotes significant kidney diseases, and an obvious rise of ALT and TB normaly indicates severe liver diseases. The discovered constraints restrict that the medicines should not be used under these conditions.

We also extracted constraints for the care pathway (II) for diabetes with CVD. It has two stages: Stage 1 is similar with the pathway (I) for controlling glucose; and Stage 2 is designed to control lipid levels (TG < 1.7 mmol/L, LDL < 2.6 mmol/L and HDL > 1.0 mmol/L), which are critical indicators for CVD patients. The activities of interest in Stage 2 are two classes of medications to lower cholesterol: ST and FI. We used the dataset of the cohort of diabetes with CVD, and the parameters were the same with those in the above experiment. The discovered constraints are shown in Table 4. There is no constraint discovered for TCM and FI due to too few instances involved. Notice that the constraints in the pathway (II) are stricter than those in (I). That is because the disease condition of (II) is more severe and complex, and the interventions should be given more carefully.

Table 4– Constraints mined for (II) (θ_V=0.6,θ_S=0.75,θ_R=0.85)

Act.	#Ins.	Constraint (on *MFT*∧*RFT*∧*LFT*)	Sup	RR
BG	2326	**if** ¬*HG*∧¬*KA*∧*CR*≤2∧*ACR*≤70∧*ALT*≤60∧*TB*≤40	0.75	1.36
SU	1276	**if** ¬*HG*∧¬*KA*∧*CR*≤3∧*ACR*≤100∧*ALT*≤70∧*TB*≤30	0.91	1.41
αGI	1642	**if** ¬*HG*∧¬*KA*∧*CR*≤3∧*ACR*≤300∧*ALT*≤40∧*TB*≤30	0.83	1.42
ST	1624	**if** *CR*≤2∧*ACR*≤300∧*ALT*≤60∧*TB*≤30	0.75	1.56

The effect of varying the thresholds in Algorithm 1 was shown in Table 5. Compared with the constraints shown in Table 3, simpler constraints were extracted when using the higher thresholds, while more complex constraints can be discovered when using the lower thresholds. Therefore, clinicians can adjust the thresholds to obtain a desired constraint set, depending on how strict the care pathway is expected to be.

Table 5 – Constraints mined for (I) using different thresholds.

Thres.	Act.	Constraint	Sup	RR
θ_I=0.9	*BG*	**on** *MFT*∧*LFT* **if** ¬*HG*∧¬*KA*∧*ALT*≤50	0.93	1.40
θ_S=0.9	*SU*	**on** *MFT*∧*LFT* **if** ¬*HG*∧¬*KA*∧*ALT*≤70	0.97	1.89
θ_R=1.0	*αGI*	**on** *MFT*∧*LFT* **if** ¬*HG*∧¬*KA*∧*ALT*≤50	0.96	1.29
θ_I=0.5 θ_S=0.5 θ_R=0.7	*BG*	**on** *MFT*∧*RFT*∧*LFT* (the same below) **if** ¬*HG*∧¬*KA*∧*CR*≤3∧*ACR*≤400∧*ALT*≤60∧*TB*≤40	0.91	1.34
	SU	**if** ¬*HG*∧¬*KA*∧*CR*≤3∧*ACR*≤400∧*ALT*≤70∧*TB*≤30	0.92	1.39
	αGI	**if** ¬*HG*∧¬*KA*∧*CR*≤3∧*ACR*≤90∧*ALT*≤40∧*TB*≤30	0.78	1.30

We also compared our algorithm with the existing association rule mining algorithm on mining constraints for the pathway (I). For each activity, we applied the CBA-RG algorithm [12] to extract the rules, and selected the rule with the most items and the highest *Conf* as the constraint. We tried different thresholds for the CBA-RG algorithm, and show the results of *minsup* = 0.75 and *minconf* = 0.7 in Table 6, which are the most reasonable on the whole. Notice that some discovered conditions are less meaningful (e.g., CR ≤ 4 is too loose for restricting BG, while ACR ≤ 30 is over strict for using *αGI*), which is because the consequence of violating a constraint are not considered in the CBA-RG algorithm.

Table 6 – Constraints mined for (I) using Sup and Conf

Act.	Constraint (on *MFT*∧*LFT*∧*RFT*)	Sup	Conf
BG	**if** ¬*HG*∧¬*KA*∧*CR*≤4∧*ACR*≤60∧*ALT*≤40∧*TB*≤40	0.78	0.70
SU	**if** ¬*HG*∧¬*KA*∧*CR*≤2∧*ACR*≤300∧*ALT*≤60∧*TB*≤30	0.77	0.71
αGI	**if** ¬*HG*∧¬*KA*∧*CR*≤4∧*ACR*≤30∧*ALT*≤60∧*TB*≤90	0.76	0.74

The proposed approach was implemented using Java, and the execution of each experiment above was completed in several minutes on a laptop computer. The approach was integrated into IBM Care Pathway Workbench [16], which is a web-based platform to build care pathways. Each discovered constraint can be translated into an entry criterion in a CMMN-based care pathway model [9], and clinicians can further edit and refine the constraints in the workbench. Figure 4 shows a screenshot of the workbench, demonstrating the structured representation of the above constraint shown in Figure 3. The final care pathway models can then be loaded to a care management system to provide evidence-based decision support during individual patient care.

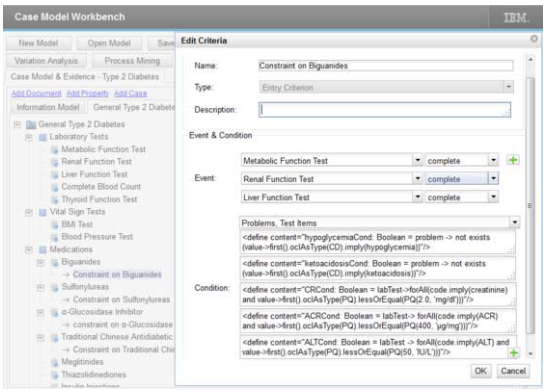

Figure 4 – The constraint in Care Pathway Workbench

Conclusion

Care pathway mining [4,5], which is aimed at discovering the frequent and best practices that impact patients in their care journeys, can provide meaningful insights into care pathway modeling and execution. Though the temporal and data preconditions of clinical activities forms the most critical part of a care pathway, it is still a challenging problem to mine the constraints that can represent the best practices for a specific group of patients. In this paper, we proposed a care pathway mining method to extract temporal and data constraints that are correlated with positive outcomes from EMR. We performed a real-world case study using our method on different cohorts of diabetes patients, and the results showed that our method can discover reasonable constraints for care pathways, which has the potential to provide meaningful decision support during care pathway execution.

One limitation of our method is the scalability of the constraint mining algorithm. Though the experiments showed that the algorithm worked well for care pathways with dozens of features and for relatively high thresholds, if it was applied to much more features and very low thresholds, its running time and space requirement might dramatically increase. In future work, a scalable algorihm with parallel computing could be developed to improve the runtime performance. Another limitation is that the activities, attributes, possible operators, and thresholds have to be manually defined before constraint mining. Potential improvements for this problem include to automatically identify activities and attributes of interest from candidate features in EMR by feature selection, and to learn possible operators and thresholds from user-defined sample constraints. Besides, our current method cannot extract the exit criteria of activities (e.g., stop using fibrates after initiating statins), which are also common and important in pathways. In future work, we could modify the mining algorithm to support the discovery of the constraints for terminating activities that are prone to cause negative outcomes in specific conditions.

