MEDINFO 2015

Studies in Health Technology and Informatics

This book series was started in 1990 to promote research conducted under the auspices of the EC programmes' Advanced Informatics in Medicine (AIM) and Biomedical and Health Research (BHR) bioengineering branch. A driving aspect of international health informatics is that telecommunication technology, rehabilitative technology, intelligent home technology and many other components are moving together and form one integrated world of information and communication media. The series has been accepted by MEDLINE/PubMed, SciVerse Scopus, EMCare, Book Citation Index – Science and Thomson Reuters' Conference Proceedings Citation Index.

Introductory Remarks from the Scientific Program Chairs

Fernando Martin-Sanchez[a], Kaija Saranto[b]

[a] *Health and Biomedical Informatics Centre, Melbourne Medical School, The University of Melbourne, Australia*
[b] *Department of Health and Social Management, University of Eastern Finland, Kuopio, Finland*

MEDINFO is the premier international Health and Biomedical Informatics event. MEDINFO 2015 is hosted by SBIS (Brazilian Health Informatics Society) on behalf of the International Medical Informatics Association (IMIA) and will take place in the city of São Paulo from the 19th to 23rd August 2015. MEDINFO 2015 continues a 41-year tradition of bringing together world leaders, policy makers, researchers, practitioners, educators, and students to exchange ideas and contribute to the latest developments, innovations, and global trends in this rapidly advancing, multidisciplinary field of Health and Biomedical Informatics. This is the first MEDINFO that has been organized to reflect the new two-yearly cycle approved by IMIA. We were thus very happy when we reached the submission and registration deadlines with numbers very similar to previous MEDINFOs that had been organized in three-yearly cycles.

Under the theme: "*eHealth-enabled Health*", the world leaders in this field will gather in Brazil to share knowledge and analyze how Health and Biomedical Informatics is contributing to address some of the most challenging problems in health care, public health, consumer health and biomedical research. Researchers, clinicians, technologists and managers will attend and share experiences on the use of information methods, systems and technologies to promote patient-centered care, improve patient safety, enhance care outcomes, facilitate translational research, enable precision medicine and improve education and skills in health informatics.

This is an historical event as MEDINFO is hosted in Latin America for the first time. Inclusiveness has been a main goal in MEDINFO 2015 with affordable registration fees for the regional audience and use of Spanish and Portuguese language in tutorials and simultaneous translation in sessions held in the main auditorium. MEDINFO 2015 features a pre-congress offering of an extensive tutorial program by leading experts and a student paper competition that draws the best young talent from all over the world. The main program includes keynote talks, papers, posters, panels, workshops, and scientific demonstrations that span a broad range of topics from emerging methodologies that contribute to the conceptual and scientific foundations of Health and Biomedical Informatics, to successful implementations of innovative application, integration, and evaluation of eHealth systems and solutions.

The conference program features five keynote presentations, 178 paper presentations, 248 poster abstract presentations, 27 panels, 30 workshops and 17 scientific demonstrations.

The contributions and presentations included in the program were carefully selected through a rigorous review process involving almost 400 reviewers for a large number of submissions (793) sent by 2500 authors from 59 countries all over the world. The Scientific Program Committee Co-Chairs are grateful to the four Track Chairs, the members of the Scientific Program Committee and all the reviewers who have contributed to the process, and thank the Editorial Committee, the Local Organizing Committee and the IMIA officers (in particular CEOs and VP Medinfo) for assisting us in putting this program together.

The conference participants come to São Paulo from all continents and 60 different countries. We hope that you will enjoy the published proceedings and the overall program!

Sincerely,

Fernando Martin-Sanchez, PhD, FACHI, FACMI &
Kaija Saranto, PhD, FACMI, FAAN
Co-Chairs, MEDINFO 2015 Scientific Program Committee

Introductory Remarks from the Editorial Committee Chair

Indra Neil Sarkar[a]

[a] *Center for Biomedical Informatics, Warren Alpert Medical School of Brown University, Providence, RI, USA*

Let me join the rest of the organizing committees in welcoming you to MEDINFO 2015 in São Paulo. As the Editorial Committee Chair, I had the distinct honor to review every accepted submission to this year's congress. I personally wish to extend a thanks to the authors for their fine contributions. Together with the meeting participants, MEDINFO 2015 is positioned to be an unprecedented exposition of the finest biomedical informatics innovations with global impact.

Appreciating the international scope of the MEDINFO congresses, it is essential to embrace principles to support scientific inclusivity. Therefore, in contrast to many scientific meetings, the general criteria used for selection into the MEDINFO proceedings is based mostly on scientific merit; language issues are not reason alone for a submission to be not selected. The cost of this inclusivity is that each accepted submission must be carefully reviewed and edited to adjust for language that does not impact the scientific contribution. It is important to note that even submissions from native English speakers may require editing due to variance from the required template, typographical errors, or grammatical issues.

Building on the framework developed by Christoph Lehmann for MEDINFO 2013, Assistant Editors (AEs) were recruited from biomedical informatics training programs (Table 1). The minimum criterion for selection as an AE was at least one first author peer-reviewed English publication (ideally in an informatics conference or journal). Poster submissions were reviewed by one AE; paper submissions by two AEs. The edits were then finalized and assembled into the final proceedings that are in front of you now.

It is important for authors to understand the costs associated with the editing and overall production efforts to ensure the MEDINFO proceedings are of the highest quality possible. Following my esteemed colleagues who served as Editorial Committee Chairs for previous MEDINFOs, I make a plea to each of you to consider the work that is involved when aiming to circumvent the standards established by the organizing committees.

Even moreso than in previous MEDINFOs, strict adherance to the template guidelines was deemed an essential criterion for inclusion in the proceedings. Nonetheless, a number of submissions did clear the peer-review process that still required formatting edits to ensure consistency in font size, spacing, and overall style. In some instances, text had to be significantly edited or figures drastically shrunken or eliminated all together to ensure page limits were respected. Even with such edits, a good faith effort was still made for preserving the scientific message of the contributions. I am thankful for the dedication and hard work of 26 AEs that worked, word-by-word, through each submission and made edits that were ultimately vetted and approved by me.

Table 1– Assistant Editors (AEs) for MEDINFO 2015

Assistant Editor	Institution
Samira Y. Ali	Carlow University
Andrew B.L. Berry	University of Washington
Haresh L. Bhatia	Vanderbilt University
Richard Brandt	Texas Tech University
Matthew K. Breitenstein	Mayo Clinic
Jacqueline E. Brixey	University of Texas at El Paso
David Chartash	Indiana University
Perry M. Gee	Dignity Health
Mattias Georgsson	Blekinge Institute of Technology
Anupama Edward Gururaj	University of Texas Health Science Center at Houston
Zhe He	Columbia University
Kate Fultz Hollis	Oregon Health & Sciences University
Silis Y. Jiang	Columbia University
Saeed Mehrabi	Mayo Clinic
Amir Mohammad	Yale University
Tiffany Nicole Moncur	University of South Florida
Shauna Marie Overgaard	University of Minnesota
Jennifer Elizabeth Prey	Columbia University
Lisiane Pruinelli	University of Minnesota
Balaji Polepalli Ramesh	University of Massachusetts
Joseph D. Romano	Columbia University
Charlene Ronquillo	University of British Columbia
Ning Shang	Columbia University
Harry Tunnell	Indiana University-Purdue University Indianapolis
Mary Regina Wysocki	University of Texas Health Science Center at Houston
Rafeek Adeyemi Yusuf	University of Texas Health Science Center at Houston

Finally, I wish to acknowledge the other members of the Editorial Committee (Paulo Mazzoncini de Azevedo Marques and Andrew Georgiou), along with Alvaro Margolis (IMIA Vice President for MEDINFO), Peter Murray (Immediate Past IMIA CEO), Elaine Huesing (Interim IMIA CEO), the leadership of the Local Organizing Committee (Beatriz de Faria Leão and Claudio Giulliano Alves da Costa) and the Scientific Program Committee Co-Chairs (Fernando Martin Sanchez and Kaija Saranto). These proceedings and this meeting are the product of a true team effort– I hope you enjoy MEDINFO 2015 in São Paolo!

Sincerely,

Indra Neil Sarkar, PhD, MLIS, FACMI
Chair, Editorial Committee

Papers

Electronic Health Records

Validating the Access to an Electronic Health Record: Classification and Content Analysis of Access Logs 3
Leandro Noer Alassia, Sonia Benítez, Daniel Roberto Luna and Fernán González Bernaldo de Quiros

A Practical Approach to Governance and Optimization of Structured Data Elements 7
Sarah A. Collins, Emily Gesner, Steven Morgan, Perry Mar, Saverio Maviglia, Doreen Colburn, Diana Tierney and Roberto Rocha

Systems Architecture for a Nationwide Healthcare System 12
Jorge Abin, Horacio Nemeth and Ignacio Friedmann

Electronic Dental Records System Adoption 17
Renata Abramovicz-Finkelsztain, Claudia G. N. Barsottini and Heimar Fatima Marin

Characterizing the Structure of a Patient's Care Team Through Electronic Encounter Data Analysis 21
Shan He, Greg Gurr, Susan Rea and Sidney N. Thornton

An Information Paradigm Shift is Required to Realize EHR Benefits 26
Evelyn Hovenga and Heather Grain

Template and Model Driven Development of Standardized Electronic Health Records 30
Stefan Kropf, Claire Chalopin and Kerstin Denecke

Fast Model Adaptation for Automated Section Classification in Electronic Medical Records 35
Jian Ni, Brian Delaney and Radu Florian

Using EHRs and Machine Learning for Heart Failure Survival Analysis 40
Maryam Panahiazar, Vahid Taslimitehrani, Naveen Pereira and Jyotishman Pathak

Towards the Implementation of an openEHR-Based Open Source EHR Platform (A Vision Paper) 45
Pablo Pazos Gutiérrez

An Ecosystem of Intelligent ICT Tools for Speech-Language Therapy Based on a Formal Knowledge Model 50
Vladimir Robles-Bykbaev, Martín López-Nores, José Pazos-Arias, Diego Quisi-Peralta and Jorge García-Duque

Identification of Patient Safety Risks Associated with Electronic Health Records: A Software Quality Perspective 55
Luiz A. Virginio Jr. and Ivan Luiz Marques Ricarte

Nonadherence to Oral Antihyperglycemic Agents: Subsequent Hospitalization and Mortality Among Patients with Type 2 Diabetes in Clinical Practice 60
Vivienne J. Zhu, Wanzhu Tu, Marc B. Rosenman and J. Marc Overhage

Standards and Guidelines for Telehealth and Telemedicine

Validation of Minimum Data of Archetyped Telehealth Clinical Report for Monitoring Prenatal Care 64
Danielle Santos Alves, Valéria Cesário Times and Magdala de Araújo Novaes

Design, Implementation and Evaluation of Telehealth Solutions

One Million Electrocardiograms of Primary Care Patients: A Descriptive Analysis 69
Emmanuel Chazard, Milena Soriano Marcolino, Chloé Dumesnil, Alexandre Caron, Daniel Moore F. Palhares, Grégoire Ficheur, Barbara C. A. Marino, Maria Beatriz M. Alkmim, Régis Beuscart and Antonio Luiz Ribeiro

ePoint.telemed – An Open Web-Based Platform for Home Monitoring of Patients with Chronic Heart Failure 74
Halgeir Holthe and J. Artur Serrano

Mobile Healthcare System for Health Checkups and Telemedicine in Post-Disaster Situations 79
Min Hu, Megumi Sugimoto, Andrew Rebeiro Hargrave, Yasunobu Nohara, Michiko Moriyama, Ashir Ahmed, Shuji Shimizu and Naoki Nakashima

Assessing the Potential Use of Eye-Tracking Triangulation for Evaluating the Usability of an Online Diabetes Exercise System 84
Clara Schaarup, Gunnar Hartvigsen, Lars Bo Larsen, Zheng-Hua Tan, Eirik Årsand and Ole Kristian Hejlesen

Mobile Technology (m-Health), Apps and Sensors

Mobile App to Reduce Inactivity in Sedentary Overweight Women 89
Joseph Finkelstein, McKenzie Bedra, Xuan Li, Jeffrey Wood and Pamela Ouyang

iDECIDE: A Mobile Application for Insulin Dosing Using an Evidence Based Equation to Account for Patient Preferences 93
Buffy Lloyd, Danielle Groat, Curtiss B. Cook, David Kaufman and Adela Grando

Reconfigurable Embedded System for Electrocardiogram Acquisition 98
Marcel Seiji Kay and Fábio Iaione

Availability Communication: Requirements for an Awareness System to Support Nurses' Handling of Nurse Calls 103
Joakim Klemets and Pieter Toussaint

Optimizing Decision Support for Tailored Health Behavior Change Applications 108
Rita Kukafka, In cheol Jeong and Joseph Finkelstein

Towards an Ontology-Driven Framework to Enable Development of Personalized mHealth Solutions for Cancer Survivors' Engagement in Healthy Living 113
Sahiti Myneni, Muhammad Amith, Yimin Geng and Cui Tao

A Mobile and Intelligent Patient Diary for Chronic Disease Self-Management 118
William Van Woensel, Patrice C. Roy, Samina R. Abidi and Syed S.R. Abidi

Mobile Early Detection and Connected Intervention to Coproduce Better Care in Severe Mental Illness 123
Pauline Whelan, Matthew Machin, Shôn Lewis, Iain Buchan, Caroline Sanders, Eve Applegate, Charlotte Stockton, Sally Preston, Robert Andrew Bowen, Zhimin Ze, Chris Roberts, Linda Davies, Til Wykes, Nicholas Tarrier, Shitij Kapur and John Ainsworth

Mobile Health Applications, in the Absence of an Authentic Regulation, Does the Usability Score Correlate with a Better Medical Reliability? 127
Mobin Yasini and Guillaume Marchand

Ubiquitous (u-Health), Pervasive Computing

Towards Improving Hypertensive Patients Care: Pervasive Monitoring and Diagnosis Support 132
Jorge Céspedes and Cynthia Villalba

Web-Based Interventions, Web 2.0, Social Media and Networks

E-Patient Reputation in Health Forums 137
Amine Abdaoui, Jérôme Azé, Sandra Bringay and Pascal Poncelet

Web-Based Self-Management Support Interventions for Cancer Survivors: A Systematic Review and Meta-analyses 142
Ae Ran Kim and Hyeoun-Ae Park

The Shared Decision Making Frontier: A Feasibility and Usability Study for Managing Non-Critical Chronic Illness by Combining Behavioural & Decision Theory with Online Technology 148
Amina Russell, William Van Woensel and Samina Raza Abidi

Patient Portals and Personal Health Records and Systems

Experiences of Healthcare Professionals to the Introduction in Sweden of a Public eHealth Service: Patients' Online Access to Their Electronic Health Records 153
Ture Ålander and Isabella Scandurra

Characterizing Patient-Generated Clinical Data and Associated Implications for Electronic Health Records 158
Elliot G. Arsoniadis, Rabindra Tambyraja, Saif Khairat, Cyrus Jahansouz, Daren Scheppmann, Mary R. Kwaan, Gretchen Hultman and Genevieve B. Melton

Robotics and Virtual Reality Systems (eg. Surgery)

Recognizing Clinical Styles in a Dental Surgery Simulator 163
Phattanapon Rhienmora, Peter Haddawy, Siriwan Suebnukarn, Poonam Shrestha and Matthew N. Dailey

Aged Care Systems and Solutions for People with Special Needs

Web-Based Auditory Self-Training System for Adult and Elderly Users of Hearing Aids 168
Simone Virginia Vitti, Wanderléia Quinhoneiro Blasca, Daniel Sigulem and Ivan Torres Pisa

Hospital and Clinical Information Systems

Design, Implementation and Evaluation of an Architecture Based on the CDA R2 Document Repository to Provide Support to the Contingency Plan 173
Fernando Campos, Daniel Luna, Dean F. Sittig and Fernán González Bernaldo de Quirós

Archetype Based Patient Data Modeling to Support Treatment of Pituitary Adenomas 178
Claire Chalopin, Dirk Lindner, Stefan Kropf and Kerstin Denecke

Evaluating Business Value of IT in Healthcare: Three Clinical Practices from Australia and the US 183
Peter Haddad, Jonathan L. Schaffer and Nilmini Wickramasinghe

Toward User-Centered Patient Safety Event Reporting System: A Trial of Text Prediction in Clinical Data Entry 188
Lei Hua and Yang Gong

The Role of Hospital Information Systems in Universal Health Coverage Monitoring in Rwanda 193
Gustave Karara, Frank Verbeke and Marc Nyssen

Bluetooth Roaming for Sensor Network System in Clinical Environment 198
Tomohiro Kuroda, Haruo Noma, Kazuhiko Takase, Shigeto Sasaki and Tadamasa Takemura

On Building an Ontological Knowledge Base for Managing Patient Safety Events 202
Chen Liang and Yang Gong

Case Study: Applying OpenEHR Archetypes to a Clinical Data Repository in a Chinese Hospital 207
Lingtong Min, Li Wang, Xudong Lu and Huilong Duan

Quality Indicators from Laboratory and Radiology Information Systems 212
Matthieu Schuers, Mehr B. Joulakian, Nicolas Griffon, Joanne Pachéco, Carine Périgard, Eric Lepage, Ludivine Watbled, Philippe Massari and Stéfan J. Darmoni

Standards for Exchanging Health Information

Building a Semantic Interoperability Framework for Care and Research in Fibromuscular Dysplasia 217
Marie-Christine Jaulent, Ariane Assélé-Kama, Sébastien Savard, Alessandra Giavarini, Emmanuel Touzé, Xavier Jeunemaître, Adrien Ugon, Pierre-François Plouin and Laurent Toubiana

Micro- and Macrointegration Profiles for Medical Devices and Medical IT Systems 222
Raluca Pahontu, Angela Merzweiler, Gerd Schneider and Björn Bergh

eHealth Standards Development Projects

Product-Based Safety Certification for Medical Devices Embedded Software 227
José Augusto Neto, Jemerson Figueiredo Damásio, Paul Monthaler and Misael Morais

Electronic Prescription and Computerized Provider Order Entry

Patient Safety at Transitions of Care: Use of a Compulsory Electronic Reconciliation Tool in an Academic Hospital 232
Daniel A. Rizzato Lede, Sonia E. Benítez, John C. Mayan III, María I. Smith, Analía J. Baum, Daniel R. Luna and Fernán González Bernaldo de Quirós

Lead User Design: Medication Management in Electronic Medical Records 237
Morgan Price, Jens H. Weber, Iryna Davies and Paule Bellwood

High Override Rate for Opioid Drug-Allergy Interaction Alerts: Current Trends and Recommendations for Future 242
Maxim Topaz, Diane L. Seger, Kenneth Lai, Paige G. Wickner, Foster Goss, Neil Dhopeshwarkar, Frank Chang, David W. Bates and Li Zhou

Nursing Information Systems

Usability Testing of PROCEnf-USP: A Clinical Decision Support System 247
Heloisa Helena Ciqueto Peres, Diná de Almeida Lopes Monteiro da Cruz, Michelle Tellez, Rita de Cassia Gengo e Silva, Diley Cardoso Franco Ortiz and Regina Celia dos Santos Diogo

Patient Safety in Critical Care Unit: Development of a Nursing Quality Indicator System 251

Diagnostic Imaging Integrated Network: A Teleradiology Pilot in Public Hospitals in Uruguay 923
Lilian Acosta and Karime Ruibal Faral

First Step to Big Data Research in Hospital 924
Yongdon Shin, Changmin Choi, JaeHo Lee and Soo-Yong Shin

Implementing Georeferencing in the Decision-Making Process of a Health Care Provider in Uruguay 925
Elizabeth Silva Layes, Fernando Morales and Julio Leivas

A Development of Automatic Audit System for Written Informed Consent Using Machine Learning 926
Hitomi Yamada, Tadamasa Takemura, Takahiro Asai, Kazuya Okamoto, Tomohiro Kuroda and Shigeki Kuwata

Service Quality: A Main Determinant Factor for Health Information System Success in Low-Resource Settings 927
Binyam Tilahun and Fleur Fritz

Taming the Data Quality Dragon – A Theory and Method for Data Quality by Design 928
Jens H. Weber, Morgan Price and Iryna Davies

Medical Image Management, Including Standards

A Medical Image Backup Architecture Based on a NoSQL Database and Cloud Computing Services 929
Luan Henrique Santos Simões de Almeida and Marcelo Costa Oliveira

Digital Imaging and Electronic Data Capture in Multi-Center Clinical Trials 930
Thomas M. Deserno, Verena Deserno, Daniel Haak and Klaus Kabino

Standards for Exchanging Health Information

An Exponential Increase in Regional Health Information Exchange with Collaborative Policies and Technologies 931
N. Lance Downing, Steven Lane, Mathew Eisenberg, Christopher Sharp, Jonathan Palma, Northern California HIE Working Group and Christopher Longhurst

Towards Standardized Patient Data Exchange: Integrating a FHIR Based API for the Open Medical Record System 932
Suranga N. Kasthurirathne, Burke Mamlin, Grahame Grieve and Paul Biondich

Development of Clinical Database System Specialized for Heavy Particle Therapy 933
Masami Mukai, Yutaka Ando, Yuki Yokooka, Yasuo Okuda, Masayoshi Seki, Masahiro Kimura, Hiroshi Tsuji and Tadashi Kamada

Interoperable Archetypes with a Three Folded Terminology Governance 934
Rune Pederson and Gunnar Ellingsen

Standardization of Information about Birth in the Obstetric Discharge Summary 935
Zilma S. Nogueira Reis, Juliano S. Gaspar, Isaias J.R. Oliveira, Andreia C. de Souza and Thais A. Maia

Hospitalization Discharge Summary: Standardization of Information Model 936
Andréia Cristina de Souza, Claudia Moro and Zilma S. N. Reis

eHealth Standards Development Projects

The Challenge of e-Health Presence on a Petroleum Platform: Using Telemedicine to Make Operation of Pre-Salt Wells a Reality 937
R. Nunes Ferreira, T. Lopes da Rosa, C. Benevenuto de Campos Lima, G. Brito Alves de Lima, P. dos Santos Ramos, T. Dias da Silva, A. Barbieri and E. Takeo Ueda

Archetype Development Process of Electronic Health Record of Minas Gerais 938
Thais Abreu Maia, Cristiana Fernandes De Muylder and Rodrigo Mendonça Queiroga

Electronic Prescription and Computerized Provider Order Entry

Unanticipated Consequences of Hospital-Based Insulin Management Order Sets 939
Eunme Cha, Sherita Hill Golden and Joseph Finkelstein

The Impact of Implementing a New Computerized Physician Order Entry (CPOE) System on Pharmaceutical Interventions in a Tertiary Brazilian Hospital 940
Vladimir Ribeiro Pinto Pizzo, Paula Brito Gonçalves, Lívia Maria Goncalves Barbosa, Debora Cecilia Mantovani Faustino de Carvalho, Margareth Ortiz de Camargo and Carlos Onofre de Lira

Nursing Information Systems

Methodology to Establish Associations Between Data and Clinical Assessment for Computerized Nursing Process in Intensive Care Units 941
Daniela Couto Carvalho Barra, Grace Teresinha Marcon Dal Sasso and Fernanda Paese

Nursing Software for Emergency Triage (NSET) 942
H.F. Mandirola Brieux, S. Guillen, F. La Rosa, C. Moreno and S. Benitez

Nursing Clinical Documentation System Structured on NANDA-I, NOC, and NIC Classification Systems 943
Heloisa Helena C. Peres, Diná de Almeida Lopes M. da Cruz, Michelle Tellez, Rita de Cassia Gengo e Silva, Regina Celia dos S. Diogo, Diley Cardoso F. Ortiz and Dóris R. Ortiz

A Trial of Nursing Cost Accounting Using Nursing Practice Data on a Hospital Information System 944
Akiko Miyahira, Kazuko Tada, Masatoshi Ishima, Hidenori Nagao, Tadashi Miyamoto, Yoshiaki Nakagawa and Tadamasa Takemura

An Electronic Nursing Patient Care Plan Helps in Clinical Decision Support 945
C.M. Wong, S.Y. Wu, W.H. Ting, K.H. Ho, L.H. Tong and N.T. Cheung

Clinical Decision Support and Guideline Systems and Protocols

Clinical Decision Support to Implement CYP2D6 Drug-Gene Interaction 946
Pedro J. Caraballo, Mark Parkulo, David Blair, Michelle Elliott, Cloann Schultz, Joseph Sutton, Padma Rao, Jamie Bruflat, Robert Bleimeyer, John Crooks, Donald Gabrielson, Wayne Nicholson, Carolyn Rohrer Vitek, Kelly Wix, Suzette J. Bielinski, Jyotishman Pathak and Iftikhar Kullo

A Scalable Architecture for Rule Engine Based Clinical Decision Support Systems 947
Soumi Chattopadhyay, Ansuman Banerjee and Nilanjan Banerjee

Clinical Decision Support Based on Integrated Patient Models: A Vision 948
Kerstin Denecke

Impact of Specific Alerts in Potassium-Increasing Drug-Drug Interactions 949
Emmanuel Eschmann, Patrick E. Beeler and Jürg Blaser

Detecting, Monitoring, and Reporting Possible Adverse Drug Events Using an Arden-Syntax-Based Rule Engine 950
Karsten Fehre, Manuela Plössnig, Jochen Schuler, Christina Hofer-Dückelmann, Andrea Rappelsberger and Klaus-Peter Adlassnig

Systems Medicine for Multiple Myeloma: A Review on Decision Support Systems 951
Matthias Ganzinger, Christian Haux, Christian Karmen, Thomas Wetter and Petra Knaup

Bridging the Gap Between Clinical Practice Guidelines and Archetype-Based Electronic Health Records: A Novel Model Proposal 952
Diego Garcia, Claudia Maria C. Moro and Lilian Mie M. Cintho

Virtual Oncological Networks – IT Support for an Evidence-Based, Oncological Health Care Management 953
Katja Heiden, Monika Sinha and Britta Böckmann

Computer-Interpretable Clinical Guidelines: A Review and Analysis of Evaluation Criteria for Authoring Methods 954
Soudabeh Khodambashi, Laura Slaughter and Øystein Nytrø

Internal Domain-Specific Language Based on Arden Syntax and FHIR 955
Eizen Kimura and Ken Ishihara

Computationally Comparing and Analyzing All Published Scoring Systems for Diagnosis of Disseminated Intravascular Coagulation 956
Fabrício S. P. Kury and James J. Cimino

Precedent Approach to Decision Making in Clinical Processes 957
Vladimir L. Malykh and Yadulla I. Guliev

Semantic Interoperability in Clinical Decision Support Systems: A Systematic Review 958
Luis Marco-Ruiz and Johan Gustav Bellika

Development of a Mobile System Decision-Support for Medical Diagnosis of Asthma in Primary Healthcare – InteliMED 959
Júlio Menezes Jr. and Cristine Gusmão

Using Discrete Event Simulation to predict KPI's at a Projected Emergency Room 960
Pablo Concha, Liliana Neriz, Danilo Parada and Francisco Ramis

Clinical Decision Support Using Electronic Medical Records: For the Improvement of Diabetes Care and Proper Use of Insulin for Inpatients 961
Ryoma Seto and Susumu Wakabayashi

eHealth Tools for Health Authorities and Professionals

Why should I? – Acceptance of Health Information Technology Among Health Professionals 962
Joseph M.J. D'Souza and Inga Hunter

Diffusion of Innovation: Telehealth for Care at Home 963

Validating the Access to an Electronic Health Record: Classification and Content Analysis of Access Logs

Leandro Noer Alassia[a], Sonia Benítez[a], Daniel Roberto Luna[a], Fernán González Bernaldo de Quiros[a]

[a] *Health Informatics Department, Hospital Italiano de Buenos Aires, Buenos Aires, Argentina*

Abstract

Electronic Health Records (EHRs) have made patient information widely available, allowing health professionals to provide better care. However, information confidentiality is an issue that continually needs to be taken into account. The objective of this study is to describe the implementation of rule-based access permissions to an EHR system.. The rules that were implemented were based on a qualitative study. Every time users did not meet the specified requirements, they had to justify access through a pop up window with predetermined options, including a free text option ("other justification").

A secondary analysis of a deidentified database was performed. From a total of 20,540,708 hits on the electronic medical record database, 85% of accesses to the EHR system did not require justification. Content analysis of the "Other Justification" option allowed the identification of new types of access. At the time to justify, however, users may choose the faster or less clicks option to access to EHR, associating the justification of access to the EHR as a barrier.

Keywords

Access Logs; Confidentiality; Accessibility.

Introduction

The health record serves several purposes, such as clinical documentation, transmission of information between clinicians, student instruction, knowledge generation, monitoring developments, and justifying interventions [1]. Hence, the medical record must be accessed by many individuals with very different aims.

In the age of the Electronic Health Records (EHRs), confidentiality and accessibility become relevant [2-4], particularly when users are not part of the care process. These issues impact the patient population, since patient records can contain sensitive information ranging from diseases, to data concerning sexuality and personal habits, to basic demographic information. According to estimates made by the American Health Information Management Association (AHIMA), 150 people on average, have access to a patient medical record during an inpatient episode [5]. Given this volume of access, the need to protect the confidentiality of patient information is evident and important [6].

In the United States, the Office of Civil Rights has reinforced the privacy and security of personal health information though the Health Insurance Portability and Accountability Act (HIPAA), setting standards and national regulations to protect sensitive electronic health information; thus defining access rights [7]. The Data Protection Act in the UK is the European counterpart to HIPAA [8]. HIPAA establishes two categories of acceptable access: "Treatment Payment Operations in Healthcare (TPO)", and "healthcare related". It is understood that research processes involve the generation of deidentified health records, which are excluded from HIPAA.

From a technical point of view, the Roles-Based Access Control (RBAC) model has shown to be useful [9-11]. In this model, people with a potential need for access to information are given permissions according to their credentials. In this way, information remains available if needed, but the aforementioned problem remains.

Different strategies have been employed to protect patient information without severely impacting the availability of data. The so-called "blue light button" strategy represents the concept of an alternate path, which allows the user to access information. This model is necessary in the context of health care where the unpredictable often happens. Violating the access control model established by RBAC can lead to confidentiality violation. For this reason, it should be subjected to an audit process [12]. This has been called an "optimistic security approach" [13].

Understanding that it is not possible to fully abandon the optimistic approach, we seek to generate a solution to minimize its use, not only because, once breached, the patient's confidentiality has been permanently compromised, but also because the subsequent audit process is cumbersome and costly in terms of human resources [14].

Some reports show restrictive approaches to users whose credentials do not justify access [15]. In others, contextual information is required to grant access, which follows the RBAC model [16,17], while other approaches tried to establish relationships through the use of relational algorithms and machine learning [18,19].

Our approach was to first examine how professionals perceive the ideal access model for EHRs [20]. The project was planned based on the results of that study as well as on the results of a field survey. The goal of this paper is to describe the implementation of access permissions to EHR based on rules.

Methods

Design

This is a cross-sectional study. A secondary analysis of a deidentified database was performed.