Acquiring Plausible Predications from MEDLINE by Clustering MeSH Annotations

Jose Antonio Miñarro-Giménez, Markus Kreuzthaler, Johannes Bernhardt-Melischnig, Catalina Martínez-Costa, and Stefan Schulz

Institute of Medical Informatics, Statistics, and Documentation, Medical University of Graz, Austria

Abstract

The massive accumulation of biomedical knowledge is reflected by the growth of the literature database MEDLINE with over 23 million bibliographic records. All records are manually indexed by MeSH descriptors, many of them refined by MeSH subheadings. We use subheading information to cluster types of MeSH descriptor co-occurrences in MEDLINE by processing co-occurrence information provided by the UMLS. The goal is to infer plausible predicates to each resulting cluster. In an initial experiment this was done by grouping disease-pharmacologic substance co-occurrences into six clusters. Then, a domain expert manually performed the assignment of meaningful predicates to the clusters. The mean accuracy of the best ten generated biomedical facts of each cluster was 85%. This result supports the evidence of the potential of MeSH subheadings for extracting plausible medical predications from MEDLINE.

Knowledge Acquisition; MEDLINE; Biomedical Terminologies.

Introduction

The availability of massive datasets in the biomedical domain presents challenges and opportunities for data management and analysis. One of the most established sources is the literature database MEDLINE[1] with over 23 million bibliographic records. One of its most valuable assets is metadata annotations performed by domain experts at the U.S. National Library of Medicine, using the MeSH[2] indexing vocabulary.

Such annotations consist of unordered lists of so-called headings, i.e., controlled terms from the MeSH vocabulary, most of which are further qualified by subheadings (Table 1).

Table 1- MeSH annotations of a sample paper (ID= 1341068)

MeSH Heading with corresponding concept IDs (UMLS CUI)	MeSH Subheading with abbreviations
Gastritis (C0017152)	Etiology (ET)
Gastritis (C0017152)	Physiopathology (PP)
Gastrointestinal Diseases (C0017178)	Etiology (ET)
Gastrointestinal Diseases (C0017178)	Physiopathology (PP)
Helicobacter Infections (C0079487)	Etiology (ET)
Helicobacter pylori (C0079488)	Physiology (PH)

The subheading information is not relational; subheadings only qualify the subject of what could be a complete statement such as, "Helicobacter pylori causes gastritis."

These annotations are available via the UMLS [1] Metathesaurus (UMLS Meta), a resource that connects over 9 million terms for some 2.8 million concepts from more than 130 biomedical terminology systems[3]. It provides a file named MRCOC5[4], which contains MeSH annotation co-occurrences. This data source has repeatedly been used to extract concept associations [2-4], such as between genes and diseases [5], as a support for text mining [6], for word sense disambiguation [7], and query expansion [8].

The large amount of data to be processed requires efficient and scalable methods related to big data analysis [9]. Such methods entail a distributed framework of multithread, massively parallelized computing tasks.

Table 2- Possible predicates between concepts ordered by selected semantic types (columns: subjects; rows: objects)

	Disease/ Syndrome	**Finding**	**Substance**	**Organism**
Disease/ Syndrome	complicates causes co-occurs with	occurs in diagnoses	treats prevents causes occurs in	affected by causes
Finding	produces diagnosed by	complicates causes co-occurs with	treats prevents causes	affects caused by
Substance	caused by treated by prevented by diagnosed by	treated by caused by prevented by	interacts	is affected by produces
Organism	caused by affected by	caused by affects	affects produced by	interacts with

Here we describe the first experiments to investigate the potential of MeSH annotation co-occurrence data from MEDLINE, in concert with machine learning methods and additional terminological resources. This is a novel approach compared to existing methodologies that use similar resources. The main goal is to extract concept-concept predications based on statistical associations regarding the distribution of 83 subheading types used in MeSH annotations. We understand by predications subject-predicate-object triplets, which convey

[1] http://www.nlm.nih.gov/pubs/factsheets/medline.html
[2] http://www.nlm.nih.gov/mesh/
[3] http://www.nlm.nih.gov/research/umls/knowledge_sources/metathesaurus/release/statistics.html
[4] http://mbr.nlm.nih.gov/MRCOC/MRCOC_Doc_2013.pdf

information that is not ontological in the strict sense [10,11] of formal, logic-based ontology, but stands for a strong or typical association between the subject and the object concept in terms of the predicate. For example, the triplet

<gastritis; has-location; gastric mucosa>

is ontological, as it can be interpreted that all instances of gastritis are located in some gastric mucosa, whereas

<gastritis; caused-by; helicobacter pylori>

cannot be translated in logics. The interpretation is less clear; it might be paraphrased as: "It is sufficiently frequent that gastritis is caused by helicobacter pylori for this to be considered in a clinical decision-making process".

We focus our experiments on the MeSH headings associated with the semantic types *Disease/Syndrome* and *Pharmacologic Substance* as defined in UMLS Semantic Network (UMLS SN). Table 2 lists possible predicates between semantic types as defined in UMLS SN. They represent probable predicates that can relate concepts from UMLS Meta that belong to such semantic types. Furthermore, we limit our dataset to MEDLINE records published in the past five years to simplify the experiments.

Materials and Methods

MRCOC provides pairs of concepts that co-occur in the same entry of an information source. It summarizes the MeSH descriptors that occur together in MEDLINE citations from the MEDLINE/PubMed baseline, a snapshot created at the beginning of each new MeSH indexing year. In this project we have used the version of MRCOC from the UMLS Meta 2014 AA release. Besides the main headings, MRCOC includes a "fingerprint" of MeSH subheadings, such as "DT" (Drug Therapy) or "PC" (Prevention & Control). They characterize the context in which the first concept occurs in the related MEDLINE records. For example, if an article is about the prevention of stroke, the concept "Stroke" in the MEDLINE record is refined by the subheading "PC".

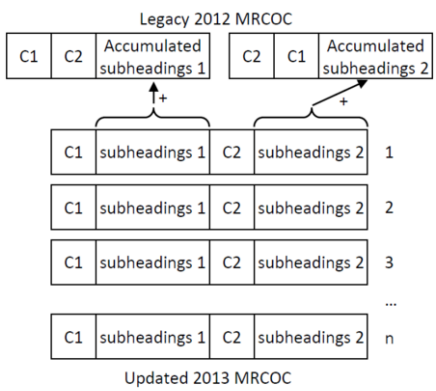

Figure 1 - It shows the content of the legacy and updated versions of the MRCOC file regarding the co-occurrences of C1 and C2 concepts and their corresponding MeSH subheadings.

Since 2013, an updated version of the MRCOC file (size 131GB)[5] is provided. Figure 1 shows how the content of the legacy and the updated version of MRCOC have changed. In the updated version, each line contains a pair of two concepts that co-occur in MEDLINE with their corresponding MeSH subheadings concepts. On the other hand, the legacy version had accumulated the MeSH subheadings of every co-occurrence in two lines, one with the pair of co-occurring concepts and the accumulated subheadings related to the first concept, and another with the co-occurring concepts but with the accumulated subheadings of the second concept. Consequently, the accumulation of MeSH subheadings now has to be computed out of the updated MRCOC file. In MRCOC, the MeSH descriptors are represented as UMLS concepts, identified by concept identifiers (CUIs), and the subheading information as two-letter abbreviations (see Table 1). The UMLS semantic types and relations (used as a source of candidate predicates like in Table 2) were obtained from the files MRSTY and SRSTRE1.

The methodology to extract plausible predications from MEDLINE records consists of the following sequential steps: (1) aggregate the co-occurring concept pairs and their subheading information; (2) obtain the corresponding log-likelihood rates (LLRs); (3) cluster the co-occurring concept pairs based on the vector of accumulated MeSH subheading values; and (4) manually associate meaningful predicates to the resulting clusters.

Aggregate co-occurring concept pairs

Due to the huge volume of data in our project we applied the MapReduce [12] programming paradigm and the Amazon cloud services (Amazon Elastic MapReduce[6], Amazon S3[7]) together with Apache Hadoop [13] for generating the aggregated version of MRCOC, as depicted by Figure 2. MapReduce has two procedures: *Map*(), which filters and sorts the elements to be processed; and *Reduce*(), which takes the resulting elements from *Map*() and performs operations on the accumulated values to the unique key. Input and output data are represented as of key/value pairs, thus facilitating data access and distribution across several computers. Hadoop is a software framework that supports the distributed processing of large data sets across clusters of computers. As a result, jobs can be easily scaled up and parallelized. We therefore implemented four JobFlowSteps within a JobFlow executed on Amazon Elastic MapReduce. The first job filtered (past five years, ZY-Yes) the detailed_CoCoccurs_2014.txt.gz file (split and uploaded to Amazon S3) and obtained the aggregated values for co-occurring concept pairs.

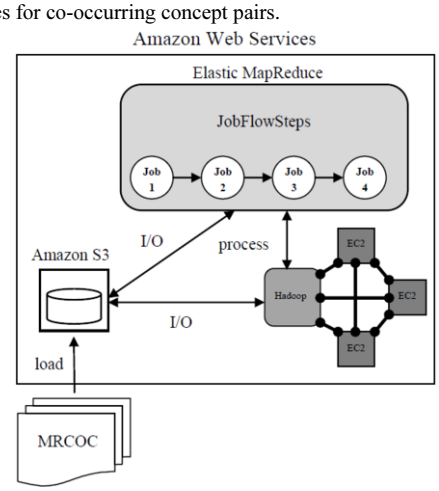

Figure 2 - System architecture in Amazon cloud services of the processing of MRCOC file and the calculation of the corresponding likelihood.

[5] http://mbr.nlm.nih.gov/MRCOC.shtml

[6] http://aws.amazon.com/elasticmapreduce/?nc2=h_ls

[7] http://aws.amazon.com/s3/?nc2=h_ls

Obtaining LLRs

The log-likelihood rates (LLRs) are calculated to filter co-occurring concepts that are not significant or without sufficient scientific impact. The LLRs were determined as part of the MapReduce JobFlow exploiting the Apache Mahout[8] implementation along with the aggregation of MRCOC. Thus, the *Map()* procedure populates the intermediate key/value pairs by using the first concept (CUI1) combined with the second concept (CUI2) as the key, the MeSH subheading abbreviations from CUI1 as the value, and, inversely, CUI2 combined with CUI1 as the key and the MeSH subheading abbreviations from CUI2 as the value. The reduce phase generates the accumulated MeSH subheading vector per key "CUI1CUI2" along with the number of times CUI1 and CUI2 co-occur (#CUI1CUI2). The second job takes the output from the first job and computes the absolute number of occurrences for CUI1 (#CUI1) and CUI2 (#CUI2).

The third job performs a reduce-side join on CUI1, adding the absolute number of occurrences for CUI1 to the output from the first step, with respect to "CUI1CUI2". The last job once again applies a reduce-side join but this time on CUI2, adding the number of absolute occurrences for CUI2 to the co-occurrence under inspection. Now in this final JobFlowStep missing parts for calculating the LLR (see Table 3) are resolved (#notCUI1notCUI2 #CUI1notCUI2 #notCUI1CUI2), and finally the LLR is added to the accumulated subheading information.

Table 3. It shows a summary of the relations between the different counts calculated from the concept co-occurrences.

Co-occurrences	CUI1	not occur CUI1
CUI2	#CUI1CUI2	#notCUI1CUI2
not occur CUI2	#CUI1notCUI2	#notCUI1notCUI2

Formula (1) shows how the log-likelihood ratio (LLR) [14] is computed:

$$LLR = 2 \times \left(H(matrix) - H(mRows) - H(mCols) \right) \quad (1)$$

The function H is the Shannon entropy [15]. *H(matrix)* corresponds to the entropy of #CUI1CUI2, #notCUI1notCUI2, #CUI1notCUI2, and #notCUI1CUI2. *H(mRows)* is the sum of entropies of the pairs (#CUI1CUI2, #notCUI1CUI2) and (#CUI1notCUI2, #notCUI1notCUI2). *H(mCols)* is the sum of entropies of the pairs (#CUI1CUI2, #CUI1notCUI2) and (#notCUI1CUI2, #notCUI1notCUI2). Applying a threshold of 10.83 (chi-squared test, f=1, p<0.001) to the calculated LLR in the last job, we obtain the list of relevant co-occurrences that are used for the clustering approach.

Co-occurrence clustering

In this phase, the resulting list of co-occurrences is grouped based on the accumulated list of MeSH subheadings. The clustering was performed using WEKA [16], which provides a set of machine learning algorithms mainly for data mining tasks. We chose the simple k-means clustering algorithm. In order to decide the types of predicates to assign to the co-occurring concept pairs we first identify the UMLS semantic types of each concept. In this experiment, we have focused on the predications that relate concepts from the semantic types *Disease/Syndrome* (T047) and *Pharmacologic Substance* (T121). According to UMLS SN, concepts under these semantic types can be related via the predicates (SN relations) *diagnoses, affects, treats, complicates, prevents,* and *causes* (Figure 3).

[8] http://mahout.apache.org/

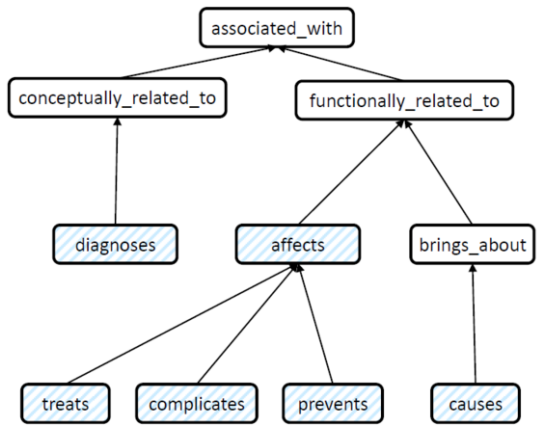

Figure 3 - Excerpt of the UMLS Semantic Network related to the predicates (UMLS SN relations): diagnoses, affects, treats, complicates, prevents, and causes.