Setting

Hospital Italiano de Buenos Aires (HIBA) is a high complexity teaching hospital with 750 inpatient beds, located in Buenos Aires, Argentina. HIBA is part of a health network that includes a second hospital, 25 outpatient centers, and 50 private clinics. HIBA's workforce consists of 2,800 doctors, 2,800 healthcare related personnel, and 1,900 administrative

personnel. Since 1998 HIBA has been using an "in house" Health Information System (HIS) that includes a unique, modular, problem-oriented, and patient-centered web based electronic health record (EHR). In the EHR system, all staff with valid credentials can access and review all medical records, regardless of the nature of their duties. Each entry has a potentially traceable access log.

Figure 1 shows the steps in the project. This work analyzed different justifications and categories of EHR access.

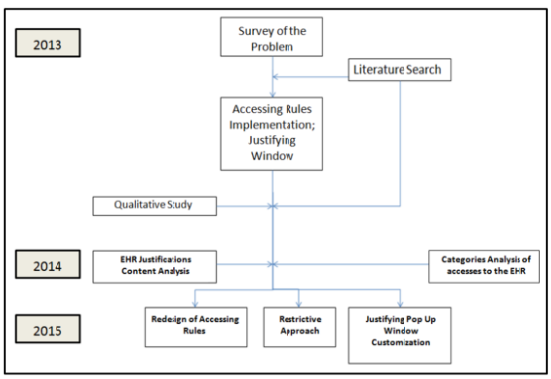

Figure 1- Data Confidentiality Project

Implementation of Access rules

Access permissions to the EHR based on specific rules were implemented in July 2013. The rules considered the most frequent use cases depending of the level of care. Ambulatory-level family physicians and physicians with a visit occurring within the last 180 days or with a scheduled visit do not need to justify access to the EHR. Attending physicians, nurses, pharmacists in the emergency department, and home care providers had the same privileges. At the inpatient level, physicians from the medical department where the inpatient was admitted, referral physicians with a referral request in the EHR, nurses working in the ward where patient is located, and pharmacists all have access to the EHR without any explanation. The qualitative study carried out in the first semester of 2013 helped to construct the different use cases [20].

Every time users did not meet the requirements listed above, they had to justify access through a pop up window with predetermined options (See Figure 2). Some options were: "medical auditor", "health informatics", "patient in my care", and "other justification". The "other justification" option allows the user to declare the reason of access in free text format. These options were chosen for different reasons. Most of them were sourced from the previous survey, in which we asked different types of users for the reasons they access the EHR. Some of them were included after the discussion, with the rest of the Medical Informatics team. We left the "other justification" option to capture not previously considered use cases. For more information, see http://www.hospitalitaliano.org.ar/infomed/index.php?contenido=ver_curso.php&id_curso=17942 .

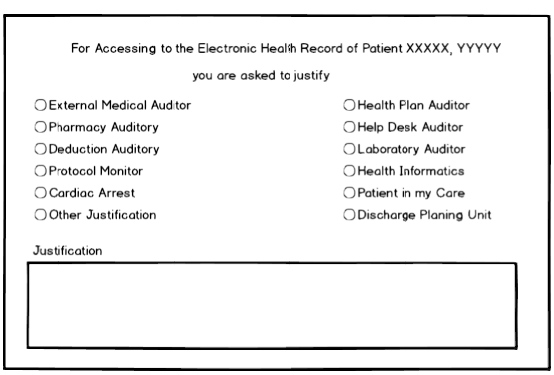

Figure 2- Pop Up Justification Window

Analysis Plan

Data from July 2013 to June 2014 were analyzed comparing both semesters, and descriptive statistics were performed. Categorical variables were presented as percentages. Free text from the "other justification" option was evaluated via content analysis. Because we did not make any adjustments in the short term, we looked for large variations occuring in the annual data over two periods.

Results

The total log accesses included 9,755,752 hits for the first period, representing an average of 62,536 hits per day, and 10,784,956 for the subsequent period (average of 59,916 daily). Of a total of 20,540,708 hits on electronic medical records, we found that 85% of access to the EHR did not need to be justified. In the remaining 15%, there were variations in the occurrences of the "patient under my care" and "other justification" options in both semesters.

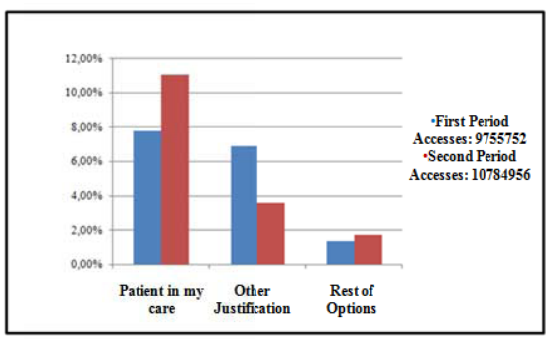

Figure 3. Remaining 15% of accesses by semester

Finally, from the content analysis of the "other justification" field, the new categories of access identified are shown in Table 1. Over all types of users, 52% of all written justifications corresponded to nonsensical text or acronyms with uncertain meaning.

Table 1 - Content analysis of the "other justification" option

Identified Case	Repetitions n=1060217 (%)
Nutrition Personnel Access	203, 693 (19.21)
Referral	131, 946 (12.44)
Billing Access	124, 681 (11.76)

Discussion

In this paper, data regarding justification of access to EHRs were analyzed. The majority (85%) of accesses responded to the rules, and users did not need to clarify the reason to access the EHR. Of the remaining 15%, the two predominant categories were "patient under my care" and "other Justification", the latter of which instructed the user to write additional information in free text.

There was a marked decrease in the selection of the "other justification" option between the first and second periods of the study. We considered that this could be due to user adaptation. This phenomenon may be considered similar to alert fatigue [21,22]. Given the repeated appearance of the pop up window, it is possible that it disrupted workflow, such that many professionals who initially justified access eventually transitioned to selecting the "patient under my care" option, which allowed entry with only two clicks. This may also explain the nonsensical text in the "other justification" option, which may have been entered in order to access records more expeditiously. Further research will help to understand the problem. On the other hand, new residents begin their training at our hospital every June/July, increasing the probability of this option being used more frequently in the first period.

With respect to the "other justification" option, content analysis allowed us to find new use cases not covered before, which led to their addition to the rules of validity for access in the next phase of the project. Comparing our experience to those in other publications, we see that the RBAC model – the major paradigm for access control over the last fifteen years – is frequently adapted to different settings. In some cases, the model is applied to make access more restrictive [15], while in others it is to allow access in the combined context of team collaboration [23], using captured information on context metadata to optimize control permissions [16,17] or even trying to predict association rules between users and patients [18]. We think that a qualitative approach followed by a content analysis of the information (provided by users, even when not formally verified because of the deidentified data use), can offer a solution to find new rules, enabling a continuous quality improvement cycle and engaging users with regard to this important topic. Further research would be useful to evaluate the accuracy of the "other justification" option, if necessary.

This study has some limitations. It is a cross sectional study, and information is from a single academic healthcare center, therefore the results cannot be generalized without validation. Additionally, we cannot ensure that the selected options in the analysis corresponded to the real reason of access, because the categories outlined in Figure 2 could be accessed by all users without any validation.

Based on data from this study, we plan to make access to the EHR more restrictive, allowing access only if the user is a family doctor or a member of a registered care team. We will maintain a "blue light button" for emergencies, accompanied by an agile and effective audit. This option will trigger a self-audit mechanism through institutional e-mail. The rules of access will be extended according to the content analysis of written justifications. Finally, we will customize the options in the pop up window according to the department and/or service where the user belongs, to allow a more accurate granularity and to reduce the need to write extra text. With these changes, we aim to improve the workflow in the newly identified use cases, improve the fidelity of structured options for justification, and reduce the need for justification in free text.

Finally, it must not to be overlooked that an EHR provides the technical infrastructure to aggregate information and establishes a longitudinal record of health information for individual patients. This accessibility of information has already opened the debate about who should grant permission for a user to access the information in the EHR. For several years, it has been postulated that the patient, as owner of the information, is the one who should define who can access their record. This permission, in turn, must be sufficiently flexible to allow the patient to set the privacy level from accessible only to a few professionals, to having no privacy restrictions, according to each owner's preferences [24]. In this sense, open questions remain about what measures can be taken to protect patients' information, such as clarifying who can access and why they are accessing the clinical data repository, while interfering as little as possible with the workflow of each healthcare professional.

Conclusion

In this analysis of access permissions to the EHR based on rules, the majority of users did not need to clarify the reason why they needed access. Rules implemented were based on a qualitative approach, and content was analyzed using information provided by users. At the time of justification, however, users may consider access justification a disruptive barrier, often choosing the faster (or "fewer clicks") option to access the information.

Abstract

Definition and configuration of clinical content in an enterprise-wide electronic health record (EHR) implementation is highly complex. Sharing of data definitions across applications within an EHR implementation project may be constrained by practical limitations, including time, tools, and expertise. However, maintaining rigor in an approach to data governance is important for sustainability and consistency. With this understanding, we have defined a practical approach for governance of structured data elements to optimize data definitions given limited resources. This approach includes a 10 step process: 1) identification of clinical topics, 2) creation of draft reference models for clinical topics, 3) scoring of downstream data needs for clinical topics, 4) prioritization of clinical topics, 5) validation of reference models for clinical topics, and 6) calculation of gap analyses of EHR compared against reference model, 7) communication of validated reference models across project members, 8) requested revisions to EHR based on gap analysis, 9) evaluation of usage of reference models across project, and 10) Monitoring for new evidence requiring revisions to reference model.

Keywords:

Structured data elements; EHR optimization; Data governance.

Introduction

A lack of consistent data capture has profound implications on reporting, e-measures, and clinical decision support and other secondary uses of EHR data [1]. Much work has been performed on the development and use of controlled terminologies to mitigate inconsistent data capture [2–8]. In an ideal EHR implementation project, the initial definition of structured data elements would require mapping to a controlled terminology *with* comparison of each newly defined data element to all other data elements that have been defined previously. Such a data governance process requires extensive resources, particularly: *training* for analysts, clinicians and informaticians in terminologies and clinical content management; *sophisticated data management tools* to continuously search, view and compare all draft and final structured data elements; and *sufficient time* to allow for iterative, analytical, and collaborative content management and validation cycles [9]. Training, tools, and time are limited resources in large scale EHR configuration and implementation projects. While best practice certainly should require tightly controlled data governance of structured data definitions at the beginning of an EHR implementation, in many cases this is not done due to limited resources, a lack of expertise, or competing priorities [9].

Challenges

A lack of consistent shared data definitions across EHR applications and clinical settings, prevent reuse and interoperability of healthcare data. EHR data collection forms defined without reference models, compromise information consistency and completeness. Adding further complexity, many healthcare organization's EHR implementation and optimization projects are quite large with limited interaction between individuals responsible for distinct applications within the EHR system [9]. These limited interactions may lead to decreased sharing of data definitions and an increase in the number of distinct data elements defined to represent similar topics.

In the absence of a pre-defined reference model for a given clinical topic, data governance requires extensive manual effort to verify completeness and consistency of documentation and this effort constantly increases with the creation of new EHR forms. This manual effort trickles down as a significant negative effect on the accuracy, timeliness, and relevance of downstream processes that use the collected data, such as billing, clinical decision support, reporting, population management, and analytics (risk estimation, prediction) [10]. Overall, a lack of well-defined data definitions that are not shared across EHR applications will require additional resources to design, build, deploy, and manage large quantities of data definitions and to remediate consequences to downstream processes [10]. Adding to the challenges, correction of data inconsistencies after data elements and forms are in active use invariably require expensive and error prone data conversions.

Potential consequences

As noted in the previous section, challenges that arise from poor data definitions are well-known, significiant and far-reaching. A solution needs to be tractable; hence, we believe focusing on measureable consequenses to help target specific efforts to improve the definitions of data across applications in an EHR is a practical approach that can be implemented in organizations with limited resources, expertise, and time.

Measureable potential consequences of poor data definitions include: regulatory and compliance requirements, billing, reporting, and clinical decision support.

Specific consequences of inconsistent data definitions that relate to regulatory and compliance requirements include:

incomplete or inadequate reporting, inconsistent evidence during auditing events, and difficulties to implement quality improvement interventions.

Billing consequences include: inconsistent evidence to confirm level of care and decreased coding accuracy and speed due to data variability. Consequences for reporting include highly complex reports that need to account for data being defined in multiple different ways, the design of reporting processes that attempt to "normalize" data to enable consistent interpretation, and the risk of not including relevant data when data elements are missed or incompatible.

Clinicial decision support (CDS) rules have to account for data being defined in multiple different ways which leads to variability and highly complex CDS design. Incomplete or incorrect data triggers can result in false positive or false negative CDS alerts and reminders. Finally, CDS maintainance requires expensive updates and re-testing to accommodate new data definitions or to remediate CDS interventions after data conversions.

Given the “real-world” resource limitations that often lead to a state of inconsistent data definitions, and the subsequent challenges and potential consequences that may result, our goal in this study was to define a practical approach for governance of structured data elements that is sustainable and repeatable. Within our proposed process, specific analytical processes (e.g., formulas, calculations, and weighted scores) require in-depth exploration of assumptions and variables and are likely dependent on an organization’s strategic aims and priorities. Therefore, detailed descriptions of analytics within our proposed process are out of scope of this paper and are planned for dissemination in a future publication.

Materials and Methods

Setting

Our method development was conducted by a workgroup comprised of informaticians, project analysts, and clinical experts. The combination of these three roles enabled a collaboration comprised of multiple expertises. For example, informaticians had expertise in data modeling, terminologies, software development lifecycle stages, and measurement research. Project analysts were highly knowledgeable about the EHR configuration and project management and helped ensure the practicality of our proposed method. Clinicians provided clinical expertise across a variety of specialties and professions to ensure the clinical relevance of our work.

Acceptance Criteria

To meet our aim of defining a practical approach for data governance for structured data elements that is sustainable and repeatable, we defined criterion for an acceptable approach. This criterion was to: 1) make efficient use of existing, though limited, resources, 2) deliver clinically relevant, reusable information, 3) reuse existing data models, 4) leverage reliable metrics for comparative decision-making, 5) manage competing priorities from various stakeholders, and 6) follow a lifecycle stages process model.

Clinical relevance was maintained by focusing on clinical topic categories as the unit of analysis. To increase reliable and practical decision-making, we defined objective measures to analyze downstream data needs and comparisons against current state. The management of competing priorities from various stakeholders was handled by prioritizing clinical topics and revisions based on consensus defined weighted scores and thresholds. Finally, each process in our practical approach was aligned with a stage from the software development lifecycle framework to provide a foundation for a repeatable approach.

Results

After iterations within our team, we identified a 10 step approach that was efficient, clinically relevant, rigorous, and practical for managing competing priorities from various stakeholders, demonstrating evidence to support decisions overtime, and ensuring sustainability for data governance needs identification. The 10 steps of our method for data gov-

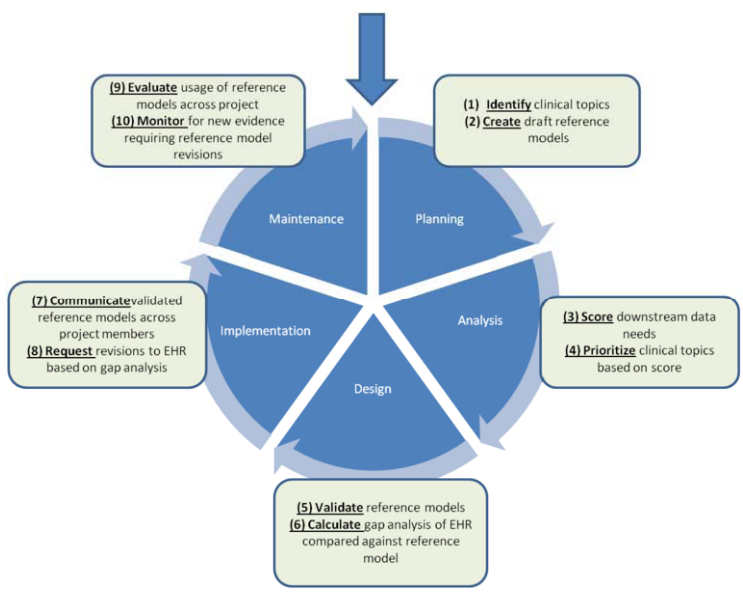

Figure 1 - Practical Approach for Data Governance for Structured Data Elements

ernance needs identification are: 1) identification of clinical topics, 2) creation of draft reference models for clinical topics, 3) scoring of downstream data needs for clinical topics, 4) prioritization of clinical topics, 5) validation of reference models for clinical topics, and 6) calculation of gap analyses of EHR compared against reference model, 7) communication of validated reference models across project members, 8) requested revisions to EHR based on gap analysis, 9) evaluation of usage of reference models across project, and 10) monitoring for new evidence requiring revisions to reference model.

Proposed Approach

1) Identification of clinical topics

The aim of identifying clinical topics is to align analytic focus with the strategic aims of an organization and data governance optimization. A key factor in identification of clinical topics is to select topics that are orthogonal to topics previously used to define the clinical content that is being optimized. For efficiency and minimal engagement of resources, certain assumptions may be made that topics focused on previously are a lower priority than topics that have yet to be analyzed. For example, the documentation of intravenous line placement and *urinary catheter management* may have been defined previously, but independent of each other. A focus on *catheter* placement and intravenous line *management* would allow an efficient evalution of discordant and overlapping data definitions among the topics.

2) Creation of draft reference models for clinical topics

The aim of creating a *draft* reference model is to quickly produce an artifact that can be used for initial analyses in the next stage. A reference data model for a clinical topic provides the names of each structured data element that pertains to that topic, data definitions, data types, values sets, abbreviations, synonyms, unique identifiers and original resources. We propose a targeted environmental scan of resources which publish clinical data element reference models such as: 1) HL7 Domain Analysis Models, 2) LOINC, 3) Intermountain Healthcare Clinical Element Model Browser (http://www.clinicalelement.com), 4) salient professional societies, and 5) peer-reviewed literature. This list is not intended to be exhaustive, but rather, is intended to allow for a repeatable and efficient search to identify existing reference models from organizations that are most likely to have produced them.

Existing reference models that result from the search should be compared by mapping synonymous data elements and value sets and forming a comprehensive list of data elements relevant to the clinical topic. This analysis should result in a draft reference model. In the case of retrieval of one extensively validated reference model, that should be used in its entirety.

3) Scoring of downstream data needs for clinical topics

The aim of scoring downstream data needs for clinical topics is to differentiate which clinical topics are most important for an in-depth analysis and development of a validated reference model. Given unlimited resources and time, all identified clinical topics (and in fact all content) within an EHR could be defined consistently. However, we are focused on real-world EHR implementation and optimization projects with competing priorities and limited resources; hence, a requirement of our approach is to focus and prioritize governance efforts for structured data elements.

Consistent data definitions are critical for interoperability, however, there is a lack of measureable benchmarks for interoperability for discrete clinical topics to differentiate which topics are most important to focus on. Yet, there are a set of measurable rationales for increasing the consistency of data definitions: enabling automated reporting, demonstrating adherence to regulatory requirements, maintaining clinical decision support, documenting accurate billing codes, adhering to best clinical practices and terminology described in protocols, guidelines and evidence-based literature and order sets and plans of care.

We propose an approach that identifies measurable downstream data dependencies, calculates a weighted score based on importance of each dependency and results in a total weighted score that can be used to rank the priority of each clinical topic. See Table 1 for an extract of a sample "scorecard" for this downstream data needs analysis.

4) Prioritization of clinical topics

The aim of prioritizing clinical topics is to target the highest priority topics and plan the sequence in which topics will be

Table 1 - Extract of a sample "scorecard" for downstream data needs analysis

[Clinical Topic Name] Scorecard= [total weighted Data Need Score score]

		Data Need Tallies					
Reason Data is Needed	**High Priority Data Needs**	**Data Element 1**	**Data Element 2**	**Data Element 3**	**Data Element 4**	**Data Element 5**	**Data Element 6**
Regulatory	Regulatory requirement A	✓	✓	✓	✓	✓	✓
	Regulatory requirement B	✓	✓				✓
Billing	Billing needs identified by subject matter expert	✓	✓	✓			✓
Reports	Report A		✓				
	Report B		✓				
CDS	CDS Intervention A		✓				
	CDS Intervention B			✓			
Weighted Data Need Score		[score]	[score]	[score]	[score]	[score]	[score]

addressed for data governance optimization overtime. A critical assumption is that this list is dynamic and is constantly being refined, based on scores of downstream data needs for new or re-evaluated clinical topics.

5) Validation of reference models for clinical topics

The aim of validating a reference model for a clinical topic is to produce a standard data model that is clinically accurate and complete and can be disseminated broadly for implementation. The validation of a reference data model may be completed by asking clinical experts to review the draft reference model for missing, superflous, and inaccurate information and asking analysts to review the draft reference model for any feasibility issues or technical constraints to implementation in the EHR system.

Clinical validation of reference models should be based on best practices, is consensus driven, and can be a time intensive activity. Due to the resources required validation of a reference model is done for prioritized clinical topics, and not all clinical topics.

6) Gap analysis of EHR compared against reference model

A validated reference model is useful when used as a reference standard to assert how similar or different EHR data elements are from the defined ideal state (the reference model). We have applied validated metrics for information extraction to this gap analysis [11]. These metrics can be used for a reliable gap analysis measure to identify structured documentation forms within the EHR that do not match the validated reference model. Please see Table 2 for the list of these metrics and their definitions. Documentation forms developed prior to the development of a reference model may not match exactly, but for practical purposes may be "good enough" and not a priority for revisions in the short-term. A pre-defined threshold for a total mismatch score is useful to identify the cut-off score for revisions based on mis-matched data elements. The particular threshold for this cut-off score will dependent on available resources to revise content and push changes into production for the EHR system.

7) Transparent communication of validated reference models across project members

Transparent dissemination and open and ongoing feedback about validated reference models is aimed at increasing the use of the organization's validated reference models across EHR applications and continuing efforts to optimize the models.In our proposed approach, validated reference models are actively used to conduct gap analyses. However, to make efficient use of resources all validated reference models should be communicated across all project members and available for use. Expectations should include that any newly developed content or current revisions will utilize any related validated reference models. Desired exceptions should be communicated for two purposes: 1) to clarify if information is missing or wrong in the reference model that should be added or corrected, and 2) to discover if the exception is appropriate.

8) Request EHR revisions based on gap analysis

The gap analysis provides objective and reliable measure of prioritized areas for revisions in the EHR to match validated reference models. This step to request revisions is included for consistency with change request processes that are common in many organizations. The formality of this step allows for communication about dependencies related to the requested revisions and resources needed for the revision and to manage dependencies of the revision. Additionally, this step offers an opportunity to discuss any contextual information that may impact the appropriateness of the change. For example, a gap analysis may identify 5 documentation forms that vary signficantly from Reference Model A and revisions are requested for all 5 forms. It may be identified at this stage that the 5th documentation form includes structured data elements from a research study that should not be changed during the course of the 12 month study period. A decision could then be make to make revisions for forms 1-4 now and to revise form 5 in 12 months.

9) Evaluation of usage of reference models across project

Use of an electronic collaborative tool to disseminate validated reference models would allow project members to search all validated reference models. An electronic collaboration space could enable the capture of usage metrics with little overhead by providing users the opportunity to document where and how the validated reference model was applied to the EHR application. Usage metrics of reference models can inform: 1) an understanding of the nature of clinical topics that have highly utilized reference models as a method to identify similar important topics, 2) EHR applications that are underutilizing validated reference models and may require training, 3) EHR applications that are proficient in utilizing reference models and could assist teams that are less proficient.

10) Monitoring for new evidence requiring revisions to reference model

An annual clinical subject matter expert review of validated reference models is ideal, and may be extended as limited by resources. As protocols and guidelines change, reference models with related data elements should be reviewed by a clinical subject matter expert to determine if a change is required. Consistent with our goals of a practical, efficient, and reliable approach, the downstream data analysis performed in step 3 should be re-purposed, and not replicated for this step. For example, if a pain documentation ICU protocol was updated to include new evidence, the downstream data analysis that referenced to that pain documentation ICU protocol could be easily identified and the related reference model revised to reflect new evidence.

Table 2 - Proposed Metrics for gap analysis of EHR compared against reference model

Metric	Definition
Match	Data element in the EHR is the same as the data element in Reference model
Partial Match	Data element in the EHR is different but intended to capture the same type of data as the data element in Reference model
Conflicting	Data element in EHR is not equal to the data element from Reference model
Extra	Data element is in the EHR but does not exist in Reference model
Missing	Data element is not in EHR but does exist in Reference model

Discussion

We proposed a 10 step practical approach to governance and optimization of structured data elements. Ten steps may appear to be lengthy, however, we included explicit communication and documentation steps as they are critical to effective governance. It is important to note that organizations may identify shorter paths to prioritizing clinical topics for analyses and identifying gaps in current state for redesign, however, we believe that our proposed approach most effectively combines scientific rigor, collaborative decision-making, and sustainability with efficiency.

Defining data consistently at the outset of an EHR implementation project is the ideal and our research team promotes this pro-active approach. However, we sought to provide organizations who did not or could not effecively govern consistent data definitions initially when configuring and implementing their EHR with a practical approach to remediate inconsistencies and decrease potential downstream consequences. This practical approach is being applied in our organization for a number of clinical topics and is expected to continue as an ongoing activity throughout optimization of our EHR system.

Limitations

The proposed approach is based on the experience of one integrated health system in the Northeast United States during configuration of a vendor based EHR. It is reasonable that the application of this proposed approach to governance of structured data elements would require modifications to fit within the existing infrastructure of other organizations. Our description of the proposed approach is purposefully general to increase the ability for organizations to apply the steps and concepts to meet their needs. As with the design of most best practice and governance approaches, we expect this approach to be iteratively revised and modified to fit different types of health care organizations with varied available resources and expertise.

Conclusion

We defined a 10 step practical and rigorous approach to structured data element governance in EHRs: 1) identification of clinical topics, 2) creation of draft reference models for clinical topics, 3) scoring of downstream data needs for clinical topics, 4) prioritization of clinical topics, 5) validation of reference models for clinical topics, 6) calculation of gap analyses of EHR compared against reference model, 7) communication of validated reference models across project members, 8) requested revisions to EHR based on gap analysis, 9) evaluation of usage of reference models across project, and 10) monitoring for new evidence requiring revisions to reference model. This approach should be evaluated for its applicability across difference types of health care organizations and stages of EHR implementation. We believe that practical and applied approaches that streamline analytical steps while maintaining scientific rigor are highly needed and beneficial to the clinical informatics and health information technology communities amidst the great changes and adoptions that are occurring every day in health care systems throughout the world.

Acknowledgments

We would like to acknowledge all members of the Structured Data Element Workgroup at Partners eCare and all members of Partners eCare project that contributed to this work.

Systems Architecture for a Nationwide Healthcare System

Jorge Abin[a,b], Horacio Nemeth[a], Ignacio Friedmann[a]

[a] Agency for the e-Gov and the Information Society & Knowledge of Uruguay (AGESIC)
[b] Systems Integration Laboratory (LINS), Institute of Computer Studies (InCo), School of Engineering, University of the Republic (UdelaR)

Abstract

From a national level to give Internet technology support, the Nationwide Integrated Healthcare System in Uruguay requires a model of Information Systems Architecture. This system has multiple healthcare providers (public and private), and a strong component of supplementary services. Thus, the data processing system should have an architecture that considers this fact, while integrating the central services provided by the Ministry of Public Health. The national electronic health record, as well as other related data processing systems, should be based on this architecture. The architecture model described here conceptualizes a federated framework of electronic health record systems, according to the IHE affinity model, HL7 standards, local standards on interoperability and security, as well as technical advice provided by AGESIC. It is the outcome of the research done by AGESIC and Systems Integration Laboratory (LINS) on the development and use of the e-Government Platform since 2008, as well as the research done by the team Salud.uy since 2013.

Keywords:

eHealth Information Systems; eHealth; Interoperability; e-Government; HL7; IHE; System Architecture for Nationwide ehealth; Nationwide Healthcare Systems Architecture.

Introduction

From the perspective of conception and systems architecture, this document includes two relevant aspects that constitute the conceptual model of a technological platform to support the Electronic Health Records System at a National level (HCEN in Spanish).

As it will be stated below, this “eHealth Platform” (PS in Spanish) is implemented as an extension of the "e-Government Platform” (PGE in Spanish), reusing and expanding security components and interoperability.

In Uruguay, the development of the Electronic Health Record (EHR) at a national level is included as a goal in the Digital Agenda 2011-2015 [1]. In fact, objective number 14 includes four specific goals; two of them are relevant to this document: 1) "During 2012, to create a health data network..." 2) "Since 2012, to create and manage a platform on electronic health records..." The concept and design of the whole system architecture is based on the context where it will be applied and, obviously, it must consider the legal and technical framework. Under the heading "Context: The Health Ecosystem in Uruguay," there is an outline of the framework within which HCEN will be developed in Uruguay. The heading "Health Platform: Architecture of a Nationwide Solution" includes a description of this platform. Finally, respective conclusions and current stage of evolution will be presented.

Justification

With focus on the particular features of the Nationwide Integrated Healthcare System in Uruguay, this article shows the need of having a national system of interoperable EHR, the possibility of applying acquired knowledge and lessons learned when conceiving, designing and operating the e-Government Platform in Uruguay, the experience on health information systems, and the inherent technological challenges.

Context: The Health Ecosystem in Uruguay

Legal Framework

Act 18211, from December 13, 2007, Nationwide Integrated Healthcare System. [2]

Act 18331, from August 11, 2008, Act on the Protection of Personal Data.

Act 18335 from August 15, 2008, on rights and duties of patients and users of healthcare services. [3]

Act 18600 from September 21, 2009, which acknowledges legal effects and validity of e-documents and e-signature.

Nationwide Integrated Healthcare System (SNIS)

In Uruguay, the Nationwide Integrated Healthcare System (SNIS in Spanish) has the following features: gives universal coverage, is tax-financed, and services are delivered by networked healthcare providers. There is one public provider and multiple private providers that may give full coverage or partial coverage, depending on the services they deliver.

The underlying principle is that the users form the core and backbone of this healthcare system. The user is entitled to choose freely a healthcare institution; once the user selects a healthcare institution, the relationship user-institution shall last at least 3 years, and the SNIS is aware of this affiliation. HCEN is the main part of the Health Information System, and it is a key component of the SNIS. National authorities have imposed an additional investment levy to service providers; most of them have submitted projects on ICTs, specifically on the development of EHR.

Apart from comprehensive healthcare providers, there are partial providers, such as private medical labs, imaging clinics, non-hospital emergency services, private physician offices, or office networks among others that are authorized and operate under regulations issued by the Ministry of Public Health (MSP in Spanish), but are not part of the SNIS. Those service providers also produce relevant medical information which must be considered by HCEN. Usually, people are affiliated with comprehensive healthcare providers and mobile emergency services, and also undergo medical examinations in private offices. Pharmacy networks must also be considered. The SNIS has been operating since 2008.

Salud.uy Program

This program results from the agreement entered into the Presidency of the Republic, the Ministry of Public Health, the Ministry of Economy and Finance and AGESIC. It is aimed at the implementation of goals included in the Digital Agenda Uruguay 2011-2015.

It is focused on the development of the HCEN and the creation of the National Bank of Health Records, which will act as the institution in charge of the HCEN management after the completion of this program.