We used the number of suggested predicates as the parameter of the number of clusters to be produced by the k-means algorithm. The preparation of the co-occurring concept pairs involves the division of the list into two, the first list containing the co-occurrences *Disease/Syndrome* concepts with *Pharmacologic Substance* concepts, whilst the second list contains the co-occurrences in the inverse order. The reason is that in the original record, subheadings are only assigned to the first (subject) concept. For example, in C_1;C_2;DT, the subheading DT ("drug therapy") refers to C_1, in C_2;C_1;TU, the subheading "therapeutic use" (TU) belongs to C_2. Besides, to normalize the frequency of MeSH subheadings for each co-occurrence we divided them by the total times the pair of concepts co-occurs. Consequently, the normalized values are in the range 0-1.

Cluster association

This final phase connects resulting clusters to some of the suggested predicates. The matching of predicates to cluster and the evaluation of the plausibility of the resulting predications is a manual task to be performed by domain experts. To facilitate the association, we selected the ten best co-occurrences of each cluster, i.e., the ten nearest co-occurrences to each cluster centroid based on their Euclidean distance from the normalized MeSH subheading vector to the centroids subheading vector. The experts evaluated the plausibility of each collected co-occurrence with the matched predicate of the cluster to estimate the accuracy of the inference. The distance of the co-occurrences to their corresponding cluster centroid and the accuracy of the associated predicate in the cluster indicate the consistency of the inferred biomedical fact.

Results

The main result of the project is the definition and implementation of the methodology to extract meaningful Subject-Predicate-Object triplets through the processing and clustering of statistically associated concepts from MEDLINE records.

The method was applied only to the predications between diseases and substances, limited also to the years 2009 – 2013, where the two concepts are flagged major topics (Flag ZY). These co-occurrences were processed and filtered using the system described in Figure 2. As a result, we obtained a list of 17,908 co-occurrences such as "Addison's Disease" and "Cortisol", or "Osteoporosis" and "Calcium".

The UMLS Semantic Network identifies six different predicates (SN relations) between the semantic types *Disease/Syndrome* and *Pharmacologic Substance*. Therefore, the clustering process grouped the list of co-occurrences into six different clusters.

The clustering is based on the subheadings vector of each concept pair. Consequently, some subheadings are more predominant in one cluster and other subheadings in other clusters. Table 4 shows the number of different co-occurrences in each cluster.

Table 4 - Total number of co-occurrences in each resulting cluster.

Cluster	Disease/Syndrome vs. Pharmacol. Substance
0: Diagnosis and Etiology	2,422
1: Chemically Induced	2,015
2: Prevention and Control	1,741
3: Drug Therapy	7,668
4: Complications and Therapy	2,543
5: Metabolism and Pathology	1,519

The clustering process creates the clusters that minimize the distance of co-occurrences based on their MeSH subheading vectors and indicates the nearest cluster centroid to each co-occurrence. This means that the co-occurrences are associated to only one cluster. This is a limited approach since many drugs can both be used to prevent and to treat a disease. However, we can calculate the distance between a co-occurrence and each other cluster and obtain the plausibility of also being close to a second or third cluster. Moreover, we can calculate the mean values of two cluster centroids and check whether the joint cluster represents co-occurrences related to both predicates at the same time.

The manual association of a predicate to each cluster by a domain expert produced a list of plausible SPO triplets. To evaluate these triplets, we collected the elements nearest to each cluster centroids and manually analyzed their accuracy. Because this manual evaluation is a time consuming task we limited it to the ten best elements of each cluster. Consequently, the domain experts only evaluated 60 plausible triplets. The manual association and evaluation of the predicates with clusters provided the following results:

- Cluster 0 with the predicate *diagnoses* gave an accuracy of 50% and the mean of the distance values for the ten nearest co-occurrences is 0.3537.
- Cluster 1 and the predicate *causes* were manually associated. The resulting accuracy of the association is 90% and the mean of the distance values is 0.2136 for the top ten co-occurrences in the cluster.
- Cluster 2 was linked to the *prevents* predicate. It has an accuracy of 100% for the ten nearest co-occurrences in cluster 2. The mean value of the distances of the top ten co-occurrences is 0.2590.
- Cluster 3 with the *treats* predicate also has an accuracy of 100%. The ten nearest co-occurrences were manually examined and associated to the *treats* predicate. The mean of the distance values of the best co-occurrences in the cluster is 0.1621.
- Cluster 4 was related to the *affects* predicate. The inspected co-occurrences were not clearly related to a more specialized relationship and *affects* was general enough to cover them. Therefore, we obtained an accuracy of 100% but a mean distance value of 0.3194.
- Cluster 5 was linked to the *causes* predicate. The calculated accuracy is 70% and the mean of the distance values of the top ten co-occurrences is 0.2440.

Discussion

The association of predicates to co-occurrences presents some difficulties. Many of the concepts that co-occur represent general terms and, therefore, the acquired facts represent coarse-grained knowledge. For example, the co-occurrence in cluster 0 “Drug Allergy” and “Anticoagulants” are related to the predicate *causes*, but in fact, any drug has the potential to cause drug allergy. Furthermore, MeSH’s granularity is limited both regarding disorders and substances. Another problem is the ambiguity of co-occurrences from which more than one predicate can be inferred. For example, the co-occurrence in cluster 0 of the disease concept *Coagulation Defect* and the pharmacologic substance concept *Blood Coagulation Factor* could be linked either to *treats* if there is a substitution of the coagulation factor or to *diagnose*, because the lack of certain coagulation factor proteins in blood is used to diagnose corresponding coagulation defects. This ambiguity is reflected in the fact that the clusters have a higher distance value of their members to their centroids. We also found that certain associations do not correspond to any of the assigned predicates. For example, cluster 4 contains the co-occurrence of *Asthma* with *Insulin*, from the experimental treatment of patients with asthma using inhaled insulin [17]. This has not yet been universally accepted as a therapy, and its translation into a generalizable predicate would be problematic.

An important observation was that the most predominant MeSH annotations mostly agreed with the assigned predicate and, hence, they could be used to support the manual curation done by the physicians. For example, in cluster 3 the most predominant subheading was *Drug Therapy*, which corresponded quite well to the assigned predicate *treats*.

In general, we have observed a good correlation between the accuracy of the predicates and the distance values of co-occurrences, i.e., the lower the accuracy the higher the distance values to the centroid of the cluster. For example, the *treats* predicate, which exhibited an accuracy of 100% based on the nearest ten members of cluster 3, is related to more specialized concepts such as *Cerebrovascular accident* and *Alteplase*, and, thus, the distance to the centroid of cluster 3 is lower than in the other clusters. On the other hand, the cluster 0 has an accuracy value of 50% for the predicate *diagnoses* and the mean value of the distance of the top ten co-occurrences is 0.3537.

Conclusions and Further Work

MapReduce and cloud services have demonstrated the potential of big data analysis, with the processing of more than 11 million co-occurences in minutes, a process that would take hours in a centralized single-thread architecture. It will therefore be no problem to extend the analysis to the complete dataset, including all annotations, even inferred ones, and possibly extending it to additional features extracted from titles and abstracts.

Our methodology demonstrated its ability to extract biomedical facts from MEDLINE records. However, there was a focus on very general statements due to the predominance of coarse-grained MeSH headings. Consequently, the acquired knowledge may be trivial for experts but could be of interest to lay persons in medical domain. We plan to improve the specificity of the generated facts by including additional knowledge from

bibliographic records using Natural Language Processing methods that recognize terms in abstracts and map them to SNOMED CT and other more fine-grained terminologies. In this case, subheading information can still be used if one of the two concepts stems from the MEDLINE metadata.

More evaluation would be necessary to rate the plausibility or correctness of the extracted facts, in order to assess the suitability of our methods for different use cases and to detect weaknesses that could trigger methodological modifications or enhancements.

Considering that every pair of co-occurring concepts provides two different subheading vectors, because the subheadings associated with either concept are different, a more subtle distinction between the extracted facts would be possible. Other information could be obtained from the analysis of temporal trends, publication types, or the extraction of negations and other epistemic information (e.g., "does not influence", "no evidence of") from titles and abstracts.

Effects of Plasma Transfusion on Perioperative Bleeding Complications: A Machine Learning Approach

Che Ngufor, Dennis Murphree, Sudhindra Upadhyaya, Nageswar Madde, Daryl Kor, and Jyotishman Pathak

Department of Health Sciences Research, Mayo Clinic, Rochester, MN, USA

Abstract

Perioperative bleeding (PB) is associated with increased patient morbidity and mortality, and results in substantial health care resource utilization. To assess bleeding risk, a routine practice in most centers is to use indicators such as elevated values of the International Normalized Ratio (INR). For patients with elevated INR, the routine therapy option is plasma transfusion. However, the predictive accuracy of INR and the value of plasma transfusion still remains unclear. Accurate methods are therefore needed to identify early the patients with increased risk of bleeding. The goal of this work is to apply advanced machine learning methods to study the relationship between preoperative plasma transfusion (PPT) and PB in patients with elevated INR undergoing noncardiac surgery. The problem is cast under the framework of causal inference where robust meaningful measures to quantify the effect of PPT on PB are estimated. Results show that both machine learning and standard statistical methods generally agree that PPT negatively impacts PB and other important patient outcomes. However, machine learning methods show significant results, and machine learning boosting methods are found to make less errors in predicting PB.

Blood Transfusion; Bleeding; Treatment Effect; Classification; Machine Learning; Electronic Health Records.

Introduction

Bleeding in patients undergoing surgical procedures is a serious and relatively common complication that has been found to be associated with increased health care resource utilization, morbidity, and mortality. Although the origin of bleeding during surgery may be due to multiple factors, surgical factors and pre-existing abnormalities of the hemostatic system represent the principal causes of significant perioperative hemorrhage.[1] Excessive bleeding, reoperation for bleeding, and the need for transfusion of blood products are common both during and shortly after some types of surgical procedures. In spinal surgery, for example, between 30% and 60% of patients require allogeneic blood transfusion.[2] Reoperation for bleeding and administration of blood products are associated with postoperative complications including transfusion-associated lung injury (TRALI).[3] Despite the known negative effect on immunomodulation and increased risk of postoperative complications and mortality, various studies have shown large variability in the use of blood products among different centers, and even among individual anesthesiologists within the same center.[4, 5] For example, the number of red blood cell (RBC) units transfused annually in the US alone is about 14 million. Cost-wise, at an estimated cost of $761 per unit of RBC, this amounts to $10.5 billion in health care expenditures.[4] Therefore, strategies to minimize the need for allogeneic blood transfusions and perioperative bleeding complications are of great interest.

A key step to reduce the need for transfusion of allogeneic blood product is to assess patients who might bleed pre-transfusion. This might involve the identification of patients with impaired hemostasis and increase bleeding risk. However, our ability to predict these adverse events, typically estimated with a combination of patient- and procedure-related factors,[6] is incomplete. For patient-related factors, substantial emphasis is often placed on preoperative screening tests, such as the international normalized ratio (INR): a major driver for decisions about preoperative plasma transfusion.[7]

Fresh frozen plasma infusions are commonly used to improve coagulation or clotting and are the main therapy option for patients with elevated INR. A large proportion of the plasma components are transfused in the perioperative environment,[7,8] however, they are frequently administered prophylactically in the absence of significant active bleeding. This practice persists despite a growing body of literature questioning its efficacy.[8, 9] Moreover, plasma transfusions are increasingly recognized as important contributors to transfusion-related complications, including allergic reactions, TRALI, and transfusion-associated circulatory overload (TACO).[3, 10]

The goal of this study is to apply advanced machine learning methods to study the effect of preoperative plasma transfusion (PPT) on perioperative beeding (PB). The study is built on recent work described in Jia et al.[11] Based on propensity score matching estimated via standard statistical methods, Jia et al showed that PPT does not improve PB complications for patients with high INR scores. Generalized linear models such as logistic regression or linear regression are frequently used to estimate the propensity scores and models for the outcome. However, parametric models require assumptions regarding the functional form, distribution of the variables, and variable selection. If any of these assumptions are incorrect, the derived causal relationship may be misleading. Contrary to statistical approaches, machine learning methods can estimate complex relationships between the outcome and observed variables producing consistent estimates of the propensity scores and hence more reliable causal relationships.

Unlike the standard statistical analyses in Jia et al,[11] this work investigates the causal relationship between PPT and PB

by making use of modern machine learning algorithms to obtain consistent and reliable relationships. The relationship between PPT and other secondary outcomes such as intraoperative RBC transfusion (Intra-RBC), blood loss, Re-operation for bleeding (Re-OP), need for ICU care, ICU length of stay (ICU-LOS), hospital length of stay (LOS), and mortality are also studied. Different from the approach in Jia et al,[11] the analyses in this study are geared towards designing advanced techniques to identify early patients who might bleed during or after a surgical operation. In particular, in the interesting case where potential non-bleeding patients are identified, a more conservative practice can be adopted in which PPT is administered not only based on elevated INR, but on accurate predicted individual need for PPT. The presented work is an initial step towards achieving this larger goal. In this light, the problem is studied under the framework of causal inference by estimating the causal effect of the treatment (in this case PPT). Thus, estimates of the average treatment effect for those who received PPT can be used to quantify the independent association of PPT with PB. The computed average treatment effect can be regarded as a form of attributable risk, comparing the overall risk of bleeding to the risk of bleeding for those who received PPT.[12] Large values can be interpreted as increased risk of bleeding.

Although machine learning methods have been applied extensively in healthcare, to the best knowledge of the authors, their use for estimating the causal treatment effect of blood product transfusion has not been investigated. Thus, besides being one of the first works on the application of machine learning for blood transfusion, this paper strives to study PPT on several important patient outcomes in the context of causal inference by computing robust estimates of the average effect of PPT that can be used to answer questions like "what and how big is the effect of PPT on patient outcomes?"