AGESIC is in charge of the implementation of Salud.uy. There is a program board formed by one representative of each agency that is part to the above mentioned agreement and the project manager. It is supported by international funding (IDB) with domestic counterparts.

Current Situation of Healthcare Providers from the Perspective of eHealth

Every healthcare provider maintains and is responsible for providing custody for health records of their affiliates.

All healthcare providers were surveyed to assess the current situation from the perspective of ICT. They were also questioned on the acceptance of EHR and its current level of incorporation. This survey revealed a great disparity in ICT maturity levels. Regarding the incorporation of EHR, most of the comprehensive providers are carrying out projects in different stages. Practically, interoperability between healthcare providers does not exist.

Problems on Interoperability, Lessons Learned and Solutions Adopted

Uruguay, through AGESIC, has widely defined the standards on interoperability, people and addresses metadata, regulations, and recommendations related to best practices on the subject [4]. Also, Uruguay has an Object Identifier (OID) managing body (UnaOid) [5].

The interoperability use made by State agencies evolved positively with the adoption of technological solutions that were not dependent on the technological maturity of agencies. Early stages, based on training courses, manuals, workshops, were complex; the level of acceptance and adoption was very slow. The PGE-connector [6] is an abstraction that encapsulates problems related to PGE connection (security and interoperability), considerably simplifying programming related to connections or service supplying to PGE. Since the inclusion of this tool, levels of acceptance and adoption increased exponentially.

Lesson learned: interoperability, in the area of health, is even more complex than e-Government transactions; standards and profiles (IHE and HL7) establish complex mechanisms that must be solved with a high level of abstraction to facilitate their early adoption.

Connectivity, Health Network

Uruguay has one data communication network, “red.uy,” which provides the connectivity infrastructure required to link State bodies in a secure way, with proper levels of service, IT security and high availability.

The health network is consistent with the model of complementation of services of the SNIS. The core is formed by red.uy and it is extended through connections with local existing health networks (public health network, networks from private providers, and public internet access for low scale users and providers). Figure 1 shows that network. Thus, a national network is set up.

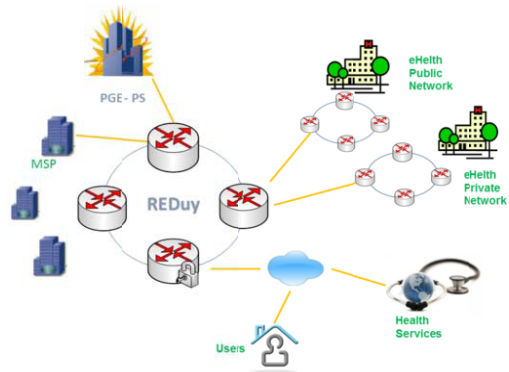

Figure 1 – The eHealth network

Table 1 – Context Summary

Context Summary
The Nationwide Integrated Healthcare System establishes the right to quality healthcare, individual's right to access his or her own health records and that this medical information should be available when needed.
The EHR is a key component for the Nationwide Integrated Healthcare System success.
All health institutions that are part of the health system must contribute to the HCEN.
Each citizen is affiliated to at least one comprehensive healthcare provider.
Each individual may receive medical care from another institution, different from the healthcare provider to which is affiliated.
Each healthcare provider develops its own EHR.
Many healthcare institutions are using specific applications, e.g., RIS-PACS, LIS.
Some pilot applications on imaging (remote diagnosis) and oncology are being implemented by salud.uy program.
There are some interoperable applications: vaccines, births and deaths certificates, childhood and adolescence cards, old people cards, pregnancies, which are centrally managed by MSP.
Master Tables, Catalogs, Dictionaries are managed by MSP but the e-services provider is the salud.uy program through the eHealth platform.
Terminology services will be managed by salud.uy program. Salud.uy program also will provide them as centralized services.
Currently, each healthcare provider adopts its own criteria for patients and EHR identifications.
There is a base platform, PGE, which was designed considering health standards, and it is currently operating.
Interoperability: a successful model on complexity abstraction has been developed to facilitate the adoption of standards, as well as to ease interoperability itself.
The key components of the health data transmission network are available (health network).

eHealth Platform: Architecture of a Solution at a National Level

Background and Preliminary Studies

During preliminary studies before designing the PS, various models were analyzed, in particular, models from Canada [10], Catalonia, Italy, France, Austria and Australia [11]. Many of their components were considered when designing our model. Of course, we also considered HL7, IHE, ISO, IHTSDO, SNOMED CT, DICOM, LOINC standards and recommendations.

Architecture of a Solution at a National Level

Every ICT platform requires the prior solution of some basic infrastructure functionalities, such as: i) security (users authentication and access control); ii) routing and transformation of messages (ESB); iii) implementation of standards on interoperability and usability; iv) offering continuation mechanisms and data access; v) offering ready access to information (portal); vi) connectivity at different levels; vii) management and administration tools; viii) governance; ix) ensuring privacy and data protection.

All those basic functionalities, including citizen single Sign On, are provided by the PGE. Hence, eHealth Platform (PS) will be considered as a specialized extension of the PGE.

PGE Technical Features

The e-Government Platform has three layers: one is physical and two are logic. The physical layer is formed by the Cloud, which supports the whole platform infrastructure. This physical layer implements the following: Infrastructure as a Service (IaaS) and Platform as a Service (PaaS).

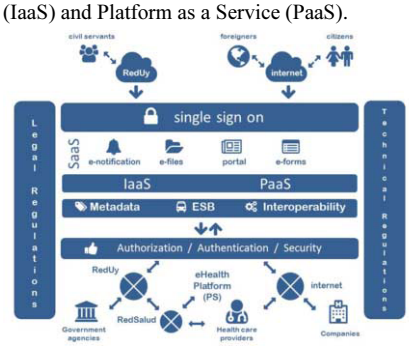

Figure 2 – PGE diagram

This allows selecting the best way to manage the solution infrastructure, optimizing physical resources.

The logic layers, the Crossed-Application layer (Saas) and the Interoperability Platform, refer to two visions of this business: one is oriented to final users (Crossed-Applications layer) and the other is oriented to integration services for backend systems (Interoperability Platform).

Crossed Applications

The layer of Crossed Applications is divided in two layers; security and applications. The security layer, in this case, offers security services not only for internal applications, e.g., State Portal and Electronic File, but for the implementation of a Single Sign On solution which allows adding applications hosted within other State agencies or the PS. This implementation is based on the fact that the identities of application users are federated and that authentication is centralized in the PGE. This is achieved by the use of SAML 2.0 tokens, which allow validating individual's identity through the addition of tokens to HTTP requests.

Interoperability Platform (PDI in Spanish)

The PDI integrates the systems within the State at the back end level [9]. It has two layers: one of security and the other of interoperability (semantic and technical). Technical interoperability is solved by the use of an Enterprise Service Bus (ESB) and the semantic is solved by a number of metadata definitions, which allow simplifying data exchange and offering added value services on it. Those exchanges are based on Web Services SOAP 1.1. All web services used by this platform comply with WS-Security Profile 1.0 and WS-Basic Profile 1.1 standards. SSL v3.0 (HTTPS) with mutual authentication used for physical security. Service authentication and authorization is carried out by SAML1.1 tokens, which are exchanged with the platform using WS-Trust and WS-Security standards. E-signature is used to ensure tokens authenticity through certificates X.509 v3. Messages received by PDI are dynamically routed to various recipients using WS-Addressing standard. Internally, XACML 2.0 is used for validation and communication of security components. XLST 2.0 is used for ESB transformations. Open standards allow universal use of the platform, becoming independent from proprietary protocols and overcoming difficulties at the integration stage.

eHealth Platform (PS in Spanish)

Featured by the existence of multiple healthcare providers, the SNIS creates the need of building a federated model of Electronic Health Records [7]. SNIS requires that everyone is responsible for managing and providing custody for health records of their affiliates, apart from the need of having a complete view of the EHR whenever and wherever it is required.

HCEN context requires the fulfillment of interoperability rules and data integrity rules. First rules are supported by the three main levels of interoperability: organizational interoperability, semantic interoperability and technical interoperability. Data integrity is based on rules and policies on auditing, traceability, identity, reliability and auto-verification.

Organizational interoperability is based on two elements: design based on the affinity domain concept [8] and SNIS regulations.

Designs are based on the affinity domain concept, according to the definition included in IHE technical specification. IHE refers to a number of healthcare providers that share some policies within a cooperation environment, using a shared infrastructure.

Considering that this model was designed for a nationwide system, governance of this domain is required, in order to establish and ensure shared rules or policies with which healthcare providers agree to comply.. Some of the policies to be defined are the following: organizational rules (legal, roles, and structural, basically established by SNIS), operational rules (e.g., SLA, backup and recovery policies, modification and deletion of medical and administrative data), domain registration rules, authentication and access policies, privacy policies, consent, auditing.

Semantic interoperability is based on the definition and management of document formats accepted by repositories, as well as on terms and vocabulary. Moreover, it is also based on the implementation of terminology services, according to a controlled framework with limited and distributed access

Technical interoperability is based on the adoption of some standards and instruments provided by the PDI that are

expanded to include defined standards and profiles established by HL7 and IHE, and implemented on specific instruments such as ESB-PS, EMPI, XDS, and Appliance-PS which are described below.

The integration engine (ESB-PS) is formed by the ESB from the Interoperability Platform, to process specific messages of health protocols. It plays the role of transforming, validating, routing, integrating and performing broadcast actions on messages received from health applications. Within this engine, various source and target ports are set up to carry out data exchange processes. Messages are issued and sent from and to the applications that will be integrated, according to different communication protocols (TCP/IP, HTTP, SOAP, WS*, REST, MLLP) and different messaging formats (HL7 V2.x, HL7 V3, DICOM, X12, XML, EbXML, EDI, delimited text). After receiving the message from a port, it is identified and processed syntactically. Messages are directed within the engine and may be validated and/or transformed. After message is transformed, it may be sent to another target port, according to certain format and protocol. As any ESB, it provides functionalities for managing and monitoring service and traffic.

Appliance-PS allows easy interoperability between healthcare providers and the PS. It is based on lessons learned on e-Government interoperability and it seeks an important level of abstraction to simplify messages exchange and integration. It is an artifact formed by hardware and software that implements layers of services and simple user interfaces. It has two components: one is located in the PS (software) and the other is physical (software and hardware) and is located in provider's sites on a high availability basis. The main functionalities of this artifact are:

Locally, for each provider: i) PGE connector, which solves connectivity, authentication and access to PGE and PS; ii) Messaging, registry XDS (IHE) and HL7v2 and HL7 v3; iii) To make an easier use of EMPI through abstraction and encapsulation of services; iv) Messaging services for XDS Registry for healthcare providers which do not have XDS, as well as for specialized repositories, e.g., PACS and LIS, no XDS. v) Messages withholding in case of interruption of services; vi) Management of Publish & Subscribe services to update EHR of their patients and affiliates; viii) Functionalities for local use of digital signature.

Regarding PS: i) Transforming to CDA Salud.uy those documents which contain minimum required data, but do not meet format standards; ii) specific adapters according to non-standard system's requirements; iii) other nonstandard transformation service for legacy systems.

Other Specialized Components of the PS

The PS hosts the National Index of Healthcare Users (INUS in Spanish), usually known as master table of patients, enterprise version (EMPI), which contains updated information of different individuals ID to supply the affinity domain. This allows each provider to maintain its current ID and to share medical information with the HCEN through a local XDS registry, managed by the provider, which is copied to the National Registry of Medical Information. This registry is also located within the PS, and it receives the information supplied by local registries kept by each provider.

To keep the EHR updated, and in order to minimize data collection during patient's visit, healthcare providers have a Publish & Subscribe service. They may subscribe to this service in order to receive reports on medical acts occurred within the system related to their affiliates. Furthermore, healthcare providers may subscribe to receive medical information related to users registered on special vertical programs, e.g., chronic diseases.

The PS also contains necessary software components to deliver MSP main services related to: i) individuals health; ii) healthcare services (master tables); iii) dictionaries and terminology; iv) reporting systems to inform MSP.

Authentication and authorization

The authentication and authorization model of PS is based on the PGE model, which is based on the federation of identities and, hence, on reliability. This model is centered on PGE and uses SAML 1.1 tokens signed with X509 v3 certificates, to be the unique access point to different services. To do this, the PGE uses a system based on RBAC, where every provider and service consumer has a branch in the LDAP directory of the PGE. In this directory, organization existing roles are defined, which will be used afterwards to authorize the consumption of certain service. This authorization may be achieved with finer granularity: to the extent of a web service operation. Specific roles used by health applications will be managed within the respective applications.

Integrating Multiple Repositories - Specialized and Distributed

Reality demonstrates that different healthcare providers, as well as the PS, have specialized services which require specialized repositories; e.g., PACS (local for each provider and centralized, e.g., imaging experimental plan), LIS, HCEO and other highly specialized services. According to reality, those repositories not always comply with XDS standards; this is the case of current PACS and LIS. But regarding HCEN, it is necessary to integrate information and access. The goal is to obtain an integral view of the patient's EHR, regardless used technologies or data location.

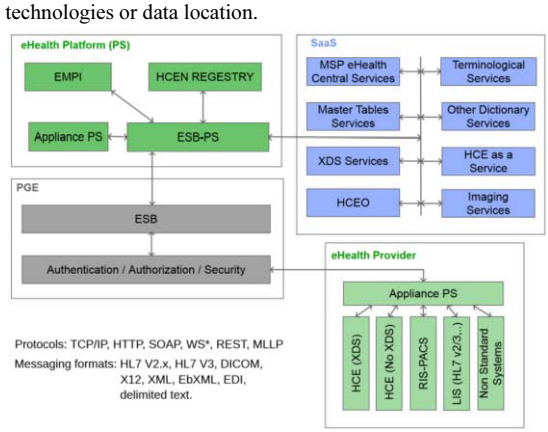

Figure 3. e-HEALTH Platform - components view

Prerequisites: 1) All medical acts, regardless the act type, must be included in the Registry of the HR; 2) All documents, images, reports, among other documents, must be available to duly authorized healthcare staff, whenever is required; 3) The final format of representation must comply with document standards defined by Salud.uy; specifically, regarding images it will be established suitable compression levels for each intended use; 4) Documents must be electronically signed by the healthcare provider, to ensure the identity, authenticity and inalterability of the document; 5) Local representation adopted by each provider regarding their own repositories must ensure the existence of the minimum data required for each kind of document. Moreover, each provider must ensure the fulfillment of the above-mentioned prerequisites.

Mechanisms for the integration of repositories: This diagram (see Figure 3), which naturally shows a diversity of technologies, requires the existence of an integration layer, capable of routing and message transformation. Data transformation to standard formats of presentation is also required. This layer may have specialized services, e.g., Dicom images and their services of publication and access. Figure 3 shows a simplified view of its implementation. As it is illustrated, Appliance-PS is a key part of this architecture.

Current Stage of the PS Development

PGE platform is working with very high and increasing rates of message traffic and implemented services per day. All the functionalities mentioned herein, which are required for the PS operation, are currently operating in a daily basis.

PS platform is still under construction. However, there are two experimental applications which are already operating: HCEO and remote imaging diagnosis. Both led to the experimental use of certain tools, e.g. OpenEmpi, MIRTH. Moreover, it was developed as a specific XDS, which gave us relevant experience and learning. Currently, pilot activities on terminology services are being carried out, in cooperation with the Italian Hospital from Buenos Aires (HIBA in Spanish). Uruguay has entered into an agreement with the International Health Terminology Standards Development Organization (IHTSDO), and plays an active role as an IHTSDO member.

Evolution of the PS platform

This platform will be further developed by the acquisition, construction and integration of products. In addition, the development and creation of tables, dictionaries, minimum data sets, MSP regulations, among other required elements, will contribute to its continuous evolution. Each healthcare provider shall continue with the development of their own EHR, according to standards and technical specifications laid down. Moreover, an appliance-PS will be supplied, which should be integrated in their respective platforms. Cloud services (SaaS) will be further developed in order to make EHR registration, search and exchange of information easier for small health care institutions.

Table 2 – Platform Summary

Platform Summary
The PS is a specialized extension of the PGE, which uses it as foundation for common functionalities.
PGE´s architecture is defined in three layers: a Physical layer, implementing IaaS and PaaS, and two logical layers, IaaS or Crossed-Aplication and the Interoperability Platform (PDI).
All three interoperability layers are covered (Organizational, Semantic and Technical) by the eHealth Platform.
Healthcare providers may be in different stages of technical development. The use of the Appliance-PS accompanied with the PGE Connector fulfills the technical gap, simplifying the interaction with the PS, as well as giving a powerful tool for service governance.
Each Healthcare provider will maintain their user registry, keeping their own ID and information, but feeding the National Index of Healthcare Users.
The existence of a local XDS provided with the Appliance-PS, allows to share medical information with the HCEN
Even the PS is still in working progress, HCEO and remote imaging diagnosis application are on pilot over it.

Conclusion

It has been established that a technological platform with a scalable, reliable, and secure architecture fulfills the needs of the Nationwide Health System. The platform also considers the public policies focused on citizens, contributing to improve their quality of life, and duly assuring information security and personal data protection.

Lessons learned on interoperability at a national level have been applied to the health platform. The integration between the e-government platform and the e-health platform, as well as the operation of the referred networks—salud.uy, red.uy and private networks—allowed the reuse of knowledge, infrastructure and services.

Complex engineering mechanisms related to authentication and access control, exchange of messages assuring security, privacy and information completeness, as well as supporting various protocols and data models, has been solved and will be used by all health care providers.

The challenge that lies ahead is the incorporation of different participants to the eHealth Network, as well as achieving citizens' ownership and use of this platform.

Electronic Dental Records System Adoption

Renata Abramovicz-Finkelsztain[a], Claudia G N Barsottini[a], Heimar Fatima Marin[a]

[a] *Department of Health Informatics, Universidade Federal de São Paulo, Brazil*

Abstract

The use of Electronic Dental Records (EDRs) and management software has become more frequent, following the increase in prevelance of new technologies and computers in dental offices. The purpose of this study is to identify and evaluate the use of EDRs by the dental community in the São Paulo city area. A quantitative case study was performed using a survey on the phone. A total of 54 offices were contacted and only one declinedparticipation in this study. Only one office did not have a computer. EDRs were used in 28 offices and only four were paperless. The lack of studies in this area suggests the need for more usability and implementation studies on EDRs so that we can improve EDR adoption by the dental community.

Keywords:
Electronic Dental Records; adoption; case study.

Introduction

During recent years, there has been an increase in the adoption of current generation technologies in dental offices. Some reasons for adoption include: increasing "green" practices, increasing efficiency, usage of technology as a marketing element, and exchanging patient information with insurance companies.

Green practices include the use of digital photography and radiographs as well as the use of EDR to decrease the consumption of paper and the production of chemical waste.

To improve efficiency and productivity, some offices use rotary instruments, apex locators, computerized anesthesia, intraoral cameras and scanners and CAD-CAM systems.

Additionally, the use of any of the above mentioned technologies themselves are perceived as marketing elements for the patient. The patient notices the up to date context of the office and services provided.

The presence of a computer in an office also allows usage of other applications such as patient scheduling, communication with patients, colleagues and providers, clinical and financial management and also the use of EDR systems.

Lastly, some offices have acquired computers to be able to exchange information with insurance companies, as these companies continually demand this exchanged information to be made digital.

Literature Review

As highlighted by the literature, the use of technologies in dental education began in 2000. In clinical practice computers, in particular, have already been used as an administrative management tool since the 1980's [1]. In 1996, Paul R. Rhodes discussed the main differences between electronic and paper records, as well as their advantages and disadvantages [2]. The visual resources of the EDR were the most positive features in the author's opinion because once the patient was allowed to visualize graphically his or her clinical needs, the satisfaction and acceptance of the treatment were enhanced [2]. Visual resources were also seen as important features by Delrose and Steinberg for use in patient education [1].

As more technologies for dentistry became available on the market, research to evaluate the relationship between dentists and these technologies began to evolve. In Canada there was research to evaluate dentists' perception regarding the use of new technologies and also to determine the presence and use of computers in Canadian dental offices. Researchers verified that 60% of the dentists believed that technology could improve their clinical practice and 90% of the dentists already had computers in their offices [3, 4]. Similar results were found in the USA and England, with 85% of American dentists having computers in their offices while 77% of British dentists having or declaring the intention of acquiring a computer in the near future [5, 6].

Having established the presence of computers in the dental offices, and the use or intention of using an EDR system, authors began to investigate the annotation fields both in paper and electronic records. They noticed a great difference between the records and reasoned that the digital records have a limited coverage of the patient clinical information. Furthermore, they found that fields that are usually together in paper records, are often separated in the EDRs, possibly making it difficult to be filled by the dentists [7]. In order to investigate possible usability problems on EDR systems, Thyvalikakath et al carried out a heuristic evaluation of four systems [8]. The authors described 229 heuristic violations and suggested potential usability problems in all four systems [8]. Despite the deficiencies and difficulties already described, EDR systems are commonly used in dental offices in North America and Europe, as well as in some North American dental schools. Studies have also been performed in dental schools. These studies cover the use of EDRs for a wide variety of themes: pharmacology education [9], the use of controlled terminology to annotate diagnosis [10] and treatment planning by undergraduate dentistry students [11].

A literature review conducted in 2014 showed that despite the great number of articles regarding EDR published over the last decade, only 22% of those were about EDR design and architecture, while 78% were editorials, reviews or articles describing the use of EDR data. In addition, taking a closer look at the articles regarding EDR, only 20% of the studies represented research related to EDR use (adoption, usability, implementation, tools). The other 80% was research that used clinical data from the EDRs to make new scientific discoveries.

Objectives

This study aims to identify and evaluate the adoption of EDR systems in the São Paulo city area.

Methods

Due to the fact that the study comprises contemporary phenomena, a case study design with a quantitative approach was the chosen method for this research [12, 13].

The Ethical Committee of Universidade Federal de São Paulo approved this project.

First, a translation, adaptation and validation of the questionnair,used by Schleyer et al [5] in a similar study in 2006, was performed. This occured after getting permission from the mentioned author. This instrument was chosen for the study because it is well established and frequently used in the literature.

A dentist with proficiency in English did the translation and adaptation into Portuguese. In order to validate the translation, another dentist with proficiency in English back-translated the questionnaire into English. Both versions were compared and if there were a disagreements between the translations these were reconciled by both dentists [14].

A convenience sample of dentists working in the Sao Paulo city area was selected.

Due to the length of the questionnaire (31 questions) and the resistance of the dentists to spend 20 minutes over the phone answering it, the questionnaire was divided into two sections. The first section contained questions regarding the presence of computer and internet access, the size of the staff, quantity and location of computers; and therefore, could be answered by any staff member (receptionist, dental assistant, dental hygienist or the dentist himself). The second section, with more specific details over technologies and EDR adoption was shorter and more objective in order to be answered by the dentist himself.

Each office was contacted at least twice: on first contact the purpose of the study was explained and if consent to participate in the study was given, the first section of the questionnaire was answered. A second telephone contact was made at a more convenient time for the dentist to answer the second section of the questionnaire.

Results

Up to the present moment, seventy-one offices were contacted. For 28 offices there were no successful contacts and for the other 53, contacts were successful.

Of the 54 contacted offices, only one did not have a computer. Of the 53 computerized offices, three did not have internet access, and 47 had cable internet access. In two of the offices that did not have internet access, the computer was used rarely and at the third one daily. For the rest of the offices, the computer was used daily at 44 offices and weekly at the remaining four (Figures 1 and 2).

In terms of the location of computers: four offices had computers only the reception, ten offices had computers only in the office, 11 offices had computers in the reception and in the office, 13 offices had computers in the operating room and in the reception and 15 offices had computers only in the operating room (Figure 3).

The use of EDR systems was observed in 28 offices. The most commonly used system was Easy Dental™ (Easy Software SA, Brasil), being used in 19 offices. The software DentalMaster™ (Micro Imagem, Brasil) was used in four offices and Excel™ (Microsoft, USA) was used in two offices (Figure 4). The majority of offices kept only paper records (29 offices) and only six offices were paperless. The remaining 17 offices maintained records both in paper and in digital format. (Figure 5)

In the offices contacted, there was a great variation regarding the insertion of information in the records as shown in Figure 6.

Figure 7 shows the frequency of computer and internet use to search clinical information.

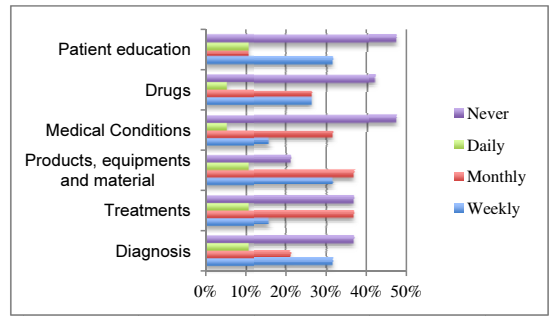

Figure 7- Clinical information search using internet and computers

Discussion

Although computers are available in the majority of the contacted offices (98%), EDR systems have not been used by most of the contacted dentists. The most common scenario is the duplication of records (paper and digital), resulting in an increase in the time spent writing notes on records and a decrease in productivity [5]. Some of the reasons for this duplication of records might be: difficulties in using the systems, mistrust for the EDR systems and a lack of a standardized nomenclature in dentistry. In Brazil, there are at least 14 available EDR systems, with some dating back to 1994. Even though they have been available for 20 years, none of the systems complies with the security requirements of the current Brazilian legislation. In addition, neither the federal, nor the regional Dentistry Councils issue digital certificates for the professionals.

The lack of a standardized nomenclature has been addressed in a number of studies, and specifically in Brazil, the nomenclature used dates from 1995 [15]. More recently, in 2007, the Brazilian National Health Agency established a nomenclature pattern to be used in the information exchange by all insurance companies, including dental ones. Since then, most EDR systems use this pattern to describe dental treatments, but still misses a standard for dental diagnosis. It is important to stress that only the dentists that are registered with the insurance companies use this nomenclature, and therefore, the other professionals are not familiar with it.

Another reason for the incomplete adoption of the EDR systems might be the fact that some of the dentists declared being forced into adopting the systems by the insurance companies, since processing issue treatment authorizations have to be done online. Therefore, they use only the functionalities that are necessary for the authorization process, i.e., registering the patient, his/her insurance information and the suggested treatments.

Although present in the majority of the contacted offices, Internet and computers are not usually used to obtain clinical information. Almost 50% of the contacted dentists never use them to obtain information on medical conditions, and almost 40% never use them to obtain information on diagnosis. Nevertheless, these results are similar to those found in other international studies [3, 5]. In our study, most offices (73%) had two or more dentists, therefore having more than one specialty in the clinic enabling them to consult with one another for this type of information.

People are not afraid of technology anymore. New generations grow up in a world where technology does not intimidate and the way we produce and store information needs to be

efficient [16]. In addition, patients subconsciously register that better dentists have tech savvy offices; while those that do not adopt technology tend to be considered less competent [17].

Even though technology is usually charged with being responsible for impersonal relationships, professionals using them are more productive. This leaves more available time for dentists to bond with the patient in order to strengthen their relationship, resulting in greater acceptance of the suggested treatments and a more satisfied patient.

Even though the sample of this study is small, and not representative of the entire country's dental community, it should influence local councils to issue more comprehensive surveys in order to describe the regional scenario with more details. This way, policies and incentives might better influence the EDR systems adoption by the dental community.

Conclusions

This case study demonstrates a high level of modernization in dental offices as well as adoption of EDR systems, but little clinical use. Contacts with the dentists are still being made until the end of January 2015.

Characterizing the Structure of a Patient's Care Team through Electronic Encounter Data Analysis

Abstract

As the field of medicine grows more complicated and doctors become more specialized in a particular field, the number of healthcare providers involved in healing an individual patient increases. This is particularly true of patients with multiple chronic conditions. Establishing effective communications among the care providers becomes critical to facilitate care coordination and more efficient resource use, which will ultimately result in health outcome improvement. The first step for care coordination is to understand who have been involved in a patient's care and their relationships with the patient. The widespread adoption of Electronic Health Records provides us an opportunity to explore solutions to well-coordinated care. This paper presents the concept of a patient's care team and demonstrates the feasibility of identifying relevant healthcare providers for an individual patient by leveraging electronic patient encounter data. Combined with network analysis techniques, we further visualize the care team structure with quantified strength of patient-provider relationships. Our work is foundational to the larger goal of patient-centered, coordinated care in the digital age of healthcare.

Keywords:

Care coordination; Health information exchange; Electronic Health Record; Patient care team; Network analysis.

Introduction

Care coordination has been identified by the Institute of Medicine (IOM) as one of the priority areas for health care quality improvement [1]. According to IOM, the aim of care coordination is to "establish and support a ***continuous healing relationship***, enabled by an integrated clinical environment." The Agency for Healthcare Research and Quality (AHRQ) defined care coordination as "the deliberate organization of patient care activities between two or more participants (including the patient) involved in a patient's care to facilitate the appropriate delivery of health care services,…, and often managed by the ***exchange of information among participants*** responsible for different aspects of care" [2]. Improved care coordination would have an especially important impact on improving health care processes and outcomes for patients, particularly for those with one or more chronic conditions [3,4]. It also has great potential in promoting efficient use of limited resources and cost savings by avoiding duplicate tests and unnecessary hospitalizations. A recent report published by the Center for Disease Control and Prevention (CDC) estimated that approximately half (49.8%) of US adults have at least one chronic condition and about 1 in 4 adults has multiple chronic conditions (MCC) [5].

Patients with chronic conditions are usually seen by many providers at several locations such as family medicine clinics, specialty care clinics, hospitals, birth centers, urgent care facilities or emergency rooms. The average Medicare beneficiary sees 6.4 different physicians in a year, 4.6 of those being in the outpatient setting [1]. Without well-designed care coordination among various care providers, disconnects in services can occur and result in adverse drug events, missed follow-ups, unnecessary hospitalizations, and duplicative tests.

In order to achieve well-coordinated care, effective communications among the care team members and patients need to be supported. However, the first step for enabling effective communication is to identify who the team members are and what type of treatment relationship each member has with the patient. Certain providers such as primary care physicians (PCP) may maintain an ongoing relationship with the patient that lasts for years or even decades. Some providers may have a continuous relationship with the patient for a period of time. For example, patients usually go to the same obstetrician/gynecologist or maternal fetal medicine (MFM) doctor for a series of prenatal visits. However, the patient-provider relationship usually ends when the perinatal care ends. Other providers may only have a visit-specific relationship with the patient, such as emergency or inpatient physicians. Understanding the characteristics of patient-provider relationships is critical to implement standard, evidence-based care process models and deliver relevant, timely, and accurate patient information to the right care providers, patients and their families. Stage 2 of the EHR Incentive Program overseen by the Centers for Medicare and Medicaid Services (CMS) in the United States requires the summary care record for each transition of care to include a list of care team members beyond the transitioning provider and the receiving provider [6].

Related Research

Electronic Health Record (EHR) systems have been widely adopted in the United States, and a substantial amount of administrative and clinical information have been captured. Such information can be valuable to facilitate care process and improve outcomes if used properly. A previous study evaluated the feasibility of using system audit log data of EHR chart accesses to identity a patient's care team [7]. This study focused on the inpatient setting for a single hospital stay. There is a lack of research in identifying a patient's care team in the ambulatory care settings, which involve a larger number of provider roles and multiple encounters at different facilities. We searched PubMed [8] using MeSH terms "Electronic Health Records" and "Patient Care Team" and did not find relevant articles in the results.

Furthermore, not every provider involved in a patient's care has a continuous relationship with the patient. The closeness

of the relationship between providers and patients varies depending on the patient's conditions and care needs. Network analysis has been widely used in other domains such as biology, geography, web technologies and communication studies. It is a powerful tool to characterize social relationships in terms of network theory, which consists of nodes and ties. Nodes represent individual entities in the network, whereas ties represent relationships between entities [9,10]. However, network analysis has not been widely applied in the healthcare domain.

Project scope

The goal of this paper is to examine the feasibility of leveraging patients' encounter data, which include both clinical and administrative information about each patient visit, to identify patients' relevant care team members. We further quantify and visualize the strength of the relationship between each care team member and an individual patient based on the frequency and timing of office visits using network analysis technologies.

Methods

Healthcare Setting

Intermountain Healthcare is a non-profit system that operates 23 hospitals, a medical group with more than 185 physician clinics, 3,000 affiliated physicians, and an affiliated health insurance company, SelectHealth. It is the largest integrated system of health care facilities in the Intermountain West region of the United States. Intermountain Healthcare serves about 2.6 million patients, with more than 3.7 million ambulatory visits and 400 thousand inpatient stays each year.

Data Sources

The enterprise data warehouse (EDW) at Intermountain Healthcare integrates clinical data, financial data, claims and eligibility data from electronic systems across the entire enterprise [11]. The EDW loads data daily from various source systems such as the clinical data repository, pharmacy, cancer registry, enterprise master patient index (EMPI), accounts receivable, SelectHealth claims, and laboratory and radiology systems. It is designed to support Intermountain's clinical operations and research efforts. The EDW is organized as a collection of various data marts, which consolidate and integrate data from separate systems to support a specific clinical operation area.

We identified data marts in the EDW relevant to the purpose of this project containing patient encounter data dating back to 1997. Although originally designed suitable for specific use (billing), in general the data marts include visit type (e.g. inpatient, outpatient hospital, office visit, emergency department, urgent care, etc.), visit or service date, provider information, diagnosis, facility information, payer, and other financial information. The hospital data mart includes 44 million records and the ambulatory data mart includes 66 million records. Each record has a unique identifier for that specific encounter, which links to the unique patient identifier maintained by the EMPI.

Relational database tables in these data marts were queried using Oracle SQL Developer to extract patient encounter records meeting certain criteria. Resulted datasets were used for further statistical and network analysis. Specifically, queries were developed to address the following questions:

1. How many encounters (both inpatient and ambulatory) are recorded in EDW for each patient? How many encounters does each patient have for the past 7 years, and 3 years?
2. How many care providers are documented in each patient's encounter records? What are their roles?
3. What is the closeness (or distance) of the relationship between each care provider and the patient? Do patients see some care providers more often than others?

These questions are critical to help us understand the feasibility of using encounter data to extract patients' care team. If the number of encounters for each patient is too large, the care team extraction may need to be deployed offline in a batch mode so that it will not impact the real-time user experience. In order to get the complete and most relevant care team member, a time constraint may need to be applied to the encounter records. For example, inpatient stays happened 20 years ago may not have any impact on patient's current care team.

Statistical and Network Analysis

Datasets extracted from Oracle queries were analyzed using R (version 3.1). Descriptive statistics were used to characterize the patient encounter and care team patterns, both inpatient and outpatient. We performed network analysis using Pajek [12] to visualize the structure of a patient's care team. In this paper, we primarily focused on ambulatory visits that may result in a continuous relationship between the provider and the patient. For example, PCP office visits are more likely to indicate a continuous relationship between the provider and the patient compared to inpatient and urgent care visits. This assumption is based on the ultimate goal of this project, which is to facilitate care coordination by notifying a relevant healthcare provider about the patient's condition. Specifically, we extracted encounters in the ambulatory data mart that have a place of service code with any of the following values: office (11), home (12), assisted living facility (13), place of employment-worksite (18), birthing center (25), nursing facility (32), hospice (34), community mental health center (53), or end-stage renal disease treatment facility (65). The place of service codes are standardized by CMS for use on professional claims to specify the entity where service(s) were rendered [13].

As a proof of concept, we randomly selected a few sample patients to illustrate the structure of a care team. The "strength" of the relationship between a patient and each care team member is quantified by taking into account both the frequency and timing of interactions (encounters) between them. For example, if a patient had 20 encounters with his/her family doctor and only 2 encounters with a cardiologist, then we consider the patient has a closer relationship with his/her family doctor. If a patient had 20 encounters with family medicine doctor A, which all occurred five years ago and 7 encounters with family medicine doctor B in the past two years, then we consider the patient has a closer relationship with doctor B. As shown by Equation (1), the strength of the patient-provider relationship (SPPR) represents the closeness between a patient and a provider. It is measured by the total number of visits divided by the number of months between the current date and the last visit date. If the most recent visit is within a month, the closeness is simply measured by doubling

$$SPPR = \begin{cases} total\ number\ of\ visits \times \frac{30}{current\ date - last\ visit\ date} & (if\ current\ date - last\ visit\ date > 30) \\ total\ number\ of\ visits \times 2 & (if\ current\ date - last\ visit\ date \leq 30) \end{cases} \quad (1)$$

the number of visits (as is the case when current date-last visit date =15).

Results

Patient Encounter Patterns

Table 1 summarizes the distribution of the number of both inpatient and outpatient encounters for all Intermountain patients. It is a skewed, long-tail distribution, which can be indicated by the small median values. Although the maximum number of encounters is large, 96% of the patients have less than 100 encounters in the database.

Table1– Summary statistics for number of patients' encounters (derived from both inpatient and outpatient visits)

	Patient Population	Minimum	1st Quartile	Median	Mean	3rd Quartile	Maximum
All data	4.2 M	1	2	7	22.5	25	2278
Last 7 years	2.8 M	1	2	7	17.1	20	1135
Last 3 years	2.1 M	1	2	5	10.9	13	578

Figure 1 shows the number of visits by year for three randomly selected patients. As shown in the diagram, the number of visits across patients can vary greatly and there is no consistent pattern for each individual patient. The frequency of visits mostly depends upon individual patient's health status and disease progress.

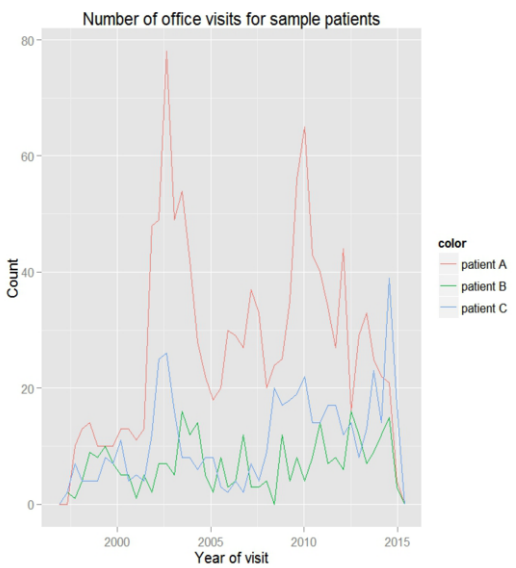

Figure 1– Number of office visits for sample patients

Care Team Patterns

Table 2 summarizes the distribution of the number of unique providers in a patients' care team, identified by querying encounter records for all ambulatory visits. Similar to the encounter distribution, the size of a patient's care team follows a long-tail distribution (as shown in Figure 2). Although the maximum number of care team members for a patient is large, 90% of the patients have less than 10 care providers recorded in their office encounter records. Figure 3 illustrates the distribution of the number of providers for patients with more than 25 care team members.

Table2– Summary statistics for the size of patients' care team (derived from office visits)

	Patient Population	Minimum	1st Quartile	Median	Mean	3rd Quartile	Maximum
All data	2.5 M	0	1	3	4.2	5	93
Last 7 years	1.7 M	1	1	2	3.1	4	56
Last 3 years	1.2 M	1	1	2	2.4	3	34

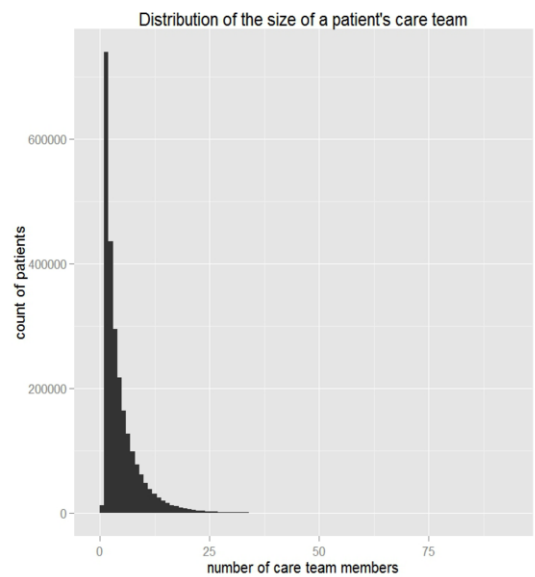

Figure 2– Frequency distribution of the size of patient's care team

Care Team Structure

Figure 4 illustrates the structure for a sample patient's care team. The patient is represented by the red dot in the middle, and each care team member is represented by a green dot labeled by a number index with his/her specialty. The distance between red dot and each green dot represent the strength of the patient-provider relationship, which is calculated as described in the method section. As a proof of concept, only a subset of the sample patient's care team is included in the diagram.

Discussion

Care teams were be built for most patients in real-time. For a small percentage of patients with large number of encounters, care team were be built offline to alleviate the impact on system

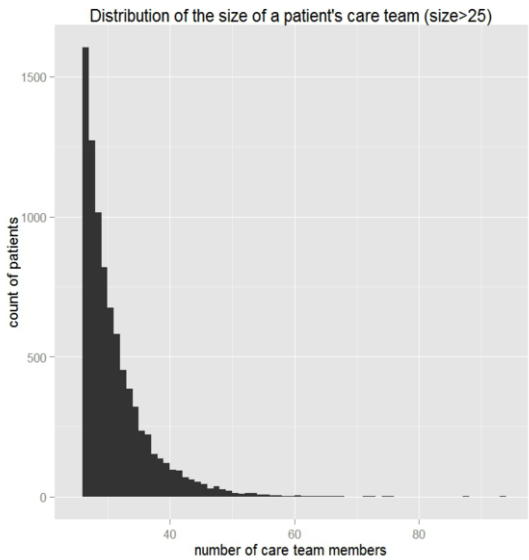

Figure 3– A zoom-in view for the distribution of the size of patient's care team for patients with more than 25 unique providers

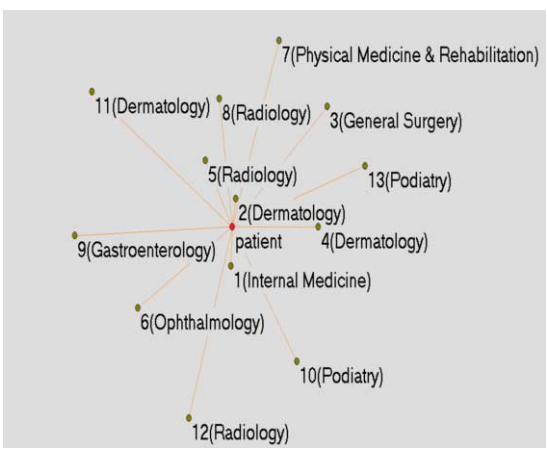

Figure 4– Structure of a sample patient's care team

performance. The structure of a patient's care team evolves dynamically and should be updated each time a patient has an encounter.

To generalize the results to other institutions, careful considerations should be followed to identify the most appropriate data sources containing healthcare providers' information.

The study is limited by the lack of formal evaluation of our proposed measurement for the patient-provider relationship. By manually examining sample patient records, the measurement reflects the closeness between a patient and healthcare providers. However, a structured methodology needs to be employed to validate and improve the accuracy of our proposed measurement. A possible approach would be to display the care team structure to patients and clinicians in patient portals or provider portals and capture users' feedback.

For future work, we plan to extend the care team analysis by including documents received from health information exchange transactions. The sender information indicates a treatment relationship with the patient and our extended analysis will generate a more comprehensive care team by including providers outside of Intermountain. In addition, we plan to analyze and visualize the provider-to-provider relationships beyond the patient-provider relationships (e.g. a cardiologist and the referral doctor). This is important to identify the disconnections in the patient care process. We plan to explore the association between the number of diseases of a patient and the size of his/her care team. Finally, to validate and improve the accuracy and completeness of the derived care team, we plan to display the care team structure to patients and clinicians in patient portals or provider portals and capture users' feedback.

Conclusion

Curating the list of the healthcare providers from multiple care settings who are involved in a patient's care to keep them informed with relevant patient health information is critical to achieve effective care coordination and improve health outcomes. We demonstrated the feasibility of identifying patients' care team members using the electronic patient encounter records.

An Information Paradigm Shift is Required to Realize EHR Benefits

Evelyn Hovenga[a], Heather Grain[a]

[a] *EHealth Education Pty Ltd, Melbourne, Australia – www.ehe.edu.au*

Abstract

The use of EHRs and the benefits from them are significant for healthcare and health informatics. Data form the basis for any EHR and its potential to realize these benefits. This paper considers the housing of information and knowledge management in an EHR system. Are we experiencing a revolution in healthcare? Findings from an investigation of alternative approaches, followed by an evaluation of the importance of the adoption of a standard information model relative to benefit realization, is presented. We conclude that an EHR in any environment is not limited to sharing or information exchange. A paradigm shift in thinking, based on the requirement for standardized concept representation, is required. This is an essential prerequisite for a new vision of healthcare supported by digital technologies.

Introduction

Healthcare in its current form is not sustainable [1]. Information technology is increasingly used as a means to improve information availability and flow to support healthcare delivery and outcome improvement. Despite this, these systems often deliver minimal benefits rather than an integrated raft of positive outcomes for the investment. Consideration of maximizing benefits is rarely undertaken.

Healthcare is dependent upon information systems from disparate vendors who have their own information structure, which they value as intellectual property. It is to the advantage of vendors to retain their existing structure as this makes their systems unique and encourages take up of associated products from the same vendor. The impact of this is information representation that is inconsistent between products and systems. There is a need for the introduction of a disruptive technology.

Healthcare is a team activity requiring multiple uses of the same data by different members of the team at different times for a variety of purposes. They need to make use of numerous alternative technologies even though many information system implementations focus on singular activities, or worse singular data representation minimizing multiple data use opportunities.

Traditional knowledge acquisition methods, such as clinical trials, are limited in scope, costly to run, and take time to deliver viable results. Information stored in health records could be used to reduce time and costs associated with knowledge discovery but this is not on the agenda for most healthcare system implementations. Traditional reporting and statistical analysis for public health, finance, and other purposes are equally expensive and dedicated to singular purposes, rather than finding their place in the data continuum.

A limiting factor in decision making and project management in health informatics is a lack of understanding on the part of healthcare administration. That is, many healthcare administrators neither know essential components, nor do they possess the skills needed to support their decision making and projects. There is a resistance to start fresh with systems due to existing investment, yet when major new investments are made the long-term vision is often lacking.

Transition strategies to move towards realizing a long-term vision are not in place. Such transition requires the use of existing systems in a manner that enables a progressive move towards a defined vision. Lack of understanding of such a journey is a consistent problem, as demonstrated by a focus on projects of implementation, rather than of progressive development of data, systems and people.

Methods

This research represents findings based upon a range of information gathering methodologies. These include literature review, participation in, and interviews with, key experienced eHealth standards developers and implementers, and an analysis of:

- The outcomes of eHealth initiatives and implementations
- The capabilities of current systems and approaches
- The outcomes declared
- Skill development initiatives
- The characteristics of data, information and knowledge and the relationship between the information to be shared, stored and retreived and how that relates to the technical infrastructure, and
- Inhibitors/enablers such as funding arrangements, organisational structures.

This paper focuses on an evaluation of our findings. It's important to differentiate between EHRs and EHR Systems. EHRs are essentially a data repository that needs to be an integral part of an entire healthcare system. Early information systems in healthcare were all about reporting and finance. Today these requirements, though still present vie with the need to represent data for healthcare requiring different data representations. This variety of data representation in information collection systems and the requirements for standardized but different representations for different healthcare reporting and other purposes present a unique data dilemma.

These differences stem from two primary causes:

1. The requirement for data use in patient care to accurately and reliably represent facts,

2. Reporting systems requiring classified data that aggregate concepts.

Classified data indicate where necessary that a case fits in the 'other category' or special rules apply for how to collect the data (e.g., when coding clinical data into the International Classification of Diseases (ICD), any version codes). Each approach to data is relevant to purpose but every purpose requires different data presentations whilst data also needs to be managed across the continuum of use. Though the principle of data re-use is often discussed, the need for consistent approaches to achieve the conversion of data from disparate systems and information models is a challenge. This challenge is made more difficult as the original data meaning may vary based on context. These differences lack clarity in the absence of a comparable information model in a system using meaning based data representation.

The variations in original systems and the requirement needs for standardized reporting, mean that conversion approaches such as data maps are being increasingly used. Such maps are only consistent when built and applied to a single known purpose [2] and must be kept up to date. Lack of appreciation of the implications of using maps results in data which appear comparable but which may not actually be so.

Importance of a Standard Information Model

Health software vendors have traditionally controlled the structure and representation of information in healthcare systems and consider these data structures proprietary. This has resulted in data representation and systems that do not share common meaning and require effort to share data with others and to manage data over time. This approach discourages healthcare system purchasers to change their systems to reduce disruption and cost, but this approach exponentially increases costs due to increasing maintenance costs with potentially negative impacts on safety, and the ability to cost effectively, accurately and comprehensively represent EHR data across the healthcare continuum.

Investigation of implementations of electronic health record systems to date has shown that it is common for these proprietary systems to be chosen and implemented with a vision aimed at solving simple problems, such as transitioning from paper based to electronic record systems or to support improved information access with little consideration of the greater list of functional requirements [3-5]. Nguyen et al. [3] identified serious 'concerns regarding the accuracy and completeness of records'. These authors also identified a need for further work into information system quality for EHR implementation evaluative research. The result of this extensive literature has demonstrated that current EHR limitations have resulted (or will result) in the need to change systems. Furthermore, systems must undergo costly reinvention of the data, and associated data exchange protocols, for current systems to be extended to address new functional needs as these arise.

The research gap identified also demonstrates a lack of understanding of the new paradigm of health data pertaining to the world healthcare initiative's focus on information exchange. Though there is no doubt such exchange is necessary, a more critical requirement is to be able to accurately extract subject data via computer processing without loss of meaning. There is a strong relationship between data accuracy and the technical schema used for data exchange. This is poorly understood and rarely seriously considered in system implementation, yet functional requirements determine the degree and type of interoperability and hence technical schema/system architecture required.

Electronic Health Record systems are being widely adopted with the intention of delivering some or all of the following benefits:

- Longitudinal patient records – records able to be retained, queried and retrieved over time to support patient care and knowledge acquisition.
- Retrieval and presentation of the right information to the right care provider or to the patient/caregiver to support clinical care and improve health outcomes
- Use of clinical decision support to improve the application of clinical knowledge and health outcomes
- Facilitate information exchange
- Enable patient / caregiver access to information
- Support reporting and data re-use
- Enable knowledge acquisition from systems
- Support research and epidemiology/public health

The implementation of electronic health record systems tends not to differentiate between the record and the systems used for data collection and exchange to support such records. Existing systems and paper-based records often convert data without considering the actual clinical knowledge relationships between the data and systems prior to the need for conversion.

In some cases, much has been achieved despite this lack of vision and understanding of system capacity and requirements through the individual efforts of clinical informaticians with the knowledge to creatively implement system approaches to data and knowledge [6]. Where understanding and skills to implement change are combined, significantly more is achieved. Of the implementations around the world, which have delivered significant benefit, few have done so without leveraging such expertise and leadership.

Significance of System Interoperability

Many standards are designed for information exchange for a purpose. HL7 internationally is moving towards a single terminology representation shared across all of its products, and many countries are standardizing national data dictionaries. The move to the use of well managed terminologies such as SNOMED CT, LOINC or the use of a machine readable terminology source such as the Unified Medical Language System (UMLS), support this need. These innovations are not required, however, to be applied to health records *per se*. We have found through experience that a general reusable terminology cannot serve all aspirations for clinical information systems that need to make use of data contained in EHRs. In addition, it is necessary to consider data structures and the meaning of data (context) relative to the technical system architectures in use. Only then are distributed systems enabled to exchange information in a meaningful and accurate manner. This requires system architectures that make use of a common standard reference model.

The development and use of sustainable clinical information (concept) models, used in conjunction with these terminologies, that use standard data types and defer to a standard information model, is less well understood and rarely implemented, Brazil [7] and Norway are two notable exceptions. National adoption is the best possible solution to maximizing the value of EHR adoption for all parties, including software developers/vendors.

Semantic requirements between distributed systems as used by the health industry were investigated with a goal of determining whether, and perhaps why, healthcare differs from other industries with similar issues.

Health data is certainly more complex than other industries (e.g. accounting), but the complexity, or even the dynamic nature of health information, is not that which sets it apart from other industries. Rather, it is that this complex and frequent evolution of knowledge must be continually accommodated by EHRs in a timely manner.

Accountancy has used a consistent information model for many hundreds of years. The terminology used is largely numeric and therefore consistent and comparable. The general ledger approach is consistent around the world and understood by all systems, with local modifications within known rules and knowledge of concepts, such as income, profit and loss, or cost of goods sold. Healthcare does not have such a standard structure for information and this, along with the complexity of health data, is a significant hindrance to progress.

Adoption of a standard information model provides context. It supports simpler and cheaper information exchanges between multiple systems using the same information model [8]. It also supports the development and maintenance of rule-based clinical decision support, which can be applied universally in such systems, automation of reporting and many other healthcare functions requiring extensive accurate data and knowledge use. This includes accurate data aggregation from multiple individual EHRs (big data) and linkages with other types of data for research, public health, and epidemiological use.

Why is This Not Well Understood?

The literature regarding research aimed to achieve semantic interoperability for distributed systems has by and large been undertaken by software architecture developers and other technical experts, who as a rule do not appear to have fully appreciated or understood health data characteristics, its variability, evolution, uses, or the need for accuracy.

A review of the courses offered for health professionals revealed that it does not have a workforce with an understanding of data and systems, today's methods of data collection, or health record data storage structures. Projects associated with health data collection rarely include an education or skill development strategy for the data, information, knowledge continuum nor its link with available information and communication technologies. Often, existing expertise is not sought, and implementation plans are developed from scratch. In addition, a review of ICT courses offered by Australian Universities revealed that semantic interoperability is rarely mentioned, nor is data science a topic that is routinely included in such courses.

The lack of a skilled workforce and poor use of expertise is another contributing factor to the cost of new initiatives and change. The health workforce is large and highly skilled already. The inclusion of additional knowledge in already stressed courses is problematic unless this can be integrated in current curricula. A significant limitation is that those who teach in university programs are often not cognizant of the impact of, or need for, knowledge of health informatics in their professions [9].

Health Informatics as a profession has worked to define its body of knowledge and to encourage quality education [10]. However, the existing workforce needs practical and often just-in-time learning opportunities. Only a small number are likely to return to university-based education to develop the skills they need. Australian universities offering Health Informatics courses struggle to attract and sustain a significant number of students. Alternative approaches to skill development are needed.

Another reality is that educational organizations have few health informatics skills. The research-based university model delivers highly skilled individuals with highly specialized knowledge, but few with skills in teaching the broader emerging societal and industry requirements of health informatics. Maintenance of skills across this broad area of needed knowledge is difficult and undervalued. Universities are hampered by the lack of demand, employers do not understand the skills they need in their organizations, and the workforce does not see rewards for having knowledge of health informatics. This cycle of demand must be broken if investment in education of practical value is to be delivered.

Discussion

If the electronic health record is to be sustainable, a technology agnostic solution is needed. An effective solution would not be system-dependent, but rather it would be data-dependent. Only then is the delivery of health record systems that are vendor, time and technology independent, possible. If this is achieved, patients, providers, vendors, organizations and governments can move to new technologies, and continue to use and gain value from the data in existing systems. It will be possible to develop any number of niche application systems that all link to EHRs with increasing sophistication.

A nationally shared standard information model, which is clinically valid, maintained and represents an ontology based concept representation system, is a key requirement to achieving this sustainability. CEN/ISO 13606, a European norm also approved as an international ISO standard [11], identifies a common high level model and archetype (content) models for such information. It defines rigorous and stable information architecture, designed to achieve semantic interoperability in electronic health record communication [12]. Implementations of this approach include the OpenEHR clinical knowledge resources, which represent a maximal model of the concepts stored in healthcare records [13]. Content models using standard terminologies such as SNOMED CT or ICNP to represent clinical concepts can reference this information model.

The relationship between the information model, concept representation and the technical infrastructure or systems architecture needs to be better understood. Collectively these components deliver digital systems that suit all healthcare environments. Achieving this vision requires the implementation and use of internationally accepted formal and informal (e.g., well governed open source standards). Adoption requires a deliberate initiative aimed at taking advantage of new technologies. This transitioning to a fully digital world is no different than transitioning from the stone or industrial or information ages; It's about empowering a paradigm shift to the use of a disruptive technology. For such a shift in thinking to be achieved there is a need for relevant professional development of the health workforce. What is the knowledge and skill gap?

Unless we understand and leverage the paradigm shift we will be implementing solutions which are not sustainable, which require change and are expensive to constantly fiddle with. The health and ICT workforce need to appreciate that:

- Change regarding data use is with us (from a technology perspective, who knows what is next).
- There is need to adopt strategic thinking, to better plan, take advantage of opportunities and minimise risk.
- Decision-making methods need to change; implementation decision making needs to be in line

with a vision for the electronic record, beyond that of simply implementing a system, or replacing paper based records. That vision seeks a more long-term sustainable solution. Community and workforce expectations can be met (sustaining the workforce) via integrated just-in-time learning.

Knowledge gaps include:

- Understanding, using and governing data, including the technical infrastructure needed to maximise potential use and the continuum of data use).
- Ability to identify key data for which data governance strategies need to be adopted.
- Understanding the pathway from business case and functional specifications development of EHRs and related system, to system acquisition, implementation and use - this is a journey; purchasing software is not a destination.
- The knowledge and skills needed to best complement existing expertise and meet potential new role requirements.
- Knowledge and skills required to design and implement systems that meet patient/customer, organisational, disciplinary, optimum work and information flow and national data requirements to suit multiple purposes.

A complete understanding of what is required of data and systems to achieve the desired outcomes across our data and systems is needed. Such understanding enables a vision of the future and a truly progressive transition to that future.

Conclusion

It was found that projects and systems around the world tend to focus on delivering local immediate needs at the expense of considering a bigger vision. Future proof and sustainable EHRs with associated systems for which the local implementation is simply a beginning representing a significant component of a much bigger system. It is about small data supporting healthcare at the point of care, but also about big data supporting research and new knowledge acquisition and discovery.

Therefore we concede six unresolved priorities: 1) Adoption of a standard open information model for all of healthcare, 2) use of consistent concept representation where appropriate, 3) an information and knowledge governance strategy and implementation approach, 4) the conversion of existing knowledge into a computational format consistent with the information model, 5) a concept representation system, and 6) appropriate workforce skill development. This includes the automation of reporting or statistical analysis. At the resolution of such priorities, technology will evolve along with the field's knowledge of best practices, and data collection processes will be usable, calculable, and sustainable.

Every nation needs a transition strategy that makes the best possible use of existing EHR systems, concurrently with a future vision and a strategic pathway towards realizing that vision. This requires a paradigm shift in thinking by all decision makers.

Template and Model Driven Development of Standardized Electronic Health Records

Stefan Kropf[a], Claire Chalopin[a], Kerstin Denecke[a]

[a] *Innovation Center Computer Assisted Surgery, University of Leipzig, Germany*

Abstract

Digital patient modeling targets the integration of distributed patient data into one overarching model. For this integration process, both a theoretical standard-based model and information structures combined with concrete instructions in form of a lightweight development process of single standardized Electronic Health Records (EHRs) are needed. In this paper, we introduce such a process along side a standard-based architecture. It allows the modeling and implementation of EHRs in a lightweight Electronic Health Record System (EHRS) core. The approach is demonstrated and tested by a prototype implementation. The results show that the suggested approach is useful and facilitates the development of standardized EHRSs.

Keywords:

Electronic Health Records, Reference Standards, Information Storage and Retrieval, Medical Informatics Applications, Medical Records Systems, Computerized, Health Information System

Introduction

Patient data are distributed in heterogeneous information systems [1] Accordingly, physicians need to interact with several systems to get a complete view of the health status of a patient. In addition, researchers need to access and reuse patient data for calculations or studies. In both scenarios, it is crucial to have all relevant patient data available and accessible in a standardized, patient-specific information model (IM) [2]. The concept of digital patient modeling adresses this issue and aims at integrating patient data which is distributed in several information systems [3]. Patient modeling on an information model layer corresponds to the development of standardized EHRSs, both for research and for health care, preferably following the open source approach [4]. At a first glance, the development of standardized EHRs and systems that handle these EHRs (an EHRS) seems to be an old-fashioned topic, where practical instructions and solutions already exist. Indeed, EHR standards are available. However, there is a lack of accessible instructions regarding how to apply these standards in practice, and more specifically, how to use standards in real world environments. Most reviewed health informatics-related standards can be classified [5] (ISO 17119) from the perspective of "what," along with conceptual specificity. Standards which can be classified from the alternative perspective of "how," and with *physical* specificity – like the ECG protocoll definition defined in EN 1064 – are rare. This is also reflected by the large number of publications that mainly concentrate on conceptual or logical specificity [6-8]. For implementing standardized EHRSs, developers need methods and instructions or practical solutions like Free Open Source Software (FOSS) analyses [9], the storage of data in persistence layers [10] or ideally an API, [11] development workflows, [12] or even a complete usable EHRS [13]. Therefore, this work introduces a system architecture that combines openEHR and XForms for the development of standard-based EHRs and EHRSs. These standards have been chosen since XForms is a well-established standard of the World Wide Web Consortium (W3C), and openEHR is recommended by e-health authorities such as NEHTA [14]. We used these technologies to build an information system for monitoring patients diagnosed with pituitary adenoma as a proof-of-concept. This paper focuses on the technical details of the development process.

Materials and Methods

We suggest a model-driven architecture based upon existing standards. Such a design principle decouples modeling processes from development processes. Standards are used to fulfill basic requirements in system design such as accessibility, reusability, and interoberability to achieve long term durability. The approach combines W3C-standards originating in web development with openEHR standards (see figure 1). These two groups of standards are interconnected: Instances of openEHR archetypes are mappable to XML.

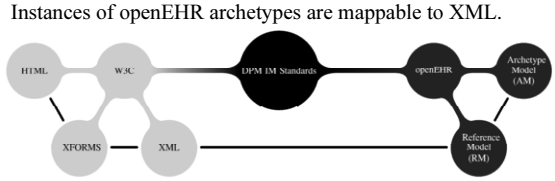

Figure 1: Selection of related W3C and openEHR standards

In the following, the selected standards, methods, and the development process are described. Later, we reflect upon issues that have been considered in the development process.