Data Structure and Parameter of Interest

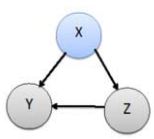

Figure 1: Causal Graph and Confounding

This study is based on an observational comparative effectiveness research analysis using a cohort design described in Jia et al [11] that was approved before initialization and this study followed all guidelines for strengthening and reporting of observational studies.

The structure of the data used in this study has the typical structure of causal inference. The observations for each patient are given by (**X, Y, Z**) where $Z \in \{0,1\}$ is the treatment indicator with **Z**=1 if patient was treated or **Z**=0 if patient was not treated. **X** is a vector of baseline covariates that records information specific to each patient prior to treatment. Y is the outcome variable such as perioperative bleeding, with **Y** = 1 if bleeding or **Y** = 0 if no bleeding. **Y** can also be continuous, such as in LOS.

In observational studies the vector of covariates **X** could be related to both the potential outcome of interest **Y** and the treatment administered **Z**. Since **Z** and **Y** are affected by **X**, **Z** is therefore not independent of **Y**. Since **X** can affect both the probability of treatment and the probability of the outcome it is referred to as confounders. Ignoring the potential confounding effects of patient characteristics may lead to biased estimation of the treatment effect.[13] Thus, it is vital in observational studies to address potential bias due to confounding. Unbiased estimates of the parameters of interest can be obtained after controlling for observed characteristics, for example with propensity scores (PS) estimated via parametric regression methods.[14] However, unbiased estimates can only be obtained if the regression models are correctly specified. To minimize bias due to model misspecification, machine learning methods have been employed recently to find the best-fitting model for the data, thus producing consistent estimates of the propensity scores. These methods have been shown in numerous simulation studies to be able to reduce bias due to model misspecification.[15, 16]

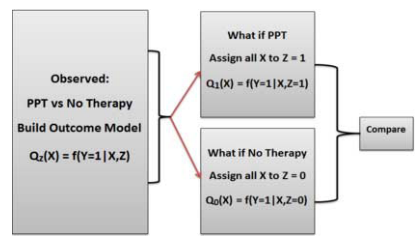

Figure 2: Potential Outcome (What If) Model

To define the parameter of interest, the problem is viewed under the potential outcome framework first introduced by Rubin [17] and the recent population intervention model proposed in Hubbard and Van Der Laan.[18] The potential outcome model defines the effect of the possible levels of treatment **Z** = 1 or **Z** = 0 for each patient and allows for the consideration and estimation of what would have happened if a patient receives a particular treatment, possibly contrary to what the patient actually received. This counterfactual procedure allows for the definition of summary measures that quantify the effect of the treatment. Figure 2 illustrates the potential outcome modeling procedure. The general procedure is to use a model to estimate the outcome of interest had the entire population been treated or not treated and compare the two estimates.

With the goal of reducing bleeding risk and optimization of plasma transfusion, this work is interested in studying for from those who received PPT, what would have happen if they did or did not receive PPT. Thus, measures like the average treatment effect for the treated (ATT) or the average treatment effect for the control (ATC) is of interest. ATC is defined as $\psi = \mathsf{E}_X[\mathsf{E}[Y \mid Z = 0, X] - \mathsf{E}[Y]$, where E_X denotes the expectation with respect to **X** (see [18, 19] for more details). ATC can be regarded as a type of attributable risk, since it compares the overall mean of the outcome to the mean of the population of interest average over strata of **X**.

Estimation Methods

Assuming no other unobserved variables are present, the relationships between the observed variables are shown graphically in Figure 1. From the graphical representation, the

factorized data likelihood can be written as:

$$\Pr(X,Y,Z) = \Pr(X)\overbrace{\Pr(Z \mid X)}^{g}\overbrace{\Pr(Y \mid X,Z)}^{Q_z}$$

Node **Z** in Figure 1 is of great interest in causal inference as the goal is to determine what happens to the outcome when some intervention is done on **Z**. The probability $g(Z \mid X) = \Pr(Z \mid X)$ represents the propensity or the causal disposition of the treatment to produce or create some outcome. $Q_z(X)$ is the outcome model which represents the mean value of the outcome **Y** given **Z** and **X**. With the factorized data likelihood, different approaches can be used to answer the question *"what and how big is the effect of PPT on PB ?"*

For a meaningful measure of treatment effect, two robust estimation methods are considered for estimating the parameter ψ: Double Robust (DR) and Targeted Maximum Likelihood (TMLE) Estimation. More in-depth treatment of these estimators can be found in [18, 19].

Doubly Robust Estimator

The Doubly Robust (DR) estimator for ATC is derived in [18, 19] and given by

$$\psi_{DR} = \frac{1}{n}\sum_{i=1}^{n}\left[\left(\frac{I(Z_i = 0)}{\hat{g}(X_i, Z_i = 0)} - 1\right)Y_i - \left(\frac{I(Z_i = 0)}{\hat{g}(Z_i = 0 \mid X_i)} - 1\right)\hat{Q}_0(X_i)\right]$$

Where I is the indicator function, $\hat{g}(Z = 0 \mid X)$ and $\hat{Q}_0(X)$ are estimates of $g(Z = 0 \mid X)$ and $Q_0(X)$ respectively.

Doubly robustness means that ψ_{DR} is a consistent estimate of the causal treatment effect when either $\hat{g}$ or $\hat{Q}_0$ is a consistent estimate of g and Q_0 respectively.

Targeted Maximum Likelihood Estimator (TMLE)

From the definition of the DR estimator, the occurrence of g in the denominator shows that the estimator may blow up when $\hat{g}$ is not well-bounded. For some patients where estimates of g is close to zero, ψ_{DR} may be unstable. The lack of boundedness in $\hat{g}$ is a violation of one of three identifying assumptions: namely, the positivity or experimental treatment assumption (ETA) that requires $0 < g(Z \mid X) < 1$. See [19] for a more thorough discussion of these assumptions.

To solve this problem, the Targeted Maximum Likelihood Estimator (TMLE) was proposed in [20]. Like DR, TMLE is also double robust and locally efficient. The technical details of this estimator are beyond the scope of this paper and the interested reader is referred to the cited reference for more details.

Machine Learning Methods

Traditionally, the estimation of the functions g or Q_0 is performed using generalized linear models such as logistic regression or ordinary least squares. However, these parametric approaches are prone to model misspecification. An alternative and more attractive approach is to employ machine learning methods. Machine learning aims to infer the true relationship between the outcomes and covariates through a learning procedure. Bias in the estimates resulting from model misspecification can thus be reduced.

This work makes aggressive use of six machine learning methods: Support Vector Machine (SVM), Neural Networks Using Model Averaging (NNET), AdaBoost (Stochastic gradient boosting), randomForest (RF), random k-nearest neighbor (rKNN), and Generalized Boosted Regression Models (GBM). A comprehensive review of these supervised learning techniques can be found in.[21] rKNN is a recent algorithm that builds multiple k-nearest neighbor classifiers or regression models and combines them using a similar strategy as in the RF algorithm.

Experiments

This section describes the experimental setup: the study population, covariate balancing, and variable importance.

Study Population

To be considered for this study, patients must meet the following criteria: age $\geq$ 18 years, noncardiac surgery and an INR ≥ 1.5 in the 30 days preceding surgery. See Jia et al [11] for more details on the selection criteria and data source.