OpenEHR

Choosing the right standard for an EHRS is a challenge [15, 16]. Normative EHR information models have already been published by the European Committee for Standardisation (CEN)/Technical Committee (TC) 251. These European Norms are based notably on openEHR [17] and Health Level 7 (HL7) v3 Reference Information Model (RIM) [18]. OpenEHR archetypes are transformable to EN 13606 archetypes and vice versa [19, 20]. Both EN 13606 [17] and EN 14822 [18] are suitable for the information model, but openEHR delivers the most comprehensive approach. In short, openEHR delivers a large set of generalized, predefined, standardized building blocks (the archetypes). Reuse of these building blocks is ideal, because they provide a highly

qualitative result of a collaborative development process of domain experts.

However, the collection and ordering of data should be a doctor's first function [21]. openEHR enables domain experts to create information structures without the need of a detailed technical understanding. Such domain modeling by experts is a great opportunity, because physicians can be integrated into the structuring process of medical records, [22] yielding a better understanding of the importance of well-structured, finely granular medical records. Further, it minimizes the need of tasks that invoke expensive downstream processing of natural language.

XForms

XForms is a standard published by the W3C. It follows the Model View Controller (MVC) pattern by seperating the model from its representation [23].

Figure 2 illustrates the XForm technique: The GUI and the input fields are bound directly to the XML via the XForms standard. Important for further reading is the model tag inside the XForms markup. It is located in the header of the file and includes the instance of the model, mapped to XML with possible localized namespace declarations.

The body of the XForm consists of model entities, referenced by a simple "ref" attribute. Figure 2 shows this convenient approach. A simple XPath reference binds input fields to the model definition. This binding concept demonstrates the core idea: The openEHR and XForms standards are glued together to benefit from their respective advantages. The digital patient model of one single EHR is represented by the corresponding model element in an XForm [2-12 in Figure 2].

Related OpenEHR Based EHRS

There are several openEHR-based frameworks available. Some of them are independently usable by the underlying persistant layer, such as Chen's openEHR Java reference implementation (http://github.com/wware/openehr-java/). Other approaches are bound to schemes in relational databases. LiU EEE (https://github.com/LiU-IMT/), medrecord (http://www.medrecord.nl/overview/), and EHRflex (http://ehrflex.sourceforge.net/) use XML databases for their persistant layer. Initial tests showed that the Representational State Transfer (REST) architecture of LiU EEE and medrecord is the most promising approach for realizing an EHRS. The REST architecture was already tested in openEHR implementations and showed how an EHRS should work physically [24, 25]. Consequently, we have chosen a REST architecture for our implementation. In addition, our approach combines XForms and openEHR, which results in a standardized storage of patient data in the system. To the best of our knowledge, such an approach has neither been introduced nor implemented previously in the context of patient modeling.

Development Process

The development process is divided into (i) model development and (ii) model-driven application development. This separation of the modeling process from the development process is highly beneficial, as it "empowers the health professional to define and alter the accurate knowledge and information they need in the granularity they need" [22]. Figure 3 shows the separation of work.

Domain Experts develop domain models

Within our concept, domain experts develop the domain model using the openEHR tools archetype editor and template designer. These tools enable clinicians to model their medical records themselves without deeper knowledge about databases.

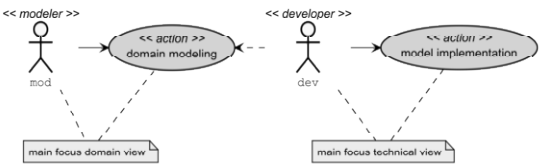

Figure 3: Separation of domain modeling and application development

Figure 4 illustrates the model development portion of the pipeline:

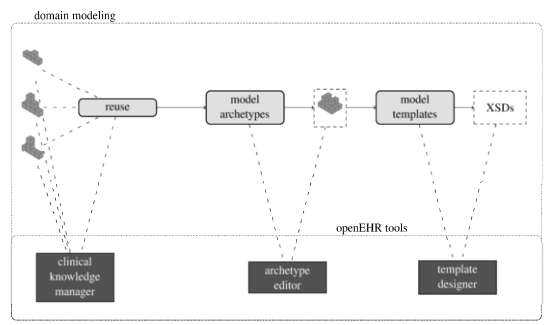

Figure 4: Domain modeling: generation of XSDs underpinned by openEHR tools

The first step in the domain modeling phase is the selection and, thus, reuse of existing building blocks – the archetypes. With the Clinical Knowledge Manager (CKM) [http://www.openehr.org/ckm/], a web repository of openEHR-compliant relevant archetypes for a specific application can be identified. Reuse of archetypes is beneficial for achieving a high degree of semantic interoperability among systems.

After identifying reusable archetypes, they are constrained to the specific use case [26]. New domain-specific archetypes can be modeled with the openEHR-tool archetype editor [27].

This modeling process yields archetypes that are formulated in a standardized language, the Archetype Definition Language (ADL). They are combined in so-called templates (i.e., larger structures), using the openEHR-tool template designer [27]. This concept of building templates out of smaller building blocks increases the probability of reusing single archetypes in different templates. Finally, after this modeling process, models are exported as XML Schema Definitions (XSDs). The W3C XML Schema provides a usable solution for the semantic validation of standard-based EHRs [28]. These

XSDs are then used as input files for the next phase: the model-driven application development.

Model-Driven Application Development and Architecture

Figure 5 shows the process of the application development and the system architecture in general. Out of the XSDs generated in the domain modeling phase, valid XML files are created. We refer to these files by the term "skeleton," because they do not contain real patient data. To put it differently, they are the EHR templates. For each XSD, at least one corresponding XML skeleton is generated. Such an XML/XSD pair enables the validation of the EHRs according to the models at any time, which is highly beneficial, because standard compliance is ensured. The XML/XSD pairs can be exploited as a starting point for development using XML techniques like XSLT, or direct programming of the XML-DOM. However, in this paper, another more accessible solution is proposed: The generated valid XML is inserted into the XForms model and input elements are bound to the XForms model.

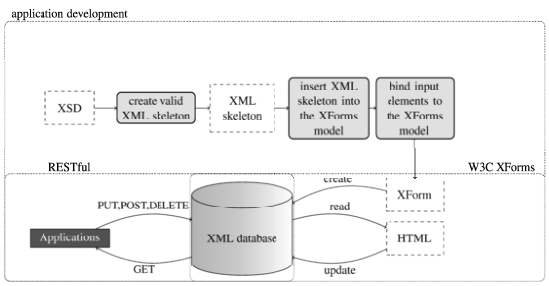

Figure 5: Model driven application development: XForm generation based on XSDs

The source code in Figure 2 shows the approach. To keep this paper as simple as possible, only an extract of one input field is listed. In practice, the instance/model part will be more complex. However, the integration of the model remains simple since it consists of only one copy/paste step. After this insert, the widgets are bound to the model with the "ref" attribute. Finally, the form just has to be designed. After these processing steps, an XForm with an integrated EHR model is stored in the XML database. The form data can then be read and viewed by clients, and updates can be stored and managed by the underlying open souce XML database system eXistdb [29].

In addition to the XML-XForm-GUI binding, the XML database enables the retrieval and storage of complete EHRs via the REST interface, which will be very handy for any kind of future development. In essence, the left side of Figure 5 illustrates that applications can easily access these XML data by a RESTful interface instantly delivered by the XML database eXistdb [30].

Results and Discussion

In this paper, a complete development process for standard-based EHRs was introduced. The domain modeling promises a high quality of the underlying models, and the application development ensures a rapid implementation. To achieve a high level of interoperability, the process starts with the reuse of archetypes, integrates free modeling tools, and ends in an accessible XML-based EHRS. The resulting XML can be interpreted as one possible representation of a personalized digital patient model. The archetypes and templates resulting from the domain modeling task are not only simple structures of information or web masks. Instead, they are valuable sources for other clinicians at other sites, formulated in a standardized language (ADL). These models can be published in worldwide repositories, which allows their reuse in other contexts where they can achieve a similar impact as publications in journals or conferences.

As a result of the combined usage of the EHR standard openEHR and the W3C standard XForms, a high level of accessibility, reusability, interoperability, and therefore long term durability is achieved. Essentially, the combination of the HL7 v3 RIM and XForms would work similar and would benefit also from the following advantages:

Nowadays, most of the information systems are internally based on traditional relational databases [31]. Much effort has to be done to convert this data into different formats (e.g., Extract Transform Load (ETL)). These ETL processes are very time consuming and also error-prone. To avoid these drawbacks, XML-based messages and whole XML-based EHRSs may become a standard solution in medical informatics (at least for small EHRSs).

The benefit of this paradigm shift is obvious when comparing this approach to other developing processes of semantically interoperable EHRs [7]. The main reason is that object-relational class mappings and ETL processes for the generation of messages or single EHRs can be ommitted.

EHRs and messages inside and between hospital information systems (HISs) are defined differently, called the "Message / Record Dichotomy" [6]. With the paradigm shift to XML for EHR storage, it is possible to use EHR extracts stored in data bases directly as messages, and vice versa. The resulting EHRs can easily be transformed to messages for exporting data to another HIS. This is an essential step towards standardized, generalized, and therefore simplified HIS-infrastructures.

Performance

A comparison of querying openEHR based XML databases indicates that XML databases today are not yet the right solution for a persistance layer of big data [32] As a proof-of-concept, we made a load test on the resulting EHRS. 10,000 (64 KB) XML files were transmitted via POST requests, and the time for GET requests was measured. Additionally, the latency time for the XForm-based GUI generation was detected. The results show that the latency ascends constantly with an increasing number of files (see figure 6).

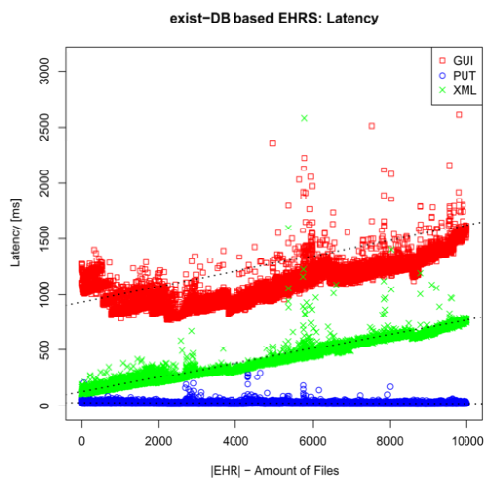

Figure 6: eXistdb based EHRS: Latency

Clearly, the performance of the application slows down with increasing database volume. However, since a total number of 10,000 EHRs will not be reached in our use case, the access times are acceptable. Anyway, because of the ongoing rapid development of storage and processing power, possible performance issues relating larger XML based EHRSs will become more and more negligible.

The Null Flavour Issue

One issue occurring in the XForms solution regards “null flavor” values. To explain this issue, consider the XForm entry in the normal case, e.g. when the value of the element “magnitude” is “507.8”:

<dpmim:value>[…]

<dpmim:magnitude>507.8</dpmim:magnitude>

[…]

</dpmim:value>

The “magnitude” element does not allow empty values, which is of course reasonable. The valid solution to map empty values in XML would be the replacement of the whole <dpmim:value> element with a <dpmim:null_flavour> element, which contains the openEHR code string “271,” which means "no information". Thus, in our example the entire <dpmim:value> element disapears, and is replaced with the <dpmim:null_flavour> element, resulting in:

<dpmim:null_flavour>[…]

<oe:code_string>271</oe:code_string>

[…]

</dpmim:null_flavour>

In combination with the XForm technique, this is an issue, because input fields can not be bound to possibly disappearing elements. One possible workaround is allowing null values in primitive data types: When a value is empty, the relating element will get a null attribute:

<dpmim:magnitude xsi:nil="true"/>

To ensure valid XML, the generated XSD has to be adjusted by allowing null values by the command `nillable="true"` in the correspondent auto-generated XSD element. This workaround allows the use of null values within the XForms model.

Minimal XML

Naturally, XML files come along with relatively much overhead. Additionally, archetypes imply intristic overhead, because they are generalized to enable their usage in different szenarios.

For our prototype system, an XML EHR template containing about 7,000 lines of code for only 24 entry fields was generated out of the XSD files. The overhead was reduced manually by removing unnecessary elements; the final EHR had about a few hundred lines. The important lesson we learned is that contraining the archetype as much as possible is one important prerequisite for the generation of minimal XML-based EHRs.

Conclusions

In this paper, a model-driven and standard-based development process for EHRs has been presented. The practical approach of rapid model driven development of standardized EHRs is recommendable for the development of small EHRSs. Aside from the benefits of standardized EHRs, this boosts the development process. After considering pros and cons of various approaches, a complete paradigm shift to XML for storing EHR data is suggested. XML containing patient data based on openEHR provides a suitable solution for representing digital patient models. The concept was validated by the development of a prototype for a special use case, which is an information system for monitoring patients diagnosed with pituitary adenoma, which will be described in another paper. In future work, additional applications will be implemented that will reuse the concept to use the strength of this approach with respect to application development.

Abstract

Medical information extraction is the automatic extraction of structured information from electronic medical records, where such information can be used for improving healthcare processes and medical decision making. In this paper, we study one important medical information extraction task called section classification. The objective of section classification is to automatically identify sections in a medical document and classify them into one of the pre-defined section types. Training section classification models typically requires large amounts of human labeled training data to achieve high accuracy. Annotating institution-specific data, however, can be both expensive and time-consuming; which poses a big hurdle for adapting a section classification model to new medical institutions. In this paper, we apply two advanced machine learning techniques, active learning and distant supervision, to reduce annotation cost and achieve fast model adaptation for automated section classification in electronic medical records. Our experiment results show that active learning reduces the annotation cost and time by more than 50%, and distant supervision can achieve good model accuracy using weakly labeled training data only.

Medical Informatics, Information Extraction, Section Classification, Active Learning, Distant Supervision.

Introduction

Medical records include a rich range of data about individual patients, such as medical and family history, medication and allergies, vital signs, laboratory test results, diagnoses, treatment plans, etc. The huge volumes of data existing in the medical records not only provide great medical research opportunities, but also raise big challenges for processing the data and extracting useful information from it.

An *electronic medical record* (EMR) or *electronic health record* (EHR) system has a number of advantages over traditional paper-based medical record systems. One main advantage is that an EMR system is designed to maintain complete, accurate and up-to-date patient data in electronic form, which can be much more easily and effectively accessed and shared by health professionals as well as patients. This makes automatic information extraction and knowledge discovery from large sets of medical and clinical data possible.

Medical information extraction is an application of the automatic extraction of structured information from unstructured or semi-structured electronic medical records [1]. Such information can be used for enhancing healthcare processes, for example automatically alerting doctors about missing or incomplete data, or automatically generating billing codes from electronic medical records. The extracted information can also be used for improving medical decision making, such as determining the most effective treatment for a specific disease.

In this paper, we study one important medical information extraction task called *section classification*. When dictating, writing or electronically entering medical or clinical documents, clinicians typically organize their narratives into *sections*, which are often labeled with frequently used but non-standardized terms termed *section headers* [2]. Howeverclinicians are not restricted in what they can write as a section header. Many headers are ambiguous (e.g., "SUMMARY:", "HISTORY:", "DISCUSSION:"), and sometimes section headers may not be given, yet are part of the sentence (e.g., "On examination, the patient's blood pressure was 130/80."). The objective of section classification is to automatically identify all the sections in a medical document and classify them into one of the pre-defined section types. Examples of section types include *History of Present Illness*, *Past Medical History*, *Family History*, *Physical Examination*, *Review of Systems*, *Medications*, *Assessment*, and *Plan*.

Section classification is an essential component of a medical information extraction system. It provides important context for other automated information extraction tasks such as word sense disambiguation, mention detection and coding. For example, the acronym PE usually means "Physical Examination" in a *Physical Examination* section while it often means "Pulmonary Embolism" in a *Past Medical History* or *Imaging* section. Similarly, mentions of diseases detected in different sections (e.g., *Past Medical History* section vs. *Family History* section) have different implications depending on who has the disease. For automated coding, procedures detected in some sections (e.g., *Past Surgical History* section and *Plan* section) may not be coded for billing purposes.

The current state of the art section classification models are based on supervised statistical machine learning frameworks [2-4]. Like other statistical information extraction models (e.g., mention detection models, relation extraction models), training section classification models typically requires large amounts of human labeled training data to achieve high accuracy. Given that annotating data in the medical domain needs specially trained human annotators, both time and expense costs can accrue quickly. This poses a big hurdle for

adapting a section classification model trained for one medical institution to a new medical institution.

In this paper, we apply two advanced machine learning techniques, *active learning* and *distant supervision*, to reduce annotation cost and achieve fast model adaptation for automated section classification in electronic medical records. Active learning aims to train a model with high accuracy using minimum annotation effort by selecting the most informative data instances to annotate [5,6]. Distant supervision uses a knowledge base to automatically generate weakly labeled training data [7,8]. We design a heuristic active learning query selection scheme, which reduces the annotation cost and time by more than 50%. In addition, we develop a distant supervision approach that can achieve good model accuracy using only weakly labeled training data.

Materials and Methods

Statistical Section Classification Model

We represent a medical document **x** by a sequence of sentences (x_1, x_2,…, x_n), where x_i is the *i*-th sentence in document **x**. A section classification model assigns each sentence x_i in the document with a section tag y_i, indicating sentence section. Our medical information extraction system has 83 section tags. Examples of some frequently occurred section tags and their counts (based on a corpus of about 8,000 medical documents) are listed in Table 1. Some sections such as *Physical Examination* and *Review of Systems* also contain subsections with finer-grained information, e.g., *Vital Signs*, *Heent*, *Abdomen*, etc. Our system has 26 subsection tags.

Table 1– Examples of Section Tags and Their Counts

Section Tag	Count
Physical_Examination	4,593
History_Of_Present_Illness	4,101
Past_Medical_History	3,666
Medications	3,641
Assessment	3,553
Allergies	3,515
Social_History	3,480
Laboratory_Data	3,331
Review_Of_Systems	3,129
Family_History	2,859
Plan	2,397
Past_Surgical_History	2,037
Description_Of_Procedure	1,552
Hospital_Course	1,536
Chief_Complain	1,479
Imaging	1,254

To capture the discourse structure of the medical documents, we formulate the section classification problem as a *sequence labeling* problem, where the section tags of the sentences in a medical document are predicted jointly. The main advantage of a sequence labeling model is that it can model the dependency of the labels of neighboring classification elements (here, a classification element is a sentence), so it has been widely used in many NLP tasks such as part-of-speech (POS) tagging and named-entity recognition [9,10].

A number of probabilistic graphical models have been applied to tackle sequence labeling problems, including Hidden Markov Models (HMMs) [11], Maximum Entropy Markov Models (MEMMs) [9] and Conditional Random Fields (CRFs) [10]. CRFs have demonstrated good performance for many sequence labeling applications. However, the training of CRFs is slow since the training time grows at least quadratically with the number of labels. On the other hand, while HMMs and MEMMs have linear training time proportional to the the number of labels, they are limited in the types of features they can use.

We applied the *Statistical Information and Relation Extraction* (SIRE) toolkit developed at IBM to train the section classification models [12]. The SIRE sequence labeling model can be viewed as a generalization of MEMMs and it has the following properties: i) fast training time (linear training time in the number of labels as MEMMS and fast convergence rate); ii) allows richer features as CRFs.

The SIRE sequence labeling model uses the following conditional probabilistic model of the section tag sequence **Y** given the input document **X** (both are viewed as random vectors):

$$P(\mathbf{Y}=\mathbf{y}\mid\mathbf{X}=\mathbf{x})=\prod_{i=1}^{n}P(y_i\mid y_{i-1},...,y_{i-o},\mathbf{x}) \quad (1)$$

where each individual conditional distribution has the following exponential parametric form (the form is motivated by the maximum entropy principle [13]):

$$P(y_i\mid y_{i-1},...y_{i-o},\mathbf{x})=\frac{e^{\sum_{k=1}^{K}\lambda_k f_k(y_i,y_{i-1},...,y_{i-o},\mathbf{x})}}{Z_i} \quad (2)$$

f_k's are the feature functions, λ_k's are the weights of the features, and Z_i is the normalization constant which ensures that $\sum_{y_i}P(y_i\mid y_{i-1},...y_{i-o},\mathbf{x})=1$. The model assumes that the tag of a sentence in a medical document depends on the tags of the previous *o* sentences.

Given a set of training documents (where the sentences are labeled with section/subsection tags), we train a statistical section classification model $P_M(\mathbf{Y}\mid\mathbf{X})$ of the form (1) and (2) that maximizes the log likelihood of the training data (plus a regularization term to avoid overfitting of the training data). For any new medical document **x**, we can use the trained model to predict (decode) the most likely section tags of the sentences using the Viterbi algorithm:

$$\mathbf{y}^{*}=\arg\max_{\mathbf{y}}P_M(\mathbf{Y}=\mathbf{y}\mid\mathbf{X}=\mathbf{x}) \quad (3)$$

Active Learning

Active learning is a machine learning technique that aims to train a model with high accuracy using as few human annotated data instances as possible [5,6]. The basic idea of active learning is to iteratively select the most informative instances and use these newly annotated instances to improve the model. This is different from traditional passive machine learning techniques in which a model is trained using whatever annotated instances provided.

Suppose we have a set of human labeled training documents ***L*** from some medical institutions, and we have trained a section classification model using ***L***. To adapt the section classification model to a new medical institution for which we only have a set of unlabeled documents ***U***, a typical active learning algorithm works as follows: A section classification model ***M*** is first trained using the initial set of human labeled

data ***L***. Then the model is used to decode the unlabeled documents ***U***, among which the top *m* most informative documents ***A*** are selected to be annotated by human. A new model is re-trained using both the initially labeled data ***L*** and the newly labeled data ***A***. This process is repeated until some stopping criterion is met (e.g., until certain model accuracy is achieved). The steps are summarized in Algorithm 1.

Algorithm 1: Active Learning for Fast Model Adaptation

Input*:* Labeled data ***L*** (from some old medical institutions), and unlabeled data ***U*** (from a new medical institution)
Repeat*:*

1. Train a model ***M*** using human labeled documents ***L***
2. Use ***M*** to decode the unlabeled documents ***U***
3. Select and remove the top *m* most informative documents ***A*** from ***U***, and ask human annotators to annotate them
4. Add the human labeled data ***A*** to ***L*** and go to step 1

Until some stopping criterion is met

In Algorithm 1, *m* is called the *batch size*. A smaller value of *m* will normally incur less annotation cost (total number of human labeled documents) required to reach a certain model accuracy, however, it will incur more cost (iterations) of re-training the model. In practice, the batch size should be selected to balance the cost of annotation and model training.

A key component of an active learning algorithm is the *query selection scheme* that determines which instances are the most informative. See reference [6] for an excellent survey of different query selection schemes. The *Least-Confidence* (LC) scheme is one of the most widely used query selection scheme for active learning [6,14]. It uses the confidence score of an instance under the current model to measure the "informativeness" of that instance. The idea is that the instances with the lowest confidence scores provide the maximum amount of information, and these instances should be selected to be annotated first, as well as added to the training data to improve the current model.

For our section classification model, the confidence score of an instance (here an instance is a medical document) **x** under the current model P_M is:

$$c(\mathbf{x}) = P_M(\mathbf{Y} = \mathbf{y}^* \mid \mathbf{X} = \mathbf{x}) \quad (4)$$

where **y*** is the most likely section tag sequence for document **x** (see (3)). The LC scheme will select the top *m* documents with the lowest confidence scores.

To better measure the "informativeness" of a medical document, we have designed the following *heuristic query selection scheme*. For each document, we count the number of sentences whose per-sentence confidence score is less than a threshold (e.g., 0.9). Documents with higher counts are more uncertain under the current model and hence provide more information or value for improving the model. Our heuristic query scheme will select the top *m* documents with the highest counts.

Distant Supervision

While a traditional supervised machine learning algorithm relies on human labeled data to train a model, a weakly supervised learning algorithm uses "weakly" labeled data generated by some automatic mechanism to train a model. Weakly supervised learning techniques are often used in applications where unlabeled data are readily available but annotating them by humans is difficult and/or expensive.

Distant supervision is a type of weakly supervised learning technique that uses a *knowledge base* to automatically generate weakly labeled training data [7,8]. For example, in [8] Freebase (a large semantic database containing several thousand relations), distance supervision was used to generate weakly labeled data for training relation extraction models. For our section classification problem, we apply the idea of distant supervision and construct a section header-to-tag map knowledge base to automatically label the medical documents.

In medical documents, a *header* of a sentence is a sequence of words in a special form (e.g., all capitalized, followed by colon) that occurs at the beginning of a sentence, which often indicates the start of a new section. A *header-to-tag map* includes entries of headers and the corresponding section/subsection tag associated with every header. We have developed a rule-based header extractor that can automatically extract the headers of the sentences in medical documents. We can then construct a header-to-tag map either from sentence-level annotated documents or from direct header annotation.

To generate weakly labeled training documents, we apply the header extractor to extract the headers of the sentences in the (unlabeled) medical documents, and the sentences are then labeled sequentially using the header-to-tag map as follows. If a sentence has a header *h* which is in the header-to-tag map, then the sentence will be labeled *tag(h)* where *tag(h)* is the associated section tag of *h* in the map. Otherwise, the sentence will be assigned the same section tag as the previous sentence (because without a header, a sentence is likely to be inside of a section).

Furthermore, if we have the section boundary information, i.e., if we know where a section starts and ends, we can use this information to improve the labeling of the documents. A new section tag will be assigned to a sentence if and only if the sentence has a header, which is in the header-to-tag map, and the sentence is located at the beginning of a section.

Results

Active Learning Experiment Results

We first present the results of applying active learning for fast section classification model adaptation. We use the standard *F_1 score* (or *F-measure*) to measure the performance of a section classification model on an independent test set. The F_1 score is defined as the harmonic mean of *precision* and *recall*:

$$F_1 = 2 \cdot \frac{precision \cdot recall}{precision + recall} \quad (5)$$

Precision is the number of correctly detected sections divided by the number of all detected sections in the test set returned by the model (a section is correctly detected by the model if both the section span and the section tag are correctly identified). For example, if the model detects 100 sections and 90 of them are correct, then the precision of the model is 90/100=0.9. *Recall* is the number of correctly detected sections divided by the number of true sections in the test set. For example, if there are 200 true sections in the test set and the model correctly detects 90 of them, then the recall of the model is 90/200=0.45. Ideally, we want to build a model that has both high precision and recall. While these two metrics are often competing with each other, F_1 score considers both

precision and recall, and is a commonly used metric to measure the overall accuracy of a classification model [15].

We start with a set of 1,615 human labeled training documents from medical institution A. The initial section classification model is trained with these 1,615 documents. When tested on a test set of 409 human labeled documents from medical institution A, the model achieved an F_1 score of 0.921. However, when tested on a test set of 397 human labeled documents from a new medical institution B, the F_1 score was only 0.719. This shows that a good section classification model trained for one medical institution may not achieve good accuracy for a new medical institution without any model adaptation.

To adapt the section classification model to medical instituition B, we experiment with two active learning query selection schemes: the Least-Confidence (LC) scheme and our heuristic scheme. The baseline scheme is random query selection, i.e., passive learning where the training docuemts are randomly selected from the unlabeled document pool. The batch size *m* is chosen to be 50.

The learning curves of different schemes are shown in Figure 1, where *x*-axis is the number of human labeled training documents from medical instituion B (which represents *annotation cost* or *learning cost*), and *y*-axis is the F_1 score (in percentage) of the section classification model on the test set from medical institution B (which represents *learning performance*).

As we can see from Figure 1, compared with random selection, active learning can greatly reduce the annotation cost to achieve a certain accuracy. For example, to reach an F_1 score of 0.89, we need to annotate 400 documents under the heuristic query selection scheme, while we need to annotate 900 documents under the random query selection scheme, so active learning reduces the annotation cost by 55%. The performance of the two active learning query selection schemes is very similar, while the heuristic scheme achieves slightly better accuracy (0.89 F_1 score) than the LC scheme (0.887 F_1 score) with a training size of 400 documents.

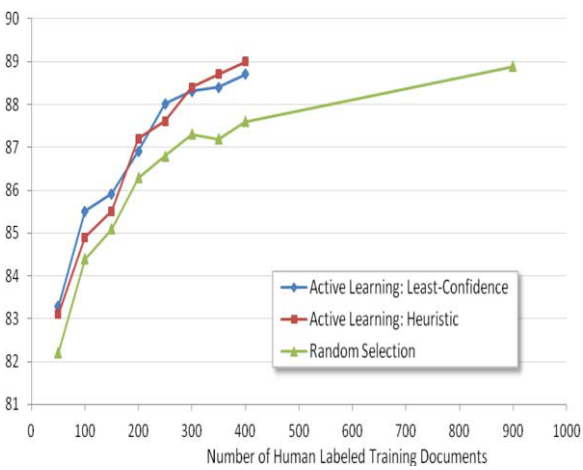

Figure 1– Learning curves of different query selection schemes for section classification model adaptation.

Saving annotation cost means saving of time. A human annotator can annotate approximately 50 documents per day. To reach the same accuracy of 0.89 F_1 score, it would require 18 days to annotate the 900 documents under passive learning, while it would only require 8 days to annotate the 400 documents under active learning, a significant saving of time in adapting the section classification model to the new medical institution.

We have conducted similar experiments to adapt the section classification model to another new medical institution using active learning, and we observed a 57% saving of both annotation cost and time.

Distant Supervision Experiment Results

Next, we present experiment results of our distant supervision approach for fast section classification model adaptation. We start with a set of 3,274 human labeled training documents (denoted as **BASIC**) from three medical institutions A, B, C. We want to adapt the section classification model to a new medical institution D. **NEW** denotes a set of 1,095 medical documents from the new medical institution.

We compare two forms of annotation for the documents in **NEW**: one is human annotation where we use $\mathbf{NEW_{human}}$ to represent the set of training documents labeled by human annotators; the other is distant supervision where we use $\mathbf{NEW_{distant}}$ to represent the set of weakly labeled training documents automatically generated by our distant supervision approach.

As shown in Table 2, a section classification model trained with the data from the old medical institutions (i.e., **BASIC**) only achieves 0.753 F_1 score on a test set of 605 human labeled documents from the new medical institution. This again shows that without model adaptation, a model trained for some medical institutions may not achieve good accuracy for a new medical institution. If we add human labeled training data from the new medical institution (i.e., $\mathbf{NEW_{human}}$), then the model achieves 0.919 F_1 score on the test set. These provide us with two baseline results: the *worst* baseline that does not use any training data from the new medical institution, and the *best* baseline that uses human labeled training data from the new medical institution.

Under distant supervision (as opposed to using human labeled training data from the new medical institution), we use a header-to-tag map to automatically label the **NEW** data. We experiment with two cases. In the first case, we do not have any section boundary information. If we detect a header *h* of a sentence and the header is also in the header-to-tag map, then the sentence will be labeled *tag(h)* where *tag(h)* is the associated section tag of *h* in the map. In this case, the section classification model trained with **BASIC** data and the weakly labeled $\mathbf{NEW_{distant}}$ data achieves 0.902 F_1 score on the test set.