Between January 1, 2008, and December 31, 2011, a total of 155,492 patients aged $\geq$ 18 years underwent noncardiac surgery at the participating institution. Of them, 14,743 had an INR measured within 30 days of the index surgical procedure, with 1,234 having an INR $\geq$ 1.5. This latter group comprised the study population.

Baseline patient demographics include age, weight, gender, and American Society of Anesthesiologists Physical Status I-V classifications (ASA). Disease conditions included myocardial infarction, congestive heart failure, cerebrovascular disease, dementia, chronic pulmonary disease, connective tissue disease, diabetes mellitus, tumor, etc. Preoperative laboratory test results included INR, hemoglobin, creatinine, albumin, and activated partial thromboplastin time. Preoperative medications such as aspirin, clopidogrel, and heparin were also included in the models.

Covariate Balancing and Variable Importance

In causal inference, the models do not have to only fit the data well, but also represent (and hence balance) the features of patients who received PPT and patients who did not. Thus an initial investigation using RF was performed to determine if there are confounding covariates in the study population. See Jia et al [11] for the results from standard univariate and multivariate statistical approach in balancing the data.

First, RF variable importance measure was used to identify features that are statistically associated with PPT (results not shown). The method described in Luz Calle et al [22] was used to estimate p-values. Then a robust Covariate Balancing Propensity Score (CBPS) method [23] was applied to estimate propensity scores by maximizing the average treatment effect (ATE). The estimated propensity scores were then used in a non-parametric matching algorithm described in Ho [24] to pair patients who received PPT to patients who did not. Table

1 shows, under the covariate balancing columns, the RF permutation variable importance p-values based on the Gini impurity measure for the adjusted and unadjusted covariates. Similarly to the results in Jia et al,[11] the RF variable importance identified many between-group differences. However, after performing CBPS, the all non-significant p-values under the *Adjusted* column of Table 1 indicates that the propensity score matching was effective in addressing covariate imbalance.

Second, the same RF permutation variable importance measure was again applied to the CBPS balanced data to identify statistical relevant predictors of perioperative bleeding. The last column of Table 1 shows that Clopidogrel , Peptic Ulcer, Chronic Renal Failure, and Creatinine are significant risk factors for bleeding at the 5% significance level.

Results

This section presents the main results: Estimates of treatment effect of preoperative plasma transfusion on perioperative bleeding and other important patient outcomes. For each estimation method described in section 3, the g and Q_z functions are estimated using the six machine learning methods. For comparison with standard regression methods, g is also estimated with logistic regression (LR) while Q_z is estimated with LR or linear regression depending on whether the outcome is binary or continuous .

For each method, the parameter estimate, standard error, and significance represented by two sided p-value are reported. All computations were performed using a modified version of the R statistical package multiPIM,[25] a causal inference approach to variable importance analysis. The standard 5-fold cross-validation training procedure was followed for all experiments.

Table 1: Random forest variable importance p-values for balanced and unbalanced data and risk factors for bleeding

Overall, all algorithms confirmed that PPT increases the risk of PB and all other considered outcomes. However, machine learning methods turn to generate significant results as illustrated by the small p-values. The significant results at the 5% level are highlighted. Results from machine learning methods show that PPT significantly impacts PB and Intraoperative RBC transfusion by 1-2 %, and need for ICU care by 1-7%. While PPT negative impacts ICU length of stay, hospital length of stay, and mortality (results not shown), the effects are not statistically significant.

The performance measures of the classifiers in predicting PB, assuming the counterfactual that no patient was administered PPT, is shown in Table 3. PCC is the percent of cases correctly classified (accuracy), AUC is the area under the receiver operating characteristic curve, while sens and spec are the sensitivity and specificity, respectively. Standard errors are also shown. The overall performance of the classifiers was very good with boosting methods tending to show a slightly better performance.

The performance of the two estimators (DR and TMLE) appear to be quite comparable, especially for logistic and linear regression. However, as noted earlier, DR may be unstable when the estimated propensity scores are close to zero. No such instability was observed for the analysis in this paper.

Conclusion and Future Work

This work employed advanced machine learning methods to measure the effectiveness of plasma transfusion from observational data. The method applies a causal modeling framework that establishes a causal relationship between administering plasma transfusion and perioperative bleeding based on two robust estimation procedures. The paper provides meaningful interpretation of the estimation results which are more intuitive to understand than estimated coefficients from regression models.

Results from the analysis show that population wise, the action of not administering plasma product has the impact of reducing bleeding and positive effects on other patient important outcomes. These results are not new, as several authors have derived these results. However this paper takes a causal approach based on modern machine learning to quantify in a meaningful way the effect of not transfusing. Given that, on average, no plasma transfusion reduces the risk of bleeding, an interesting problem warranting further investigation is: "Can machine learning methods be used to identify a sub-population for which no plasma transfusion increases the risk of bleeding?" This paper is an initial step to answering this important question.

Abstract

The quantification of fat depots on the surroundings of the heart is an accurate procedure for evaluating health risk factors correlated with several diseases. However, this type of evaluation is not widely employed in clinical practice due to the required human workload. This work proposes a novel technique for the automatic segmentation of cardiac fat pads. The technique is based on applying classification algorithms to the segmentation of cardiac CT images. Furthermore, we extensively evaluate the performance of several algorithms on this task and discuss which provided better predictive models. Experimental results have shown that the mean accuracy for the classification of epicardial and mediastinal fats has been 98.4% with a mean true positive rate of 96.2%. On average, the Dice similarity index, regarding the segmented patients and the ground truth, was equal to 96.8%. Therfore, our technique has achieved the most accurate results for the automatic segmentation of cardiac fats, to date.

Keywords:

Segmentation; Classification; Epicardial fat; Mediastinal fat; Adipose tissue; Computed tomography; Data mining; Cardiac fat.

Introduction

Extensive studies address the importance of the epicardial and mediastinal (due to a nomenclature inconsistency some call it pericardial) fats and their correlation with pathogenic profiles, risk factors and diseases [1,2]. Some work [3] associates both mediastinal and epicardial fats to carotid stiffness; others [4] associate them to atherosclerosis, coronary artery calcification and others health risk factors. Sicari *et al.* [5] have shown as well how mediastinal fat rather than epicardial fat is a cardiometabolic risk marker.

An increasing demand for medical diagnosis support systems has been observed jointly to the computational evolution in the last years. Systems of this kind speed up the tedious and meticulous analysis conducted by physicians or technicians on patients' medical data. In several cases there is a huge amount of data to be analyzed and, therefore, the diagnosis may lack of precision and suffer noticeable inter and intra-observer variation [6].

The automated quantitative analysis of epicardial and mediastinal fats certainly adds a prognostic value to cardiac CT trials with an improvement on its cost-effectiveness. Iacobellis *et al.* [7] have shown that the epicardial fat thickness and coronary artery disease correlate independently to obesity, which supports individual segmentation of these adipose tissues rather than merely and simply estimating its volume based on the patient overall fat.