In the second case, the section boundary information is available. Such information can be obtained by direct section boundary annotation, which is much cheaper than complete section annotation since here the annotators only need to label which sentences are located at the beginning of a section and do not need to assign any section tags. With the section boundary information, the performance of the section classification model improves to 0.906 F_1 score on the test set.

Table 2. Experiment Results of Distant Supervision (Test Data are from the New Medical Institution D)

Training Data	F_1 Score
BASIC	0.753
BASIC + $\mathbf{NEW_{human}}$	0.919

BASIC + NEW$_{distant}$	0.902
BASIC + NEW$_{distant}$ (with section boundary)	0.906

To adapt the section classification model to the new medical institution D, under the traditional supervised learning framework (where distant supervision or active learning is not used), it would require approximately 22 days to annotate the 1,095 training documents from medical institution D to get an F_1 score of 0.919.

Under the distant supervision approach, the main annotation cost is the cost to build the section header-to-tag map. The header-to-tag map contains 3,094 headers, among which only 375 headers are new headers from medical institution D. The other 2,719 headers are from medical institutions A, B, C, and the section tags for those 2,719 headers are readily derived from the **BASIC** data set. We only need to ask a human annotator to label the 375 new headers from medical institution D, which can be finished in one day or two – requiring significantly less time than annotating the whole set of 1,095 medical documents from medical institution D. There is a small performance drop of the section classification model trained under the distant supervision approach. Nevertheless, it can still achieve an F_1 score of 0.902, which is good for many applications of interest.

Conclusion

Section classification in electronic medical records provides important contextual information for other automated information extraction tasks. Training section classification models, however, typically requires large amounts of human labeled data to achieve high accuracy and annotating institution-specific data can be both expensive and time-consuming. In this paper, we have applied two advanced machine learning techniques, active learning and distant supervision, to reduce annotation cost and achieve fast section classification model adaptation. In particular, we have designed a heuristic active learning query selection scheme, which reduces the annotation cost and time by more than 50%. We have also developed a distant supervision approach that can achieve good model accuracy using weakly labeled data only.

There are important differences between active learning and distant supervision. Active learning belongs to the family of supervised learning algorithms, which requires human annotators to label the data. By intelligently selecting the data instances to annotate, active learning can achieve the same level of accuracy as traditional supervised learning algorithms with much less annotation cost. In contrast, distant supervision belongs to the family of unsupervised (if no human annotation is used at all) or semi-supervised (if some limited human annotation is used) learning algorithms. Its performance heavily depends on the quality of the knowledge base. Distant supervision normally does not achieve the same level of accuracy as supervised learning algorithms, but it incurs even less annotation cost than active learning. In practice, one should decide which technique to use based on the accuracy requirement and the annotation budget. It is also possible to combine the two techniques for fast model adaption.

Abstract

"Heart failure (HF) is a frequent health problem with high morbidity and mortality, increasing prevalence and escalating healthcare costs" [1]. By calculating a HF survival risk score based on patient-specific characteristics from Electronic Health Records (EHRs), we can identify high-risk patients and apply individualized treatment and healthy living choices to potentially reduce their mortality risk. The Seattle Heart Failure Model (SHFM) is one of the most popular models to calculate HF survival risk that uses multiple clinical variables to predict HF prognosis and also incorporates impact of HF therapy on patient outcomes. Although the SHFM has been validated across multiple cohorts [1-5], these studies were primarily done using clinical trials databases that do not reflect routine clinical care in the community. Further, the impact of contemporary therapeutic interventions, such as beta-blockers or defibrillators, was incorporated in SHFM by extrapolation from external trials. In this study, we assess the performance of SHFM using EHRs at Mayo Clinic, and sought to develop a risk prediction model using machine learning techiniques that applies routine clinical care data. Our results shows the models which were built using EHR data are more accurate (11% improvement in AUC) with the convenience of being more readily applicable in routine clinical care. Furthermore, we demonstrate that new predictive markers (such as co-morbidities) when incorporated into our models improve prognostic performance significantly (8% improvement in AUC).

Keywords:

Heart Failure; Survival Score; Electronic Health Records; Machine Learning.

Introduction

Heart failure (HF) is primarily caused by the inability of the heart to supply sufficient blood flow to the body. It has become one of the most deadly cardiovascular diseases in the 21st century [1]. Therefore, it is important to identify patients who are at a higher risk of mortality due to HF and assess the impact of HF therapy on their outcomes. Several studies have developed prognostic tools for HF, and one of the most commonly used tools is the Seattle Heart Failure Model (SHFM) [1]. SHFM was based on the PRAISE I clinical trial database and validated in five other cohorts.

While the derivation and validation of SHFM using such clinical trials databases provide a level of rigor in terms of data collected, they are typically limited to biased cohorts that tend to be homogenous. Further, in many cases, the environment in which the trials were conducted may not reflect the routine clinical care given to patients diagnosed with HF. Consequently, as EHRs become more ubiquitous and accessible for clinical research, it becomes imperative to investigate methods of predicting HF prognosis and the impact of HF therapy on important patient-related outcomes using EHRs–as opposed to data derived exclusively from clinical trials databases. The specific objectives of this study are to assess the performance of the SHFM using routinely collected EHR data in a community practice at Mayo Clinic, and to incorporate variables that were not part of the SHFM in our prognostic model (e.g., patient co-morbidities derived from the EHR) to assess improvement in the performance of survival analysis.

Our results suggest that (1) heart failure survival models built on EHRs are more accurate than the SHFM, (2) incorporating co-morbidities into the heart failure survival analysis prediction models improve the accuracy of our models, and (3) there are potential hidden interactions between diagnoses history of the patient, co-morbidities, and survival risk. We also build our models using multiple different machine learning algorithms and our results show that logistic regression and random forest return more accurate classifiers.

Background and Related Work

The SHFM was derived in a cohort of 1125 heart failure patients from the PRAISE I clinical trial with the use of a multivariate Cox model [1]. For variables such as medications (e.g., beta-blockers) and devices (e.g., defibrillators) that were not available in the derivation database, hazard ratios were estimated from published literature and "external" clinical trials. The model has been prospectively validated in 5 additional cohorts totaling 9942 heart failure patients and 17307 person-years of follow-up.

However, the SHFM has significant limitations for risk prediction in HF, particularly when used for routine clinical care. For instance, the hazard ratios for a subset of medications and devices variables in SHFM were estimated from prior published literature, and results from prior clinical trials may not be generalizable to a wider real-world population of HF patients. Limited patient-specific parameters (e.g., patient co-morbidities) have been used in the model to calculate survival score and can potentially lead to an improvement in the prediction of HF prognosis.

In addition to SHFM, several other risk prediction models have been developed including SHOCKED, Frankenstein, PACE Risk Score, and HFSS [1]. These have been validated in independent cohorts along with SHFM: "The Heart Failure Survival Score (HFSS) was validated in 8 cohorts (2240 patients), showing poor-to-modest discrimination (c-statistic, 0.56–0.79), being lower in more recent cohorts. The Seattle Heart Failure Model was validated in 14 cohorts (16,057 patients), describing poor-to-acceptable discrimination (0.63–0.81), remaining relatively stable over time. Both models re-

ported adequate calibration, although overestimating survival in specific populations. The other 3 models were validated in a cohort each, reporting poor-to-modest discrimination (0.66–0.74) [1-5].

Furthermore, there are also studies that applied machine-learning algorithms to study risk factors and predict patient outcomes in HF. For example, Dai et al. [6] used boosting and support vector machine (SVM) schemes to build models to predict heart failure around six months before the actual diagnosis. Their results show that SVM has poor performance. Similarly, Austin et al. [7] used regression tree, bagging, Random Forest, boosting, SVM and logistic regression to classify HF patients with preserved Ejection Fraction (EF) from those patients with reduced EF. They concluded that logistic regression returns the most accurate models.

Methods

From a cohort of 119,749 Mayo Clinic patients between 1993-2013 with research authorization to access EHR data, we identified 5044 patients with a diagnosis of HF after applying specific criteria and excluding number of patients due to incomplete data (13.3%). These criteria included:

- A confirmed diagnosis of HF based on the ICD-9-CM code (428.x).
- An ejection fraction (EF) measurement ≤50% within two months of HF diagnoses.
- No prior diagnosis of coronary artery disease, myocarditis, infiltrative cardiomyopathy, and severe valvular disease.

We divided the EHR-derived dataset randomly into training (N=1560 patients) and test (N=3484 patients) datasets. In consultation with Mayo Clinic cardiologists who routinely treat HF patients, we identified the following features (variables) extracted from EHRs to calculate the survival score:

- Demographic variables including age, sex, race, ethnicity and survival status.
- Laboratory results including cholesterol, sodium, hemoglobin, lymphocyte count, and EF measurements.
- Medications including Angiotensin Converting Enzyme (ACE) inhibitors, Angiotensin Receptor Blockers (ARBs), β-adrenoceptor antagonists (β-blockers), Statins, and Calcium Channel Blocker (CCB).
- 26 major chronic conditions (ICD-9 code) as co-morbidities as defined by the U.S. Department of Health and Human Services [8].

Table 1 represents the characteristics of the study cohort with including training and test splits. The patients were 94% white 48% female. The average range of EF was 36±10.3. In terms of co-morbidities most of the patients (81.06%) had hypertension followed by hyperlipidemia (64.3%), chronic kidney disease (55.83%) and diabetes (37.4%).

As discussed earlier, our primary goal in this study is to assess the performance of SHFM using EHR data and propose a HF survival risk prediction model by adding new variables (e.g., patient co-morbidities) derived using the EHR data to improve prediction accuracy and performance of the model. To accomplish this goal, we designed two scenarios: In scenario A, we used COX proportional regression model [9] to predict the risk of survival in HF patients in the one, two and five years after the diagnosis of HF. In scenario B, we excluded all patients who died within one year after the first diagnosis of HF, and then based on the remainder of patients who survived after one year of HF diagnosis, we developed a series of models using different classifiers to classify these two groups of patients. Since most of the well known classification algorithms are developed for binary classification, we repeated scenario B to classify patients who died within two years and five years after the HF diagnosis. The following classification algorithms were used: random forest [10], logistic regression [11,12], support vector regression [13], decision tree [14] and ada boost [15].

Table 1 – Patient Characteristics for HF Study Cohort

	Variables	Value
Demographic	Age (years)	78±10
	Sex (male)	52%
	Race (White)	94%
	Ethnicity (Not Hispanic or Latino)	84%
Laboratory	BMI	28.7±11.25
	Systolic Blood Pressure (mm/Hg)	120±25
	Ejection Fraction (EF)	36±10.3
	Hemoglobin (g/dL)	11.8±1.2
	Cholesterol (mg/dL)	144±35
	Uric Acid (g/dL)	7.1±2.5
	Sodium (mEq/L)	128±4.2
	Lymphocytes (x10(9)/L)	1.32±0.7
Medications	ACE inhibitors	55.7%
	Beta blockers	48.6%
	Angiotension Receptor Blockers	12.8%
	Calcium Channel Blockers	4.1%
	Statins	43.2%
	Diuretics	68.7%
	Allopurinol	18.5%
	Aldosterone Blockers	18.5%
Comorbidities	Hypothyroidism	21.2%
	Acute myocardial infarction	16.3%
	Alzheimers	11.9%
	Anemia	5 3.01%
	Asthma	10.72%
	Atrial fibrillation	48.56%
	Benign prostatic hyperplasia	9.5%
	Cataract	31.4%
	Chronic Kidney Disease	55.83%
	Pulmonary disease	30.4%
	Depression	25.5%
	Diabetes	37.4%
	Glaucoma	9.4%
	Hip/pelvic fracture	4.3%
	Hyperlipidemia	64.3%
	Hypertension	81.06%
	Ischemic heart disease	70.2%
	Osteoporosis	18.3%
	Rheumatoid Arthritis	39.2%
	Stroke	12.4%
	Breast cancer	2.2%
	Colorectal cancer	1.58%
	Prostate cancer	4.5%
	Lung cancer	2.45%
	Endometrial cancer	0.00%

To investigate the effect of variables extracted from the EHR data on the performance of our models, we designed two sets of predictor variables. In the first set called *baseline* (*BL*), we applied the same variables used in the SHFM. Since our EHR

derived dataset does not have information about patients' NYHA class, QRS duration, or device implantations (e.g., defibrillators), we did not include them in our models. In the next variable set called *extended (EX)*, we added the following predictor variables to the *BL* model: race, ethnicity, BMI, calcium channel blocker (CCB) and 26 different co-morbidities. Then we compared the performance of our *BL* and *EX* models with the SHFM.

Results

This section reports a systematic validation of our HF survival risk prediction model(s) in both scenarios A and B. As we mentioned earlier, to minimize the effect of overfitting and increase generalizability of our models, we separated our cohort randomly into training (N=1560 patients) and test (N=3484 patients) datasets. To validate models which are developed in scenario A (survival models), we designed two approaches. In the first approach (A1), we divided our predictor variables into two parts: variables that were common between both the SHFM model and our models (e.g., EF measurement), and variables used by just our model (e.g., patient co-morbidities). For variables that were common we used the hazard ratios defined by SHFM. For variables that were not used in SHFM we used the hazard ratios extracted from our analysis. Table 2 presents the performance of our model (A1) in the form of Area Under Curve (AUC). In the second approach (A2) we used the hazard ratio developed by our model to calculate the AUCs (also shown in Table 2).

Table 2 shows that accuracy drops on average by 9% in the AUC when using a mixture of hazard ratios from our model and SHFM. Although it is not surprising, one plausible reason might be that SHFM was developed using a clinical trials database, whereas our model has been developed using an EHR database in a real community practice. Consequently, combining hazard ratios derived from two different datasets can lead to a degradation in the accuracy of the prediction model.

Table 2 – Perfomance (Area Under Curve) of Scenario A (Survival Analysis) for both baseline and extended variable sets

	1 year		**2 years**		**5 years**	
	BL	EX	BL	EX	BL	EX
A1	0.71	0.80	0.68	0.75	0.66	0.71
A2	0.77	0.83	0.77	0.82	0.75	0.80

Figure 1 also represents the Receiver Operating Characteristics (ROC) of the models developed in scenario A on the BL variable set. From Table 2 and Figure 1, we can observe that the performance of our models drops when we want to predict the risk of heart failure two and five years after the first heart failure event. We hypothesize that the main reason of observing a drop in the accuracy is because the dataset for two and five year models are imbalanced and usually the classifiers used in this study do not work well on imbalanced datasets. Figure 2 shows the ROC curve of the scenario A models on EX variable set.

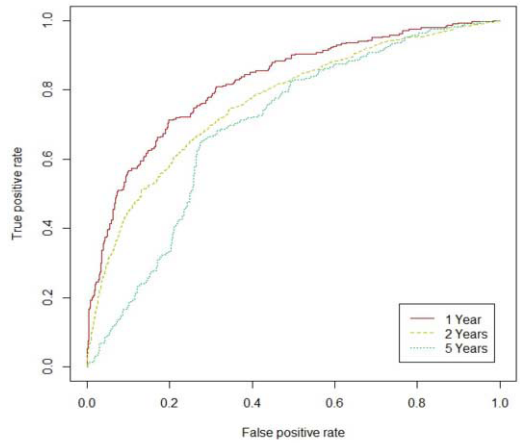

Figure 1 - ROC curve for Scenario A on baseline variable sets

As we discussed earlier, one of our goals in this study was to investigate the effect of adding more predictor variables to our models, and potentially improve model performance. To this end, we designed two variable sets called *BL* and *EX*. In the *BL* set, we have 16 predictor variables and in the *EX* set, we consider 45 variables to develop our models. Table 2 shows that the AUC for models developed using the *EX* variable set increased by 7.7%, 6.5% and 6.6% compared to the *BL* variable sets for 1-, 2- and 5-years models, respectively. In the next part of our results, we show the performance of the classification models (scenario B). In this scenario, we excluded all patients who died within 1-, 2- and 5-years after the first diagnosis of HF, and then developed models to classify them separately from patients who did survive after the HF diagnosis.

Table 3 – Perfomance of Senario B (Classification) for both baseline and extended variable sets

	1 year		2 years		5 years	
	BL	EX	BL	EX	BL	EX
Decision Tree	0.60	0.66	0.50	0.50	0.50	0.50
Random Forest	0.62	**0.80**	0.65	0.72	0.62	0.72
Ada Boost	0.59	0.74	0.66	0.71	0.61	0.68
SVM	0.56	0.46	0.61	0.52	0.55	0.38
Logistic Regression	**0.68**	**0.81**	0.7	0.74	0.61	0.73

Table 3 represents the AUC of different classifiers for both BL and EX variable sets. Much like scenario A, we make the same observation in scenario B where inclusion of additional variables derived from the EHR to the models significantly improves classifier performance.

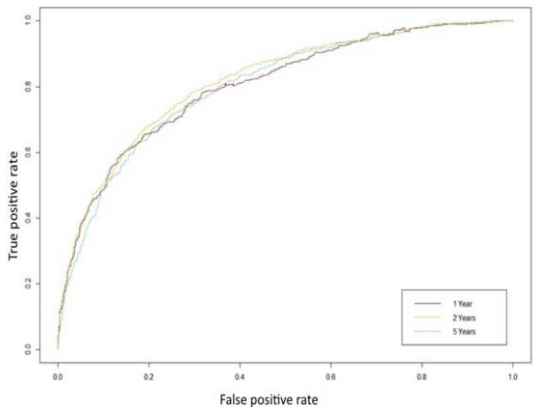

Figure 2 - ROC curve for Scenario A on exdended variable sets

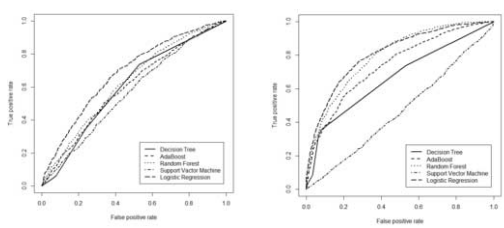
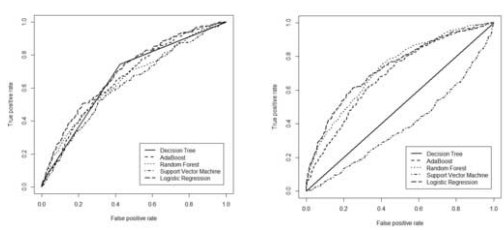
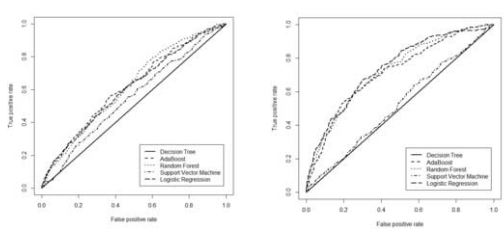
Figure 3 also represents the ROC of the models developed in scenario B on the BL and EX variable sets for one, two, and five years for all classifiers shown in Table 2, including Decision Tree, Random Forest, AdaBoost, SVM, and Logistic Regression. There are a number of reasons why SVM may have been less accurate in developing this prediction model. First, SVM is not an appropriate method for handling both continuous and categorical variables in the same model. Second, our data suggest that SVM may be more strongly affected by classification imbalance in the data than either Boosting or logistic regression.



BL model, 1 year *EX model, 1 year*



BL model, 2 years *EX model, 2 years*



BL model, 5 years *EX model, 5 years*

Figure 3 - ROC curve for Scenario B on BL & EX variable sets(x=False positive rate, y=True positive rate)

Discussion

In this study we explored how to improve SHFM by considering routine clinical care data. Since models that are built based on EHRs are more accurate (11% improvement in AUC) and are applicable in standard routine care, it is imperative to leverage EHR data for survival analysis and prediction modeling in HF and other chronic conditions. We also showed that incorporating new predictive markers (co-morbidities) in our models improved the performance significantly (8% improvement in AUC) and gives us insights about the pathophysiology of HF. Another highlight of this study is calculating the Hazard Ratio (HR) based on real-world EHR data, whereas other studies, including SHFM, have used the HR from literature and extrapolation of results from clinical trials which may not reflect routine care for HF patients [1,5]. Finally, we observe that there are potential hidden interactions between diagnoses, history of the patient, co-morbidities, and survival risk that warrant further research. Note that since we calculate the model output based on individual patient chracteristics, it is plausible to incorporate the output derived from these predictive models within EHRs and facilitate clinical decision making for managing HF patients with better treatment options–an area for future research. In summary, our results suggest that heart failure survival models built on EHRs are more accurate, and incorporating co-morbidities into the HF models significantly improves the accuracy of our models.

Conclusion

In this study we assessed the performance of SHFM using Mayo Clinic's EHR dataset. Our results demonstrate an improvement in accuracy as compared to the standard SHFM and also suggest the ready applicability of our model to standard clincal care in the community. We also incorporated additional predictor variables that included 26 co-morbidities into our models that lead to further improvement in the prognostic predictive accuracy. Finally, we built a heart failure risk prediction model using a series of machine learning techniques and observed that logistic regression and random forest return more accurate models compared to other classifiers.

Towards the Implementation of an openEHR-based Open Source EHR Platform (a vision paper)

Pablo Pazos Gutiérrez[a]

[a] *openEHR en Español, Asociación Chilena de Informática en Salud, CaboLabs*

Abstract

Healthcare Information Systems are a big business. Currently there is an explosion of EHR/EMR products available on the market, and the best tools are really expensive. Many developing countries and healthcare providers cannot access such tools, and for those who can, there is not a clear strategy for the evolution, scaling, and cost of these electronic health products. The lack of standard-based implementations conduct to the creation of isolated information silos that cannot be exploited (i.e. shared between providers to promote a holistic view of each patient's medical history).

This paper exposes the main elements behind a Standard-based Open Source EHR Platform that is future-proof and allows to evolve and scale with minimal cost. The proposed EHR Architecture is based on openEHR specifications, adding elements emerged from research and development experiences, leading to a design that can be implemented in any modern technology. Different implementations will be interoperable by design. This Platform will leverage contexts of scarce resources, reusing clinical knowledge, a common set of software components and services.

Keywords:

Electronic Health Records; Open Source Software; openEHR; Service Oriented Architecture; Data Collection.

Introduction

In this vision paper we present the basic components of an Open EHR Platform that will be used in different scenarios as a shared EHR core for country wide, federated, hospital and clinic EHRs. The term "EHR core" will be use to reference an implementation of the Platform using a specific technology stack.

The main motivation behind this EHR Platform is to create an open alternative to the closed/proprietary solutions currently offered by EHR vendors. But also to create an EHR Platform that is based on open standards and good design practices, searching for a generic, reusable, scalable, extensible, web-based, knowledge-driven, and future-proof solution.

This Platform is “open” in three ways:

1. open specification accessible for anyone.
2. open source tools and components.
3. free to use, adapt and extend.

This will help developers to create new tools and services without the hassle of dealing with e-Health standards and clinical knowledge (time consuming and costly tasks of any EHR development), and enable developments in contexts of scarce human & financial resources (small software companies, dev teams in hospitals, etc.).

In the next sections the following topics will be presented: design principles, architecture, components, services, and ideas pertaining to Platform development and use by client applications. Developers using services provided by the EHR Platform, for shared data storage, querying and Clinical Decision Support (CDS), will create these applications.

Current Status

Although this paper is about the vision and conception of a new kind of EHR systems, we and other colleagues [1][2] have been working in this area, including research, development and training, mainly to understand the problem, delineate a good solution, and validate it against functional prototypes of the EHR Platform. The outstanding component we created is the EHRServer [3]. It provides services of clinical data storage and querying for clinical information, and this system can actually be deployed and used. For Knowledge Management, the Clinical Knowledge Manager [4] of the openEHR Foundation is being used. There are also some proof-of-concept developments around a Demographic Server and a Rule Engine that will soon be released.

Methods

This paper presents the core components of the proposed EHR Platform, which is an extension/specialization of the openEHR EHR Computing Platform [5], defined by the openEHR specifications [6]. The extensions are based on research & development, project development, integration of EHR, HIS and other clinical information systems, and preparing training materials and case studies.

Design Principles of the Open EHR Platform

- Provide a minimum/common set of generic services
  - Reuse: must support a wide range of client applications with the same set of components and services, leveraging available resources.
  - Pareto principle: the platform will provide the 20% of the functionalities of a full blown EHR system to support 80% of the requirements for any EHR system, keeping the Platform small and manageable. The rest of the functionalities should be added by developing client applications, and those might be customized for each application (i.e. won’t suit as core functionalities).
  - Scope: The services will be focused on data storage and querying, permitting data interpretation and manipulation to client applications.
  - Standardization: the EHR Platform will implement open standards to reach interoperability, so developers do not need to do that work.

- Modifiability and Extensibility: the metadata-based configuration of the Platform will allow new data structures, data queries and rules to be added without modifying the database structure or source code.
- Clinical data consolidation:
  - The storage services of the Platform collect and consolidate clinical information from different client applications into a loosely centralized platform, thus facilitating a unique EHR, per patient, that is complete and ubiquitously accessible.
  - Consolidated data will be on a Cloud-ready Platform using a distributed approach, avoiding monolithic systems and one-point-of-failure.
- Secure:
  - Clinical and demographic/identification data are physically separated, allowing secondary use of anonymized clinical data.
  - All communications between client applications and the EHR Platform will be encrypted. On each communication, the client will be authenticated and permissions will be verified. Client apps should comply with security rules, and good security practices will be encouraged.
  - Modifications to the data in the EHR will be done only by authenticated and authorized client applications, and those should ensure correct authentication and authorization for their users (this item should be included in the Platform rules of use).
  - No data is actually modified or deleted; amendments, corrections or deletions all generate new versions of the data.

Knowledge Management (KM)

The KM process is grounded on four main artifacts: 1) clinical record structures, 2) terminology, 3) rules, and 4) processes. Those are defined as computable expressions that can be created and updated, using modeling tools [7], by Domain Experts (physicians, nurses, and allied health professionals). These experts, who are closer to the end users of the EHR, will play the role of Clinical Knowledge Modelers that are in responsible for defining the structure and behavior of the EHR, and how it will evolve over time.

The openEHR specifications [6] define two kinds of artifacts: archetypes and templates. Archetypes are units of content (data structures, constraints and terminology) that specify to one health concept, in a processable and self-contained artifact, that has global validity (e.g. Blood Pressure, Problem/Diagnosis, Clinical Evolution, Glasgow Coma Scale, Body Mass Index, etc.). Templates defined by specific clinical documents, valid in local contexts, refer to many Archetypes, and can use all the Archetype structure or just part of it.

Open EHR Platform Architecture

The Open EHR Platform Architecture is constituted by components with well-defined responsibilities, and provides services to other and client applications. This is based on the openEHR architecture [8].

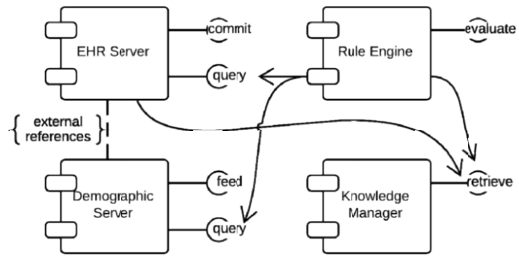

Figure 1 - Open EHR Platform Architecture

Four main components are defined to manage information and provide services for: 1) clinical data (EHR Server), 2) demographic and identification data (Demographic Server), 3) rules to enable CDS (Rule Engine), and 4) Clinical Knowledge (Knowledge Manager). The latter is where all of the metadata, authored by Domain Experts, is stored and made available for the rest of the components: clinical document and administrative data structures, terminologies, rules and workflows.

Due to the narrowed scope of the Platform, a User Interface (UI) for the end-user ought to be provided by client applications developed over the EHR platform. This is why the term "EHR platform" rather than "EHR system" may better suit this work.

Services

Each sub-system of the EHR Platform architecture will provide a set of services related to their responsibilities. Below we describe the major services and internal components of each sub-system.

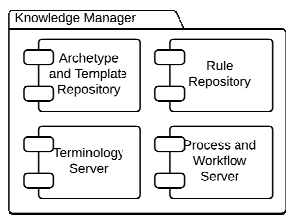

Figure 2 - Knowledge Manager Component

The KM sub-system will handle the artifacts created by the KM process. These artifacts are the heart of the whole EHR Platform, if some of those change or new artifacts are added, the data and behavior of the Platform will change, giving the Platform the "future-proof" label. There are four main components:

- Archetype and Template Repository: stores artifacts that define the data structure and low-level constraints of each clinical document in the EHR.
- Terminology Server: provides services around terminologies, classifications, thesauri, dictionaries, and mappings/relationships between them. Archetypes and Templates will use these terminologies.
- Rule Repository: manages rules that will be executed by the Rule Engine.

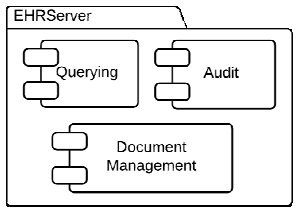

Figure 3 - EHR Server Components

The **EHR Server** is responsible for the safekeeping of clinical records and providing services to change the EHR and query for clinical data.

Document Management: Provides services to validate, create and update clinical information in the EHR of each patient, allowing the management of the internal organization of the clinical records in a directory structure (e.g. by episode or health problem).

Querying: Enables client applications such as EMRs and mHealth apps to access clinical information from the EHR. Queries are specified in an abstract declarative way, based on structures defined by openEHR archetypes [9]. Queries do not depend on specific database technologies, so there is the need to implement a crosswalk between EHR Server queries and database query language such as SQL or XQuery. In this component, queries will be created by Domain Experts and end-users [10], exported & imported and executed against a specific DB technology. So EHR queries can be shared between different implementations of the EHR Server. The results of a query will be returned in standard open formats such as XML and JSON, and organized in different ways: full clinical documents or data points, grouped by data type or by clinical document type, contextualized to time points or intervals.

Audit: Enables the management, evaluation and control of changes to the EHR of a patient, allows the detection of problems such as wrongly organized, deleted or modified clinical information.

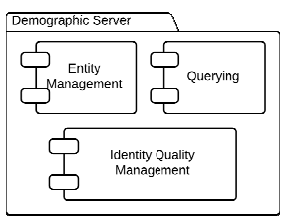

Figure 4 - Demographic Server Components

The Demographic Server is responsible for the management of varying entities such as persons, organizations, groups, devices, systems, their relationships and roles. All of these entities will be referenced from the EHR records, and all referenced entities should be stored in the Demographic Server. This sub-system will act as a Master Patient Index and Human Resource Index (but will not include information about contracts, payments, etc. that will be handled by third party applications). The Identity Quality Management includes functionalities to help detect errored, corrupted and duplicated entities in the demographic repository, and manage the repository audit to evaluate and control changes made by external applications.

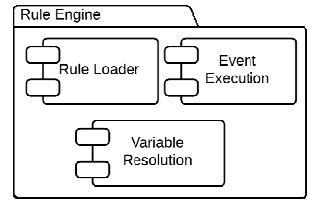

Figure 5 - Rule Engine Components

Rules are declarative units of logic that are evaluated against data, that execute actions based on conditions, and can return values. The rule execution will be triggered by events such as a user clicking a button or selecting a value from a list (e.g. a medication to create a prescription) or system events such as batch jobs executed at certain times. The data to evaluate the rules will come from the EHR Server (clinical data) or the Demographic Server (age range, sex, geographic location), and can be input data (provided by the triggered event), or rule variables (resolved when the rule is executed, e.g. querying the EHR for data). There is a proposal from the community to express rules and guideline-based workflows using a similar syntax to the one used in archetypes [11], this is called the Guideline Definition Language (GDL) [12].