Latterly, three imaging techniques appear suitable for quantification of these adipose tissues, namely Magnetic Resonance Imaging (MRI), Echocardiography and Computed Tomography (CT). Each has been used in several medical studies [5,8,9]. However, CT provides a more accurate evaluation of fat tissues due to its higher spatial resolution compared to ultrasound and MRI [10]. In addition, CT is also widely used for evaluating coronary calcium score [9].

Literature Review

Semi-automated segmentation methods for epicardial fat have been proposed since 2008. Dey *et al.* [11], for instance, apply a preprocessing step to remove all other structures from the heart by using a region growing strategy. An experienced user is required to scroll through the slices and to place from 5 to 7 control points along the pericardium border if visible. Thus, Catmull-Rom cubic spline functions are automatically generated to obtain a smooth closed pericardial contour. Finally, since the epicardial fat is inside this contour it is simply accounted by thresholding. In [12], a method is proposed for the segmentation of abdominal adipose tissue. The work of Kakadiaris *et al.* [13] has further extended the method to the segmentation of the epicardial fat.

Coppini *et al.* [10] focused on reducing the user intervention. On their method, an expert is still necessary to scroll through the slices between the atrioventricular sulcus and the apex in order to place some control points on the pericardium layer. The amount of required control points is not clearly described. Nevertheless, the amount of slices to be analyzed is apparently less than that of the method proposed by Dey *et al.* [11]. Coppini et al. also present their solution in a 3D space. The overall focus of their work was to describe their method mathematically. Nevertheless, the authors did not address the achieved general accuracy.

Barbosa *et al.* [14] proposed a more automated segmentation method for the epicardial fat. They use the same preprocessing method from Dey *et al.* [11] and further apply a high level step for identification of the pericardium by tracing lines originating from the heart's centroid to the pericardium layer and interpolating them with a spline. Although this approach may be of simple complexity and highly applicable for virtually any proposed method in the field, the reported results are not impressive. Only 4 out of 40 images were correctly segmented in a fully automatic way.

As far as we know, Shahzad *et al.* [15] proposed the first fully automated method for epicardial fat segmentation. Their method uses a multi-atlas based approach to segment the pericardium. The multi-atlas approach is based on registering several atlases (8 in this case) to a target patient and fusing these transformations to obtain the final result. They selected

98 patients for evaluation and reported a Dice similarity index of 89.15% to the ground truth and a low rate of approximately 3% of unsuccessful segmentations. Nevertheless, they did not provide any measurements of the overall processing time.

Ding *et al.* [16] proposed, in 2010, an approach similar to the method of Shahzad *et al.* [15]. They segment the pericardium using an atlas approach, which consists of a minimization of errors after applying transformations to the atlas along with an active contour approach. The mean Dice similarity coefficient was 93% and they claim that their result was achieved in 60 seconds on a simple personal computer. Although their segmentation seems to be the most precise in the literature, the reported computational time is oddly described. That is, 60 seconds is considered too fast for segmenting and transforming an entire patient scan, which consists of roughly 50 images. They also present a work [17] that segmented the aorta instead of the pericardium and compare their time (60 seconds) to the 15 minutes of the former. If these 60 seconds correspond to just the time it takes for the algorithm to minimize the transformations, then this comparison is not feasible. Furthermore, they report that their approach had the atlases' images pre-aligned to a standard orientation and that there is a comparison with just one of these atlases to speed up the process. The remaining pericardium contour follows the pre-aligned pattern, which is a reported limitation. Besides, they did not describe how each one of these atlases is chosen as suitable for each possible case.

Materials and Methods

We define the fat located within the epicardium as epicardial fat, corroborating with the majority of published works [4-8,10]. Furthermore, by following the same "first outer anatomical container" logic, we conclude that mediastinal fat is the best definition for the fat located on the external surface of the heart or fibrous pericardium. In other words, the mediastinal fat is located within the mediastinal space as long as it is not epicardial (i.e., it is not located within the epicardium). Furthermore, we have used CT scans from two manufactures (Siemens and Philips), which configures this work as being multi-manufacturer.

Molteni [18] associates values around -100 Hounsfield Units (HU) to the overall fat of the human body. Coppini *et al.* [10] and Shmilovich et al. [19] defined the cardiac adipose tissue range as starting from -190 to -30, Spearman *et al.* [20] defined it as from -195 up to -45, and Shahzad *et al.* [15] defined it as from -200 to -30. In this work, we consider the largest addressed interval for the cardiac fat, which corresponds to the one considered in the work of Shahzad *et al.*, *i*.e., from -200 to -30 HU.

Overview

We propose an automatic segmentation for the epicardial and mediastinal fats based on two main principles, namely (1) an intersubject registration and (2) a classification step. For the whole segmentation process we have used CT images ranging from -200 to -30 HU on the axial plane. However, we believe that our methodology can be easily adapted to other ranges and also to other modalities.

Image registration can be defined as the process of matching characteristics of images in order to find alignments that minimize the variation between overlapping pixels [22]. Such processes are included in panoramic assemblages, medical images, time series alignments [23,24] and many others. Registration is also alternatively treated as an optimization problem with the goal of finding the spatial mapping that will bring images, parts of them, or even a combination of these parts into minimal variation.

Machine learning algorithms are often divided in two main categories: (1) supervised and (2) unsupervised methods. The algorithm is categorized as supervised when it explicitly evaluates the class attribute of a training set as the predictive label desired to attach to an incoming unlabeled instance. Furthermore, when this assumption is formalized, the class attribute heavily induces the generated predictive model. However, without the formalization, the algorithm is defined as unsupervised and the class induces no heavy influence but of a normal attribute to the predictive model when, of course, it is not disregarded from the training pace. Classification algorithms are always categorized as supervised learning methods while clustering algorithms are often unsupervised.

Registration

In a previous work we extensively described the methodology of our intersubject registration [25]. Summing up, it is composed of (1) creating an atlas of the retrosternal area, (2) using this atlas to recognize the same area of an incoming instance, and (3) using a heuristical method to reinforce the chosen position. The atlas assemblage is done by (1) converting a number of CT slices to the fat range where black represents the background, (2) manually selecting the position of the retrosternal area, (3) thresholding each selected area to 0 or 1 (binary image) and finally, (4) performing an arithmetic mean of the binary images. The final image of Figure 1 is the result of the described process conducted for 10 randomly chosen patients. Thereafter, the proposed registration consists of fusing two approaches: a landmark with an atlas approach. The landmark approach is defined as when two selected points from the subjects to be registered are used as reference (in this case, the center of the retrosternal area) [26]. Finally, the retrosternal area is defined as the region at the back of the sternum and, in this case, it frequently captures parts of the heart if it is relatively close to the thorax as well as few parts of the thorax as shown in Figure 1 by the rectangles in red.

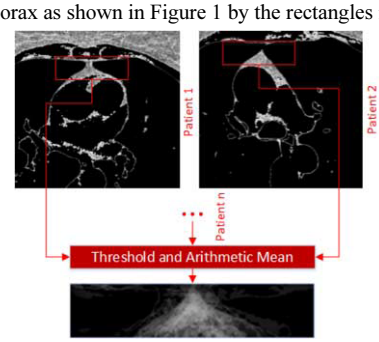

Figure 1 – Atlas of the retrosternal area.