The **Rule Engine** is in charge of loading rules from the Knowledge Manager, Resolve Referenced Values (e.g. querying the EHR Server), and Rule Execution that controls the rule logic and return values.

Customization and Extension: a better way

Since our goal is to design a low cost environment to create EHR systems, the Platform we envision will have an extreme level of modifiability, and this is a design requirement. To reach this objective we need to forget some of the traditional practices currently used to develop software for healthcare. In the traditional way we might be able to create an EHR, but we might not be able to maintain it. So, considering that the costlier and longer phase in software development is maintenance and evolution [13], and EHRs are long-term projects, thus for really effective EHR Systems we need to cut the maintainability cost to the minimum.

The Platform architectural design and the use of metadata to describe the system data structures (archetypes, templates, terminology) and behavior (rules, processes) allows a huge level of modifiability to adapt the EHR to new requirements, while maintaining the stability of the core EHR system. This is achieved because there is no need to modify source code or database schemas to make changes to the Platform, so no new bugs are introduced at the code level. To implement this, a mix of open standards, a Service Oriented Architecture (SOA), current technologies and techniques (Model-View-Controller, Object-Relational Mapping and dynamic languages) should also be applied.

Making changes and adding new features for end-users will be done over client applications, e.g. improving EMR UI or adding a feature, such as tagging patient records, so the core of the system, the EHR Platform, is not affected by these changes.

For example, on the EHR Server, extensions will be added in three main forms:

1. New archetypes and templates will define the structure of new clinical records,
2. New queries will define new ways of accessing the data stored in the EHR,

3. New rules will add behavior, to execute actions under certain conditions, using the data from the EHR.

Deployment

The proposed platform can be offered by a "Software as a Service" (SaaS) model, or software vendors and medical institutions can create their own local deployments. Either way, the platform is focused on providing high availability and data/metadata backup, two basic requirements for any shared EHR system. To provide this, some redundancy is needed; therefore more than one instance of each sub-system should be deployed.

The platform is designed to support this by providing synchronization services between different instances of the same sub-system. E.g. two instances of EHR Server will synchronize data when one instance receives a commit of a clinical document, so queries can be executed in both instances, also providing better performance. This also works when scalability is needed. When the EHR Platform needs to support more applications and users, store and retrieve more data, etc., the service level of the platform should neither deteriorate nor disturb other users. Adding more instances of the Platform sub-systems will let it to scale horizontally without huge investments.

Thinking about long-term viability of a project of this kind, offering SaaS as a hosted solution for software development companies can help to fund the EHR Platform maintenance and evolution. This strategy is implemented by a lot of Open Source projects, accompanying that with paid extensions and value-added services.

Developing Applications

The core set of services provided by the Open EHR Platform will enable developers to focus on creating client applications without starting from scratch, and solve the same problems again and again. Moreover, they get standardized data structures using communication protocols and syntaxes they are familiarized with like REST/SOAP, JSON/XML, without the hassle of implementing the standards themselves, so they create out-of-the-box interoperable applications.

Client applications can be classified into three categories: data input apps, data display apps and mixed. Vital Signs monitors and study result reporting are examples of "data input" applications, because they function to send/commit data to the EHR. Reporting tools are an example of "data display" applications that mainly will query the EHR. EMRs [14] are examples of mixed input/output. It is worth mentioning that when a deployed platform supports several applications, all the clinical documents committed to the EHR by the "data input" apps will be available to the "data display" apps with permission to query the EHR Platform, enabling the implementation of a truly shared EHR.

To help developers adopt the EHR Platform and the methodology to create client applications proposed in this paper, we visualize the creation of helper tools such as Software Development Kits, libraries for different programming languages and learning materials. Some work around this area has already been done. The first is a framework to develop EHR systems called EHRGen [15]. We have also worked in a multi-level methodology and a set of tools to automatically generate User Interfaces for Clinical Information Systems over different technologies (HTML5, Java, .Net), from openEHR Archetypes and Templates [16].

As an example, using the services provided by the EHR Platform, client applications can implement features like: browsing through the patient's medical history, generate clinical and public health reports about population's health with different aggregations (by age range, sex, geographic location, etc.), calculate for different indicators (e.g. number of births per year), sending notifications under certain circumstances to the patient, family, health care team, management team or healthcare authorities (e.g. execution of rules that notify when new test results are available, or when a diagnosis of a certain decease was added to the EHR of a patient), Clinical Decision Support features like alerts, recommendations, reminders, reference material, etc. (rules are executed, and based on context data, a correspondent result is returned, e.g. give an alert if the patient is allergic to the medications that is about to be prescribed).

Validation of the proposed architecture

The validity of the proposed architecture can, and should, be evaluated against standards and specifications, first against international ones, to satisfy generic requirements, methodologies, needs and rules, and then against local compliances that define more specific requirements. Since the architecture is the most generic and abstract definition of a complex system, it should not be evaluated against requirements related to low level designs, with a bigger amount and more specific requirements), and the use of specific technologies. After the architecture is adapted to a low level designs and mapped to a specific technology stack (this is called Implementation Technology Specification, ITS for short), those more specific artifacts can be evaluated to more specific requirements and rules.

Considering the aforementioned ideas, it would be useful to define some guidelines about how to validate the proposed architecture. The actual validation would be a good area for further investigation. Presented below is a list of varied standards and specifications that should (*) or might (+) be used as validation guidelines. In some cases just part of the standard would apply because it is too specific and the validation of the architecture should be done in a very broad, generic and abstract way, because that is the nature of a Software Architecture. After these, local standards and specifications might also apply.

Introduction, Terminology, Requirements and Architecture:

(*) ISO 18308: Requirements for an electronic health record architecture.

(*) openEHR Specifications [6]

(+) IHE IT Infrastructure Profiles [17]

(+) ISO 20514: Electronic health record -- Definition, scope and context

(+) ISO 14292: Personal health records -- Definition, scope and context

(*) ISO 14639: Capacity-based eHealth architecture roadmap -- Part 1: Overview of national eHealth initiatives

(+) ISO 14265: Classification of purposes for processing personal health information

(+) ISO 21298: Health informatics -- Functional and structural roles

(+) ISO 22790: Health informatics -- Functional characteristics of prescriber support systems

Healthcare record definition and sharing:

(*) ISO 27790: Document registry framework

(*) ISO 13128: Clinical document registry federation

(+) ISO/HL7 27932: Data Exchange Standards -- HL7 Clinical Document Architecture, Release 2

(+) ISO 12773-1: Business requirements for health summary records -- Part 1: Requirements

(+) ISO 12773-2: Business requirements for health summary records -- Part 2: Environmental scan

(+) ISO 13119: Clinical knowledge resources -- Metadata

Healthcare Records and Healthcare Data Communication:

(*) ISO 13606-1: Electronic health record communication -- Part 1: Reference model

(*) ISO 13606-2: Electronic health record communication -- Part 2: Archetype interchange specification

(*) ISO 13606-3: Electronic health record communication -- Part 3: Reference archetypes and term lists

(*) ISO 13606-4: Electronic health record communication -- Part 4: Security

(*) ISO 13606-5: Electronic health record communication -- Part 5: Interface specification

Conclusion

We are confident that creating a truly Open EHR Platform will enable e-Health developments and long term EHR projects, that are impossible today due the lack of resources. The proof-of-concept prototypes already developed are attracting attention from the academy and the industry, and we are very close to the delivery of EHR Platform sub-systems in a production-ready state. As time passes, we are also designing and developing tools that will benefit software developers in the creation of openEHR-based applications that will be compatible with the Platform. Such applications could produce a highly scalable backend for shared EHR systems, thus allowing their applications to share a common/stable set of services and easily evolve through time.

Abstract

The language and communication constitute the development mainstays of several intellectual and cognitive skills in humans. However, there are millions of people around the world who suffer from several disabilities and disorders related with language and communication, while most of the countries present a lack of corresponding services related with health care and rehabilitation. On these grounds, we are working to develop an ecosystem of intelligent ICT tools to support speech and language pathologists, doctors, students, patients and their relatives. This ecosystem has several layers and components, integrating Electronic Health Records management, standardized vocabularies, a knowledge database, an ontology of concepts from the speech-language domain, and an expert system. We discuss the advantages of such an approach through experiments carried out in several institutions assisting children with a wide spectrum of disabilities.

Keywords:
Electronic Health Records; Rehabilitation of Speech and Language Disorders; Medical Informatics.

Introduction

The language acquisition process is closely related with intellectual, psychological and emotional development of children. In the same line, speech and language serve as cornerstones for human cognition and constitute tools to interact with the fellows of the social environment. Commonly, during the first 4 years of life, children make significant progress in learning language. However, in some cases there arise delays or differences in patterns of language acquisition, aspects that constitute warnings of developmental problems [1]. These delays or differences can be related with a wide spectrum of circumstances and can appear in different stages of life. In the case of children, some disabilities are related with the following periods [2]: prenatal (chromosomal anomalies and genetic metabolic and neurologic disorders, drug and toxin exposure, congenital infections, ...) perinatal (complications related to prematurity, periventricular leukomalacia, breech or high forceps delivery, multiple births, placenta previa, preeclampsia, ...), or postnatal (undernutrition and environmental deprivation, viral and bacterial encephalitides, poisoning, ...). On the other hand, the speech, language and swallowing disorders in acquired neurological conditions arise as a result of several conditions, such as traumatic brain injury, stroke, progressive neurological conditions (Parkinson's disease, multiple sclerosis, ...), dementia, head and neck cancer, and palliative care [3].

In the same line, in a world where 1 billion people live with some form of disability, the most recent estimates about People with Communication Disabilities (PWCD) shown a complex picture. For example, nowadays 60 million persons in the world live with disabling hearing loss (5.3% of the world's population) and 15 million suffer from stutter, and there exists a lack of rehabilitation services and healthcare related to Speech-Language Disorders (SLD) in most of the developed countries [4]. The situation is even more complex in developing countries due to lack of personnel, resources, and adequate services.

Over the last years, there have been several approaches to apply Information and Communication Technologies (ICT) to support Speech and Language Therapy (SLT). However, the existing approaches to provide support tools for SLT deal with very specific problems. The aphasia treatment field [5] proposes a computer gesture therapy tool (GeST) with the aim to improve the gesture production and/or spoken naming, whereas [6] it investigates the feasibility to incorporate the Semantic Feature Analysis technique in a mobile-web paired application in domestic and clinical settings. Some speech disorders like dysarthria have motivated the application of Automatic Speech Recognition (ASR) techniques for diagnosis tasks [7]. On the other hand, the application of Auditory Verbal Therapy (AVT) to develop several speech abilities in children with cochlear implants has been successfully applied through videogames [8] and multimedia programs [9].

Nevertheless, nowadays some of the most important issues of health care field are related to maintenance, sharing and portability of clinical data, a perspective based on specific domain knowledge, and the adaptability and standardized vocabularies. Accordingly, the aforementioned approaches rely on ad hoc solutions that use particular vocabularies, languages and own data structures. Only a few recent studies have used conceptualizations and classifications (e.g. ontologies) to support the operation of an expert system aimed at the initial diagnosis of language disorders [10].

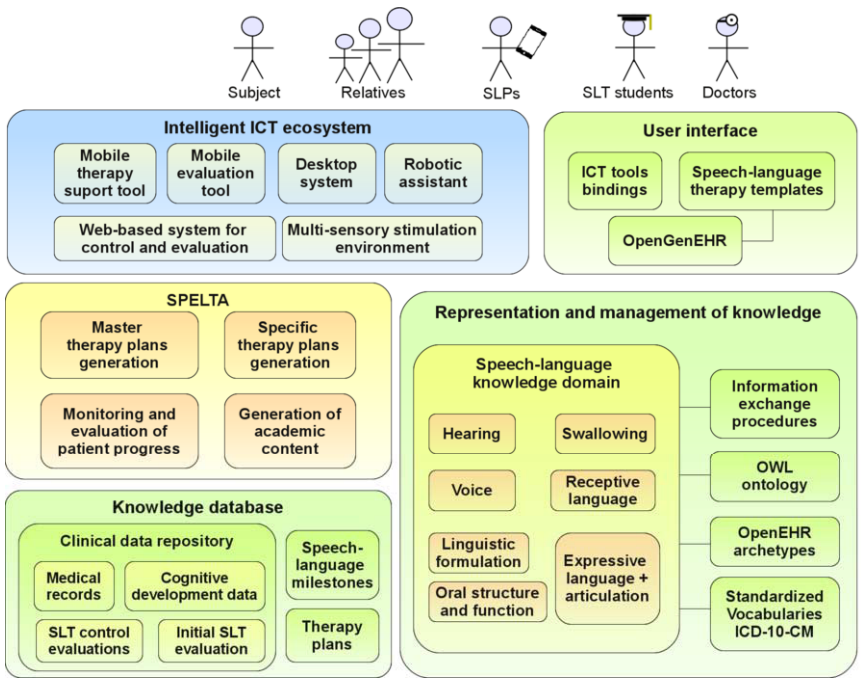

Figure 1– The high-level design and main components of our SLT ecosystem

Methods

SLT is a healthcare area that involves the active participation of different actors, such as doctors, Speech-Language Pathologists (SLP), SLT students, and patients/subjects and their relatives. Therefore, in this section, we present a complete backing ecosystem for SLT that considers these actors from a viewpoint that arises in a formal knowledge model. Likewise, this model is capable to provide an integrative perspective for ICT tools, specific SLT domain knowledge, standardized vocabularies, expert systems, and electronic health records management. Figure 1 shows a high-level model of the architecture of the proposed ecosystem for supporting SLT. This architecture allows building an integrative multi-layer framework for several therapy-related activities, users, knowledge management and portability, intelligent systems, and ICT tools. Some of the most relevant elements are described below.

The expert system layer (SPELTA)

The Speech and Language Therapy Assistant (SPELTA) is an expert system that provides the foundations to develop inference mechanisms for recommender and decision-support systems to assist in the preparation of therapy plans, the evaluation of exercise results, the generation of case studies, etc. Some of the most outstanding functionalities of SPELTA are the following:

- *Master therapy plans generation*: these kind of plans contain the general guidelines and activities that should be conducted with patients over a period of 6 months. Their aim is to develop some specific skills related to speech and language. In order to automatically generate a new master therapy plan, SPELTA uses a custom version of *Partition Around Medoids* (PAM) algorithm and KNN criterion (see more details in [11]). The PAM algorithm generates several clusters organized in two abstraction levels. The first level groups patients according to some elements of their profiles (cognitive developmental age, chronological age), medical record (diagnosis, related disorders/disabilities, and general medical condition), and the initial diagnostic of speech-language. In the second level several subclusters are created inside the general clusters, using the fine-grained evaluation of patient's speech-language skills.
- *Specific therapy plans generation*: these plans contain specific exercises and therapy activities that should be conducted with patients according to a weekly schedule. A set of specific therapy plans belongs to a master plan, and currently we are developing a semantic network using ontologies to represent the different relations between disabilities, disorders, and speech-language milestones and skills according to chronological and developmental age.
- *Generation of academic content:* the expert system is able to generate educational content for phonoaudiology students. These contents include tests about real and generated cases, training resources for decision making about therapy strategies, standardized vocabularies entries, etc.
- *Monitoring and evaluation of patient progress:* this feature of SPELTA allows to automatically analyze the patient progress and generate alerts for SLP when the master and specific plans are not effective.

Knowledge database

The knowledge database stores several information structures to support the data analysis tasks and inference process performed by the expert system layer:

- *Clinical Data Repository* (CDR): consolidates data from several clinical resources (medical records, cognitive development data, SLT control evaluations, initial SLT evaluation) and presents a unified view of patients. Our CDR uses standardized vocabularies from the American Speech-Language-Hearing Association [12].
- *Therapy plans*: these are data structures to represent either long term activities and exercises (master plans) and sets of activities scheduled according to patient's skills and therapy sessions (specific plans).
- *Speech-language milestones*: defines a set of skills according to chronological and developmental age (e.g. formal expressions of facts like "*from 1 to 2 years of normal development, a child must to be able to acquire new words on a regular basis, know a few parts of the body and point to them when asked*").

Representation and management of knowledge

In order to provide a comprehensive support for all therapy process, the model considers seven areas of speech and language: hearing, swallowing, voice, receptive language, linguistic formulation, oral structure and function (oral peripheral mechanism), and expressive language and articulation. The main processes, tests, evaluations, protocols, and therapy activities are modelled using ontologies and are implemented through OpenEHR archetypes. Figure 2 shows a screenshot of an archetype to conduct the Pure Tone Audiometry (PTA) test. As we can see, through this archetype it is possible to assess the patient's response to sound stimulation and voice commands, and determine if he/she is able to localize sound sources without visual stimuli.

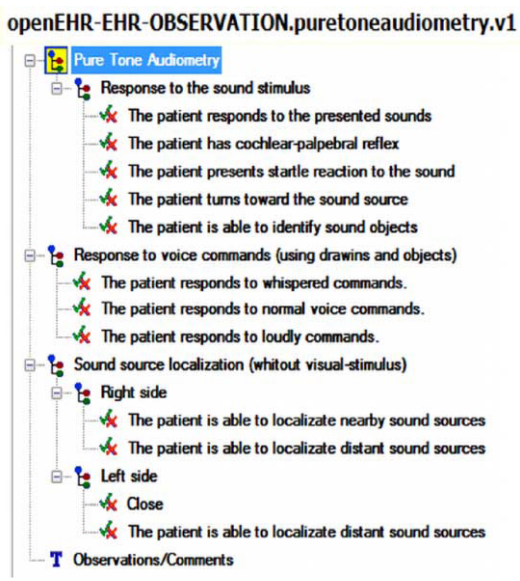

Figure 2– Partial view of the archetype that represents the Pure Tone Audiometry test

Intelligent ICT ecosystem

This layer incorporates a complete set of novel ICTs designed to support most of the SLT stages, and can easily add new tools using the bindings of the user's interface layer. Some of the most relevant elements are the following:

- *Multi-sensory stimulation ecosystem*: these kind of tools serve to support relaxation activities, early stimulation and several rehabilitation processes, for both children and adults, as was proved in [13] and [14].
- *Robotic assistant:* is a novel backing tool for therapy sessions, educational and ludic activities, and remote monitoring tasks. The robot has two main elements, an electronic displacement platform and a mobile device (Android-based tablet or smartphone). Using the mobile device the robot can tell stories, conduct exercises for motor rehabilitation (using a red glove to control a virtual hand), recognize voice commands, and interact with patients through different kinds of exercises based on multimedia resources (color discrimination, temporo-spatial notions, ...).
- *Support tools based on ICT:* through these tools the SLP is able to use desktop and web systems (Speech-language Maturation Assessment Tool, SPELMAT), and mobile devices to perform therapy exercises, assessment tasks, collection of information related with patients, registering the results of therapy sessions, report generation, and sharing data with other SLP. For example, Figure 3 (a) shows a screen capture of MOPHOC, a mobile application to support the learning process of phonetic code. This tool allows to conduct several kinds of exercises related with articulation (phonemic awareness, sentence construction, phonatory, …).

User interface

This layer contains the bindings to connect the ICT tools (Intelligent ICT environment) with the representation and management knowledge layer. Other important elements of this layer are the speech-language therapy templates generated using OpenGenEHR tool (http://www.openehr.org). These templates provide the interface to feed the different information structures related with clinical data. An example of a template to access personal data, conduct a hearing screening, conduct the PTA test, and other options is presented in Figure 3 (b).

Results

Once we have deployed the knowledge model, the information exchange mechanisms, and the main algorithms of the expert system, three pilot experiments were carried with the aim to validate the developed ICT tools with the support of five institutions of special education from Ecuador: Instituto de Parálisis Cerebral del Azuay (Institute of Cerebral Palsy of Azuay), Unidad Educativa Especial del Azuay (Unit for Special Education of Azuay), Fundación "General Dávalos" (General Davalos Foundation), Fundación "Jesús para los niños" ("Jesus for the kids" Foudation), and CEDEI School. These institutions are concerned about the health care, education, and rehabilitation of children suffering from different disabilities (cerebral palsy, dysarthria, dyslalia, athetosis, autism, Down syndrome, multi-disabilities, ...). In this line, for the first experiment, a team of 4 experts were provided with the mobile application MOPHOC to conduct several phonetic exercises and evaluations using articulatory phonetic tests. A total of 32 children were evaluated, and the system determined the error produced in the utterance production of phonemes, consonant clusters, diphones, and sentences (Table 1).

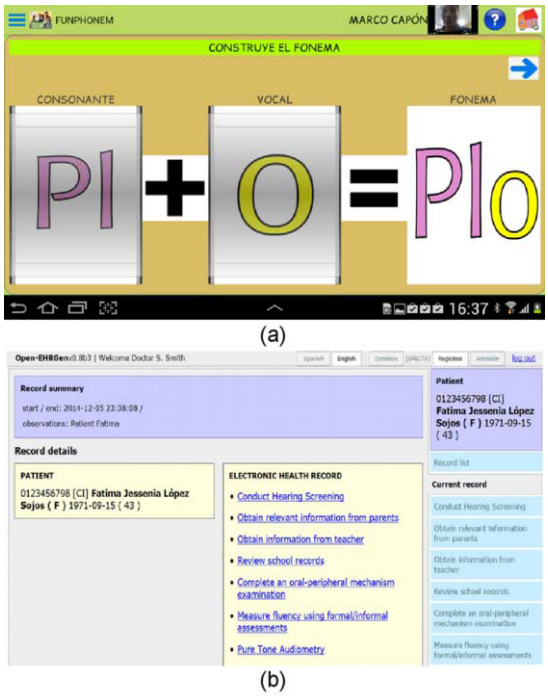

Figure 3– (a) A screen capture of the "articulation notebook" module of the MOPHOC application. (b) A screen capture from menu options of the archetype to conduct a speech evaluation for fluency

In this experiment, we also analyzed the time required to conduct the therapy and evaluation activities through the mobile application (MOPHOC). Also, we have verified an important reduction in the following activities: application of articulatory phonetics test (reduction from 30 to 15 minutes), planification of therapy activities using multimedia resources (5 minutes instead 30), and report generation (reduction from 30 to 5 minutes). These results have been validated by the experts, using manual version of PTA test.

Table 1– Most common articulatory errors detected by the system in the second group of children (32 cases)

Utterance	Average errors committed (%)
Consonant cluster	83
Sentence	77
Diphone	77
Phoneme	67

For the second experiment, a team of 6 experts was provided with the SPELMAT system to conduct evaluations on a different group of 53 children. This team of speech and language therapists had created 40 therapy plans to train the system, according to each child's profile. Each plan consists of five sub-plans to provide general therapy guidelines in 5 SLT areas: hearing, receptive language, linguistic formulation, oral structure and function, and expressive language and articulation, respectively (a total of 200 elementary plans). After that, the remaining 13 children's profiles were presented to the system, with the aim to generate a therapy plan for each (65 sub-plans). Therapists evaluated the outputs by giving each plan a rating of 1 if it was convenient and 0 otherwise, considering consistency, accurateness, and completeness. The last parameters were evaluated in the same way (1=correct, 0=incorrect); therefore, only if the three are correct, the accuracy will be 1. Table 2 shows the accuracy of SPELTA according to each area.

Table 2– Accuracy achieved in the generation of master therapy plans

Speech and language area	Plans correctly generated	Accuracy (%)
Hearing	13	100
Linguistic formulation	13	100
Oral structure and function	13	100
Receptive language	11	84
Expressive language+articulation	9	70
	Average	90

In the last experiment, we have conducted several activities to evaluate the robotic assistant as support tool for SLT. Some of the main goals were to analyze the response time of children during the relaxation activities and initial therapy, to test the robot response to the stimulation of motor skills, and to verify the robot's integration with the database of profiles and therapy plans. Some of the most relevant achievements were that the time needed to conduct the relaxation activities and initial therapy has shrunk from 40 minutes to 25, all the specialists have agreed on the usefulness of the robot, and children have shown high levels of motivation during their interactions with the robot.

Discussion

The results obtained with this study show that it is possible to automate several activities related with SLT, with the aim to provide a better service to patients suffering from several kinds of disabilities. In the same way, the use of mobile support tools allows to reduce significatively the time needed to conduct several activities related with therapy planification, assessment, and report generation. With these mobile tools, an SLP can perform several tasks from any place and assist his/her patients in a better way. Likewise, the use of expert systems based on clustering, allows SLP to discover "hidden populations" for those cases belonging to a group of subjects that suffer from the same disorders and have the same development cognitive age, but have deteriorations in different skills of the same speech-language area.

The management of electronic health record in conjunction with the concepts modeling based on ontologies have an important potential to represent the complex underlying relationships in SLT. With the use of these artifacts, it is possible to create knowledge databases for specific domains and provide efficient integration services for ICT tools and intelligent systems. The use of a model based on several layers, among other elements (archetypes, templates, ICT tools, etc.), provides a robust growing environment, able to easily incorporate new knowledge mainstays, actors, and supporting tools for sharing information through standardized languages and vocabularies.

Conclusion

In this paper we have presented a comprehensive model to support the most relevant task related with SLT. This model is designed to be adjusted or grow up according to requirements of the institutions where patients receive therapy and

rehabilitation. In the same way, given that our model uses archetypes, templates and standardized vocabularies, all generated information can be shared and updated in an efficient way.

Likewise, using this model, it is possible to improve several process related to management of SLT information, given that a SLP can generate reports, visualize data, and analyze the patients' progress quickly and from any device (web, mobile or desktop). On the other hand, the expert system layer provides support in decision making for complex tasks, such as planning and scheduling of therapy sessions and activities according to specificity of each patient's profile. The SPELTA has achieved promising results, given that the generated therapy plans were deemed consistent, accurate, and complete by the experts. Only the areas of receptive and expressive language seem to demand a refined or alternative approach.

The following are proposed lines of future work:

- Extend the proposed model to cover some deeper areas of knowledge, like the automatic generation of specific therapy plans based on daily activities and considering these elements: the existing levels of granularity of the patient's cognitive development, the incidence of other disorders (cerebral palsy, athetosis ...), etc.
- Modify the distance measures to improve the accuracy of generated plans in the areas of receptive language, and expressive language and articulation.

Abstract

Although Electronic Health Records (EHR) can offer benefits to the health care process, there is a growing body of evidence that these systems can also incur risks to patient safety when developed or used improperly. This work is a literature review to identify these risks from a software quality perspective. Therefore, the risks were classified based on the ISO/IEC 25010 software quality model. The risks identified were related mainly to the characteristics of "functional suitability" (i.e., software bugs) and "usability" (i.e., interface prone to user error). This work elucidates the fact that EHR quality problems can adversely affect patient safety, resulting in errors such as incorrect patient identification, incorrect calculation of medication dosages, and lack of access to patient data. Therefore, the risks presented here provide the basis for developers and EHR regulating bodies to pay attention to the quality aspects of these systems that can result in patient harm.

Keywords:

Electronic Health Records; Patient Safety; Quality Improvement.

Introduction

The progress of information technology has impacted the healthcare sector. Some of these impacts are caused by adoption of the Electronic Health Records (EHR) [1]. One of the main goals of EHR is to support continuity, efficiency, and quality in healthcare [2]. These systems can offer benefits, such as ease of access to patient data, research support [3], and greater completeness and documentation comprehensiveness [2]. In addition, these systems have shown a capacity for reducing medical errors and increasing patient safety, mainly by means of decision-making support mechanisms [1,4].

Despite these benefits, the literature also presents evidence that, when developed and/or used improperly, EHR can incur risks to patient safety [5–8]. Patient safety is understood as a reduction of damage risks to patients in the healthcare process [9].

For example, some real cases of problems associated with the use of EHR that jeopardized patient safety can be cited. In 2007, a maintenance error in the network configuration of the Veterans' Health Administration (VHA), one of the largest healthcare providers in the United States, caused the EHR to become inaccessible for more than nine hours. As a result, many consultations were conducted without access to any documentation, and surgeries had to be postponed because the doctors were uncertain about how to proceed without proper documentation [7].

An evaluation of adverse event database from the Food and Drug Administration (FDA) in the United States also revealed cases of incidents related to the use of EHR. Loss or corruption of data, association of information to the wrong patient, and lack of access to the EHR resulted in problems such as delays in diagnosis or treatment, incorrect administration of medication, and even death [5].

Despite the growing quantity of such evidence, there is a significant gap of initiatives that address patient safety issues associated with the use of EHR [10]. Therefore, there is a need for more research aimed at investigating the possible EHR quality problems that can negatively affect the healthcare process.

In this context, this work presents a literature review of the risks that EHR can cause regarding patient safety. The risks presented here are classified based on the software product quality characteristics specified by the 25010 standard by the International Organization for Standardization (ISO) and the International Electrotechnical Commission (IEC) [11]. This classification allows EHR developers to have better traceability of the quality characteristics of their products that can affect patient safety. According to the authors' knowledge, such an approach has not been used by any published work in the literature.

Methods

In order to search the relevant databases, we used medical subject headings (MeSH) terms and free terms defined from the two main topics associated with the theme of this work: "EHR" and "Patient Safety Risks." The electronic databases consulted were PubMed, IEEE Xplore Digital Library, ACM Digital Library, and ScienceDirect. We selected only papers published between 2010 and 2014.

The electronic database searches returned 8,609 references, 17 of which were selected for review. The works were selected by an iterative scan of these references in order to eliminate duplicate records and select only those references relevant to the purpose of this work.

After the literature review, the selected articles were submitted to an in-depth reading for risk identification. The risks were then classified based on the software product quality model established by ISO/IEC 25010 - Systems and software engineering - Systems and software Quality Requirements and Evaluation (SQuaRE) - System and software quality models. This standard establishes a model composed of eight characteristics (divided into sub-characteristics) used to evaluate software product quality and evaluate how it can meet the needs of stakeholders [11].

Results

The works included in this literature review investigated the risks to patient safety associated with EHR using approaches such as: analysis of incident reports [5,12–16], application of interviews or questionnaires to experts or EHR users [17–19], literature review [20–23], and expert opinion [24–26].

In the next sections, we present the risks to patient safety associated with EHR identified by reading the articles included in the literature review. These risks are presented based on the characteristics and sub-characteristics of software product quality set out in ISO/IEC 25010, as listed in Table 1.

Table 1– Risks classified by ISO/IEC 25010 software quality model

Characteristics	Sub-characteristics	Risk
Functional Suitability	Functional completeness	R1 - Lack of functionalities that support clinical workflow [5,17,20]
		R2 - Lack of coding, standardization, and structuring data [24]
		R3 - Lack of features to detect duplicate patient records [19,27]
	Functional correctness	R4 - Inaccurate, outdated, or incomplete decision support rules [5,20,21]
		R5 - Software bugs [5,13,14,20,23]
	Functional appropriateness	R6 - Inadequate content import features [20,21,23,26]
		R7 - Pre-populated fields [20,23,25,26]
		R8 - Inadequate alerting [19,20,22,24]
		R9 - Allow tasks to be performed simultaneously [12,19]
Usability	Appropriateness recognizability	R10 - Inadequate display of information [5,12,14,16,18,19,22,25]
	Learnability	R11 - Difficulty in understanding current status of user actions [19]
	Operability	R12 - Difficulty in interacting with EHR [19,21]
	User error protection	R13 - Interface prone to user error [12,16,17,19–22,27]
	User interface aesthetics	-
	Accessibility	-
Performance Efficiency	Time behavior	R14 - Delay in system response [12]
	Resource utilization	-
	Capacity	-
Compatibility	Co-existence	-
	Interoperability	R15 - Communication errors between systems [5,12,14–16,19,24]
Reliability	Availability	R16 - EHR unavailability [13,15,17–19,24,25]
	Maturity	-
	Fault tolerance	-
	Recoverability	-
Security	Confidentiality	-
	Integrity	-
	Non-repudiation	-
	Authenticity	-
	Accountability	-
Maintainability	Modularity	-
	Reusability	-
	Analyzability	-
	Modifiability	-
	Testability	-
Portability	Adaptability	-
	Installability	-
	Replaceability	-

Functional Suitability

The quality characteristic "functional suitability" is related to the degree to which the features offered by the software are complete, accurate, and appropriate. Risks associated with all three sub-characteristics in this category were identified.

Functional Completeness

The sub-characteristic "functional completeness" is the degree to which the software provides necessary functions for users to achieve their goals. The following risks have been identified for this category:

- **R1** - Lack of functionalities that support clinical workflow [5,17,20].
- **R2** - Lack of coding, standardization, and structuring data [24].
- **R3** - Lack of features to detect duplicate patient records [19,27].

The absence of features that support clinical workflow can cause users to decide on workarounds that could jeopardize patient safety. For example, when the EHR does not allow registration of drug administration prior to registering its order (a common necessity in emergencies), the drug application documentation will occur after administration, which can result in medication being administered again because its administration was not registered previously [20].

The lack of codification, standardization, and data structure can result, for example, in failure to issue alerts [24], whereas the absence of mechanisms to detect double-patient records can result in documentation gaps because of information fragmentation [27].

Functional Correctness

The sub-characteristic "functional correctness" evaluates the degree of accuracy and correctness of the functionalities offered by the software. For this category, the following risks were found:

- **R4** - Inaccurate, outdated, or incomplete decision support rules [5,20,21].
- **R5** - Software bugs [5,13,14,20,23].

Supporting rules for incorrect, not current, or incomplete decisions can result in the issuance of a large amount of false-positive alerts, encouraging users to overlook alerts [21]. In addition, users with high confidence in technology can be mislead when making decisions based on incorrect recommendations issued by the system. This process is known as "automation bias," in which users perform actions recommended by technology when they have decision doubts, or even when such actions contradict their knowledge [20].

Software bugs can cause incorrect dosage calculations [5] or even the corruption, loss, or improper storage of data [20]. This risk was also associated with maintenance or updates to EHR that, when poorly managed, can introduce new bugs to the software [14].

Functional Appropriateness

The sub-characteristic "functional appropriateness" verifies how the functions offered by the software are appropriate and capable of facilitating task execution by users. The following risks were identified:

- **R6** - Inadequate content import features [20,21,23,26].
- **R7** - Pre-populated fields [20,23,25,26].
- **R8** - Inadequate alerting [19,20,22,24].
- **R9** - Allow tasks to be performed simultaneously [12,19].

Text import features (such as copy/paste) are often related to the propagation of incorrect information, loss of authority assignment, or even copy of outdated information [26]. Whereas these problems occur mainly from abusing the use of these features [17,20], the EHR can help avoid them by restricting the type of data that can be imported, and including the original text source for imported content [26].

Fields with default values (such as the establishment of standard doses [23,25]) can also incur risks to patients when not reviewed by users [26]. On the other hand, issuing alerts and reminders with low specificity or sensitivity, irrelevant, or excessive, encourages users to overlook alerts that could potentially be important [19,22] and interrupts the clinical workflow and thought process of health professionals [24],.

Allowing certain tasks to be performed simultaneously, such as opening two or more patient records on the same device [19] or simultaneously editing the same record by different users [12], can result in the registration of information to the wrong patient, or in information inconsistency [19].

Usability

The quality characteristic "usability" evaluates user interface in the context of ease of understanding, learning, ease of use, user attraction, and accessibility. For this category, risks were found in the sub-characteristics "appropriateness recognizability," "learnability," "operability," and "user error protection".

Appropriateness Recognizability

The sub-characteristic "appropriateness recognizability" verifies the degree to which users recognize the software suitable for their needs. The following risk for this category was identified:

- **R10** - Inadequate display of information [5,12,14,16,18,19,22,25].

The problems related to this risk are in regards to incomplete display of information [5,12,18,19,22,25], such as not displaying pre-existing medications or patient allergy data [12]; buttons with the same label, but different features [25]; and presentation of high information volume [5]. These problems are associated with patient misidentification (caused by not displaying key identifying data) [19] and incorrect interpretation of information [16].

Learnability

The sub-characteristic "learnability" evaluates how the software allows users to understand key software concepts, thus making the concepts effective for use. The following risk was identified:

- **R11** - Difficulty in understanding current status of user actions [19].

This risk is associated with the occurrence of open or incomplete orders caused by the failure to complete an order process, including signature or submission. This problem can be caused by the user interface when it becomes difficult to understand the current status of user's actions [19].

Operability

The sub-characteristic "operability" assesses the ease of using the software. The following risk was found for this category:

- Modelo de Qualidade ISO/IEC 25010 - Difficulty in interacting with EHR [19,21].

Interface problems, such as the display of information of the same context on multiple screens or tabs [19,21], can cause user interaction with EHR difficult. Difficulty in navigating, visualizing, understanding, and interacting with the user interface can cause failure to identify and/or use the most recent patient data, thus causing clinical decision errors and generating incorrect, unnecessary, or delayed tests, procedures, and therapies [19].

User Error Protection

The sub-characteristic "user error protection" evaluates the software's ability to prevent user errors. The following risk was identified:

- **R13** - Interface prone to user error [12,16,17,19–22,27].

Many of the selected studies reported that the way in which the user interface arranges information can facilitate the occurrence of user errors. The main problems regarding this risk are related to item selection lists (such as drug lists) or drop-down menus that often have very similar items [19–21], lack of item grouping [19], or a very large amount of items [19,21]. These design issues can result in the improper

selection of items (such as incorrect patient selection) [16,17,19,27].

Performance Efficiency, Compatibility, and Reliability

The quality characteristic "performance efficiency" evaluates software optimization in connection with processing time, resource consumption, and processing capacity. For this category, only the sub-characteristic "time behavior" presented a risk:

- **R14** - Delay in system response [12].

A delay in response to a particular EHR action can cause users to click the same action several times, thus generating duplicate prescriptions, for example [12].

The quality characteristic "compatibility" refers to the degree to which two or more systems or components of a system can exchange information. One risk was identified for the sub-characteristic "interoperability":

- **R15** - Communication errors between systems [5,12,14–16,19,24].

Communication errors between systems or components of a system are often caused by difficulties in EHR interoperability with other systems [22], or failures in network infrastructure [5,12,14,16,25]. Such errors can prevent patient context and status from being consistent between components/systems, leading mainly to delays in the healthcare process [14].

The quality characteristic "reliability" evaluates software in terms of maturity (frequency with which the software is defective over time), availability (degree to which the software is available for use), fault tolerance (the software's ability to operate in the presence of hardware or software failures), and recoverability (the software's ability to recover data and return to operate after the occurrence of a failure). For this category, we found one risk with respect to the sub-characteristic "availability":

- **R16** - EHR unavailability [13,15,17–19,24,25].

When EHR is not available for use, health professionals can lose access to the documentation required for healthcare processes, which can lead to such problems as delays in diagnosis and treatment [7].

The main causes of lack of access to EHR are failures or planned downtime of some infrastructural component [19]. Therefore, it is necessary for EHR to offer redundant devices [19,24], and a read-only version to access without connection [19].

Discussion

The software quality characteristics that presented more risks to patient safety were "functional suitability" (nine risks) and "usability" (four risks). On the other hand, the risks most discussed in the articles selected for this literature review were: "Inadequate display of information" (usability-appropriateness recognizability); "interface prone to user error" (usability-user error protection); "communication errors between systems" (compatibility-interoperability); and EHR unavailability (reliability-availability).

Once the major quantity of identified risks is related to the functions provided by the EHR (functional suitability) and its usability, it is noticed the importance of the integration of the end user to the product development process. A way for achieving such integration is the use of the principles of User-Centered Design (UCD) [28]. The UCD is an approach that involves the end users along all of the development process in order to enssure that the product is suitable to their needs. This approach also seeks to take into account the needs and expectations of any person that could be affected by the use of the product [29] (e.g. the patients). Therefore, UCD may help to building EHRs more compliant to the health professionals' needs and, at the same time, safer for patients.

No risks were found for the quality characteristics "security," "maintainability," and "portability." However, the authors consider that the attribute "security" (which evaluates how the software can protect its functions and data from unauthorized access) can also be important for patient safety because problems regarding confidentiality breaches of patient information could harm their psychological well-being.

In addition to the risks specifically related to EHR quality characteristics, we identified risks that arise because of improper EHR use, such as neglecting the use of structured fields to use only free text fields [24]; infrastructure problems, such as network failures [14]; and other contributing factors, such as gaps in regulations [20] and poor user training [16,23].

Therefore, it is clear that the EHR is part of a complex sociotechnical system in which patient safety incidents can occur because of the interaction of several factors [30]. However, this study aimed to present risks in an approach that was more focused on EHR quality characteristics, and therefore, risks relating to other aspects are not discussed.

Conclusion

This paper presented risks that EHR can incur to patient safety when developed improperly. The risks were presented according to the characteristics of software product quality set out in ISO/IEC 25010, thus allowing the developers of these systems to have a reference for identifying the quality attributes of their products that might pose risks to patient safety.

In addition, the risks presented can be used as reference for the specification of more stringent requirements in the EHR certification processes, once these processes still require more direct approaches to patient safety [10,31].

However, it is still necessary to investigate strategies to mitigate the risks presented here in order to provide techniques and recommendations that can be used by EHR developers to create a product that offers greater safety to the healthcare process.

It is also necessary to examine the risks to patient safety in a sociotechnical context in greater depth, thus allowing the identification of problems related to EHR process use, specification of regulations, supervision, infrastructure, and any other factors that interact with EHR throughout its lifecycle. The identification of these problems should be followed by the identification of their solutions, indicating the role of each actor involved in this sociotechnical system in mitigating the risks to patient safety.

Nonadherence to Oral Antihyperglycemic Agents: Subsequent Hospitalization and Mortality among Patients with Type 2 Diabetes in Clinical Practice

Vivienne J. Zhu[a], Wanzhu Tu[b], Marc B. Rosenman[a,b], J. Marc Overhage[c]

[a]Regenstrief Institute, IN, USA [b]Indiana University School of Medicine, IN, USA, and [c]Cerner Corporation, Malvern, PA, USA

Abstract

Using real-world clinical data from the Indiana Network for Patient Care, we analyzed the associations between non-adherence to oral antihyperglycemic agents (OHA) and subsequent diabetes-related hospitalization and all-cause mortality for patients with type 2 diabetes. OHA adherence was measured by the annual proportion of days covered (PDC) for 2008 and 2009. Among 24,067 eligible patients, 35,507 annual PDCs were formed. Over 90% (n=21,798) of the patients had a PDC less than 80%. In generalized linear mixed model analyses, OHA non-adherence is significantly associated with diabetes related hospitalizations (OR: 1.2; 95% CI [1.1,1.3]; p<0.0001). Older patients, white patients, or patients who had ischemic heart disease, stroke, or renal disease had higher odds of hospitalization. Similarly, OHA non-adherence increased subsequent mortality (OR: 1.3; 95% CI [1.02, 1.61]; p<0.0001). Patient age, male gender, income and presence of ischemic heart diseases, stroke, and renal disease were also significantly associated with subsequent all-cause death.

Keywords

Health information exchange, type 2 diabetes, medication adherence, hospitalization, mortality

Background

Type 2 diabetes is a major public health crisis in this country. Over 29 million adults in the United States currently have diabetes mellitus, and the incidence is increasing at nearly epidemic rates [1]. This will have a significant public health impact because diabetes is a major cause of morbidity and mortality. In addition, healthcare costs are 11% higher for patients with poorly controlled diabetes compared to those with good glycemic control [2].

Clearly, pharmacotherapy for glycemic control is essential to achieving the goal of long-term metabolic control and reducing the risk of cardiovascular disease (CVD) events, the primary cause of hospitalization and mortality among these patients. However, increasing evidence suggests that patients with diabetes often have poor adherence to prescribed medication therapies. A systematic review of medication adherence in diabetes showed low adherence rates, ranging between 36-87% across numerous studies [3]. These observations have been replicated in several studies, and adherence among patients with diabetes is disappointingly low, dropping most dramatically after the first six months of therapy [4,5].

Improving medication adherence is viewed as a high priority for health care reform. The Centers for Medicare and Medicaid Service (CMS) has encouraged adherence to oral diabetes medications via quality and efficiency measures in health and drug plan performance rating [6]. However, improving medication adherence is a multifactorial challenge. Health information technology (HIT) and health information exchange (HIE) are playing an increasing role in generating, measuring, and transferring important medication adherence data between hospitals, pharmacies, providers, and patients. Recently, the electronic medical record system (EMR) meaningful use criteria and the Accountable Care Organization (ACO) have encouraged electronic prescribing, medication reconciliation, patients' accessibility to their own medical information, and care coordination [7,8], all of which support improving medication adherence and ultimately improving patient health outcomes through HIT and HIE.

Although the effects of medication adherence on patient hospitalization and mortality, as well as the significant potential of HIT and HIE for improving medication adherence, have been increasingly recognized, few population-based studies have been conducted using real-world data. The association between medication non-adherence and mortality has been chiefly demonstrated in clinical trials. In this study, we aimed to assess adherence to OHA for patients with type 2 diabetes and to analyze the association between OHA non-adherence and hospitalization and mortality, using real-world clinical data from an operational HIE.

Methods

Data sources and settings

This retrospective study was designed to analyze the association between nonadherence to oral antihyerglycemic agents (OHA) and health outcomes in the subsequent year for patients with type 2 diabetes. We used medication dispensing data from 2008 to 2009 and clinical data (hospitalization and death) from 2009 to 2010 from the Indiana Network for Patient Care (INPC). The INPC is an operational, regional, health information exchange that included over 100 hospitals, physician practices, payers, pharmacies, laboratories, and independent radiology centers. This system delivers medical record information from hospitals, laboratories, imaging centers, pharmacies and physician offices [9]. In particular the INPC included pharmacy claims data from the largest public and private payers as well as medication history data from pharmacy benefit managers obtained via the Surescripts network [10]. For this study, the patient medication history, diabetes related hospitalizations, and death (all causes) information were extracted from the INPC and were linked through a robust linkage algorithm. We additionally estimated patient income through median household income by zip code obtained from the U.S. Census Bureau website (2000 data is the most recently information available). This

study was approved by the Institutional Review Board of Indiana University and the INPC Management Committee.

Eligibility criteria

Eligible subjects were age 18 years or older in 2008, and had a diagnosis of type 2 diabetes using the *International Classification of Disease, Ninth Revision, Clinical Modification* (ICD-9_CM) of 250.x0 and 250.x2. They had at least one pharmacy claim for an OHA: Biguanides, Sulfonylurea (SU), Thiazolidinedione (TZD), other OHAs (Meglitinides and α- glucosidase), or OHA combination. Patient OHA dispensing information was extracted by the National Drug Codes (NDC) with drug names matched to OHA medications identified by the First DataBank *Standard Therapeutic Code* system (STC:71, excluding injectable: 0177, A771, A716), from 2008 to 2009. Patients who used insulin were excluded. This sample reflects patients who had a drug benefit. Also, since all included subjects had in fact filled a prescription, it suggests that they used that benefit. Therefore, it is likely that the data collected accurately reflects the pattern of medication dispensing events.

Measurements

The independent variable is the annual OHA medication adherence for 2008 and 2009, which was measured using a standard approach: the proportion of days covered (PDC). The PDC is an accepted standard measurement for evaluating medication adherence using retrospective data. It is defined as the total number of medication-covered days divided by the number of days in a certain time period. In this study, the annual PDC is calculated as the proportion of days which had at least one OHA available during a 365-day period. Medication history data, including refill date, days of supply, dosage, and frequency, are used to calculate PDC [11]. For patients who took multiple OHAs, we calculated the combined PDC. Non-adherence was defined as a PDC less than 80%, a conventional cut- off point to define poor adherence for chronic conditions [12].

The dependent variables were diabetes hospitalization and all-cause death for 2009 and 2010

(2010 is the most recent year for which death certificate data are available in the INPC). For each patient, we identify whether a diabetes-related hospitalization occurred in 2009 or 2010 according to the primary diagnosis for inpatient admissions in the INPC. Patients who had at least one recorded hospitalization related to diabetes type 2 (ICD-9: 250.*2), cardiovascular disease (ICD-9:410.*. 411.*, 412.*, 414.*), stroke (ICD-9:433.*1, 434.*), or renal disease (ICD-9:585.*) during a study year were considered to have a DM2 related hospitalization. Similarly, the patient's vital status also was identified from the INPC which was previously integrated from the Social Security Administration.

In order to control possible confounders that may influence patient hospitalization and mortality, we examined age, gender, race, income, number of concurrent OHAs (single, multiple), and baseline co-morbidities (hypertension, ischemic heart diseases, stroke, and renal disease) as covariates.

Statistical analyses

Patient OHA adherence was assessed. Descriptive statistics of patient demographic and clinical characteristics, hospitalizations, and mortality were reported for both the adherent and non-adherent groups. Continuous variables were compared using *t*-tests, and categorical variables were compared using $\chi 2$ tests. Generalized linear mixed models (GLMMIX) were performed to evaluate the association between hospitalization or mortality and OHA adherence of the previous year in the INPC DM2 population. Random subject effects were used in these models to accommodate the potential association among observations contributed by the same study subjects. Adjusted odds ratios (OR) were used to quantify the associations. All analyzes were implemented using SAS 9.1 (*SAS Institute, Cary, North Carolina*). Two-sided *p*-values less than 0.05 were considered significant.

Results

A total of 24,067 eligible patients with DM2 were identified for this study from 2008 to 2010, and 35,069 annual PDC were formed. Across the study period, 21,798 (90.6%) of the patients had a mean annual PDC of less than 80%. A total of 4,235 (17.9%) patients had at least one DM2 related hospitalization, and 319 (1.3%) patients died by 2010. Patient characteristics by adherence are outlined in Table 1. Non-adherent patients were relatively younger (60 vs 67), more were female (52% vs. 49%), fewer were white (81% vs 87%), and they had relatively lower income ($45,447 vs $46,872). Around 70% of patients had hypertension in both groups. The rates of hypertension and ischemic heart disease was slightly lower in the non-adherent group, but no significant difference was found for stroke and renal disease between the two groups.

Compared with adherent patients, patients who did not adhere to OHA had significantly higher hospital admission rates (18.1% vs. 16.6%) and higher

mortality (1.35% vs. 1.1%). Table 2 summarizes the results of the GLIMMIX model that analyzed associations between OHA adherence, patient factors and subsequent DM2 related hospitalizations and mortality. After adjusting for patient baseline characteristics, OHA non-adherence is significantly associated with hospitalizations (OR: 1.2; 95% CI [1.1, 1.3]; p<0.0001). Older patients, whites, or patients who had ischemic heart disease, stroke, or renal disease had greater odds of hospitalization. Similarly, OHA non-adherence increased subsequent death due to any cause (OR: 1.3; 95% CI [1.0, 1.6]; p<0.0001). Patient age, male gender, and presence of a co-morbid condition (including ischemic heart diseases, stroke, or renal disease) were also significantly associated with subsequent death. Hypertension had no effect on hospitalization (p=0.84) but was associated with lower risk of death (OR; 0.5; 95% CI [0.54, 0.79]; p<0.001). Multiple OHA use decreased risk of hospitalizations, but had no significant association with death. Patient income had no association with hospitalization, but it was inversely associated with all-cause death.

Discussion

This large, population-based, observational study documented a high prevalence (90%) of non-adherence to OHA in clinical practice. In the multivariable GLIMMIX analyses, after fully adjusting for baseline patient demographic and clinical characteristics, non-adherent patients had a 1.2 fold higher risk for hospitalization with diabetes, cardiovascular diseases, or renal disease in the subsequent year. In addition, we observed significantly increased rates of all-cause mortality (OR: 1.3) among patients who did not adhere to OHA. These findings are consistent with previous population-based studies. Joe Hong, *et al.*, reported that non-adherence to OHA in the first two years increased the risk of hospitalization (OR: 1.26) and death (OR: 1.4) in the third year among patients in a national insurance program [13]; Lau and Nau found a 2.5 times higher risk for diabetes and cardiovascular disease hospitalization among non-adherent patients within one year using a registry [14]; Ho, et al., showed medication non-adherence was significantly associated with all-cause hospitalization (OR: 1.6) and all cause-mortality (OR: 1.8) in 12 months of follow up of an randomized clinical trial [15];

Glycemic control is the primary goal for diabetes management. Oral antihyperglycemic therapies are effective methods to control glycemic levels among patients with type 2 diabetes, thus lowering their risks of developing microvascular and macrovascular complications [16]; Previous studies have shown that OHA adherence was independently associated with HbA1c control: HbA1c decreases 0.10% to 0.16% for each 10% increment in OHA adherence [17]; As a result, improving OHA adherence may lead to better patient health outcomes through better glycemic control. Our study confirmed the importance of OHA adherence in clinical practice. Patients who did not adhere to their OHA medication (PDC less than 80%) were at higher risk of both hospitalization and mortality within one year.

In addition to the therapeutic effectiveness of OHA adherence, good adherence could also be a surrogate for other factors that reflect a high quality of care, healthy behavior, or more effective treatment. Patients who adhere to OHA may be more compliant with other medications, such as HMG-CoA reductase inhibitors and beta-blockers, to better control complications. They may also more actively implement self-management, including monitoring blood glucose levels, following a diet, engaging in regular exercise, caring for their feet, and interacting with providers, which all lead to improved clinical outcomes in diabetes. In contrast, non-adherence may be associated with depression, cognitive impairment, or missed appointments, which may be linked to less than desirable health outcomes.

This study also found that older patients and those with ischemic heart diseases, stroke, and/or renal diseases had higher risks of both hospitalization and death. Interventions for improving medication adherence or other intensive care should target these subgroups so that patients can achieve the full benefits of anti-hyperglycemic therapies. Interestingly, hypertension was not significantly associated with hospitalization and decreased risk of death, which is inconsistent with the notion that hypertension accelerates the progression of both micro- and macro-vascular complications in diabetes. A possible explanation could be that aggressive antihypertensive treatments, including a range of antihypertensive drugs and lifestyle therapies, might be applied to diabetic hypertensive patients to reduce the risk of micro-vascular and macro-vascular disease [18].

Studies about socioeconomic status and patient health outcomes have shown mixed results. Our study found no association between income and hospitalization, while patients with lower income had higher risk of all-cause death. The study subjects are mainly resident in the central Indiana region and have insurance coverage (including Medicaid), with which they might have been provided equal access to the healthcare system. However, low income may directly influence mortality by other context, such as health behaviors, stress, suicide, and homicide, as well as environmental factors [19].

The main findings from this study add evidence to the growing need to establish interventions in medication adherence in order to improve health outcomes for patients with type 2 diabetes. Barriers to medication adherence in diabetes exist at the patient, medication, and provider levels, and a multi-dimensional approach is required to establish efficient interventions. Health HIT and HIE offer the potential to establish such a system. First, objective and data-driven approaches can be programmatically established through an HIE. Second, computerized alerts and reminders can notify pharmacists or prescribers when their patients miss an opportunity to fill a medication in routine clinical practice. Third, predictive modeling may identify patients who are at higher risk of medication non-adherence and may help evaluate specific barriers for these patients. Fourth, widely used Internet and mobile health technologies may empower patients to manage their medications. In addition, a well-established HIE/HIT could support patient-centric and team-based care that better engages patients, providers, and health care systems for improving medication adherence.

Several limitations should be noted. First, the OHA dispensing information was extracted from the Surescript in the INPC covered geographic area; findings may not apply to other population. Second, dispensing claims might not reflect patient medication-taking behavior if patients did not actually use these medications. Nevertheless, filling a prescription is usually consistent with taking the medication. Third, findings from this observational study demonstrated associations (not causations) between OHA non-adherence and hospitalization, as well as associations (not causations) between OHA non-adherence and mortality. Fourth, some patients with type 2 diabetes may use insulin to control their glycemic levels; however, we lack information regarding insulin use for this population. In addition, we were not able to identify the specific cause of death using existing data; therefore, the association between OHA adherence and mortality might be overestimated.

Conclusions

This study found that 90% of patients with type 2 diabetes did not adhere to oral antihyperglycemic agents in clinical practice. Nonadherence was significantly associated with increased risks of hospitalization and death in the following year. The study findings emphasize the importance of improving medication adherence in diabetes management. Developing HIT and HIE strategies should be highly encouraged to effectively intervene with patients and providers regarding medication adherence.

Validation of Minimum Data of Archetyped Telehealth Clinical Report for Monitoring Prenatal Care

Danielle Santos Alves[a], Valéria Cesário Times[a], Magdala de Araújo Novaes[b]

[a] *Center for Informatics, Federal University of Pernambuco (CIn/UFPE), Pernambuco, Brazil*
[b] *Telehealth Center of Pernambuco, Federal University of Pernambuco (NUTES/ UFPE), Pernambuco, Brazil*

Abstract

Studies on the validation of minimum data sets from international information standards have drawn the attention of the academic community to the identification of necessary requirements for the development of Electronic Health Records (EHRs). The primary motivation of such studies is the development of systems using archetypes. The aim of this study was to validate the minimum data set that should be used when constructing an archetyped EHR for prenatal care applications in telehealth. In order to achieve this, a data validation tool was built and used by nine expert obstetricians. The statistical analysis employed was the percentage of agreement and the content validity index. The study was conducted in three steps: 1) Literature review, 2)Instrument development, and 3) Validation of the minimum data set. Of the 179 evaluated pieces of data, 157 of them were validated to be included in the archetyped record of the first prenatal consultation, while 56 of them were allocated for the subsequent consultation record. The benefit of this research is the standardization (data validation for an archetyped system) of prenatal care, with the perspective of employing, both nationally and internationally, an archtyped telehealth system.

Keywords:

Validation; Archetype; Electronic Health Record; Obstetrics; Prenatal Care.

Introduction

Validation studies can be focused on any area of health. Primary care, especially in the form of programs focused on womens' healthcare, has been drawing attention due to its great impact on society and its repercussion on important maternal and neonatal morbidity and mortality indicators [1].

The monitoring of this population occurs at the level of primary care, in other words, it is made by the family health units (FHU) of each county throughout the state. However, it is known that there are intrisic issues with primary healthcare provision that are preventing it from fulfilling its objective. There are not enough primary care specialists for the whole population, making it therefore necessary to integrate the primary health network with secondary and/or tertiary levels of care.

For this integration, the FHU's doctor and/or nurse need to have tertiary network support in case there is the need to provide prenatal monitoring of their high-risk pregnant women. Telehealth can provide the necessary support in a timely manner, avoiding unnecessary trips and referrals, and enabling the population to remotely access and depend on specialists.

To facilitate communication between primary and tertiary levels through telehealth, it is necessary to use archetyped telehealth systems in obstetrics to allow for the exchange of information between them, and thus, detect early complications, avoid unnecessary referrals, and reduce the physical and financial costs of trips.

Studies and recommendations made by the Brazilian Health Informatics Association concerning the validation of minimum data sets of international information standards have drawn the attention of the academic community to the development of an Electronic Health Record (EHR) [2].

Furthermore, the development of systems using archetypes has been recommended by researchers [3]. Also, it has been recognised that in validation studies, the participation of health professionals is crucial. Therefore, with the help of nine experts, all obstetricians, this work aims to validate the minimum data set that should be used in the construction of an archetyped EHR for prenatal care applications in telehealth.

Many countries, including Brazil, are encouraging the use and adoption of international standards in the EHR to facilitate the exchange of information between systems and among the various healthcare levels. These recommendations have been proposed since 2011 by a decree from the Ministry of Health. It regulates the use of interoperability standards and health information for EHRs of the national health systems in municipal, district, state, and federal levels [3].

Currently, the major difficulty in the development of EHRs is that systems are built without performing minimum data set validation studies, in addition to the absence of terminology and universal standards. All of those issues, in the future, could undermine a proper and safe exchange of information between systems (interoperability), harming patients' well-being [4].

Among the proposals to help reduce the complexity barriers of interoperability and adopting standards in health are the studies proposed by the openEHR Foundation, which is a network of researchers working throughout the world, developing and testing the applicability of archetypes in healthcare systems.

Archetypes may be conceptualized as a set of specifications that define a reference model of health information, i.e., a language for constructing "clinical models" [5]. Archetypes define the concepts used in the clinical field, such as a clinical summary of a pregnant woman or the information on the patient's weight. An international repository–built by the OpenEHR foundation–already exists, containing validated archetypes that are used by researchers, developers, or health professionals while developing an EHR for many areas of health. Some of these archetypes are classified as validated, while others are under construction or being reviewed. Regarding pieces of information on women's health,

especially those related to prenatal care, the archetypes available in the OpenEHR repository may be considered weak. These archetypes are under construction and the information does not fully include the data considered important for the prenatal care attendance. One can also notice issues in the information about prenatal care in different archetypes, including dichotomy and non-sequential logic in the presentation of data related to childbirth and newborn care.

Studies show that EHRs are better received and evaluated by domain experts if they go through a process of content validation involving domain experts [6]. Hence, when seeking a more reliable structure that could also provide a higher level of satisfaction when using the EHR, validation studies with domain experts are still needed.

Before building EHR archetyped systems, content validation is needed and comprises more than a simple evaluation by a committee of experts [7]. It actually involves a trial process that consists of three steps: 1) literature review, 2) instrument development with the data, and 3) assessment of the minimum relevant data set to be used in a certain context by a committee of experts [8]. The main motivation of these studies is to develop systems using archetypes so that the women's pregnancy information, harvested during the prenatal care in a primary care setting, can be easily exchanged with specialists offering tertiary care through an archetyped clinical form of telehealth in obstetrics [3]. To achieve this, content validation studies are extremely necessary, especially if they are conducted with the participation of health professionals.

Thus, taking into account the importance of public health focused on women's health programs, and considering the national and international recommendations for structuring archetyped EHRs, the need for reviewing and validating the archetypes of the openEHR's database with the help of experts in obstetrics was identified. This process would enable faster construction of archetyped healthcare systems.

This study aims to validate the minimum data set that should be used in the construction of medical records of archetyped telehealth for prenatal care.

Methods

A descriptive and prospective study of quantitative and qualitative methodological types was conducted to determine and validate the minimum data set of a clinical record for prenatal monitoring in obstetrics [7]. The medical record must be a guiding resource for the health professional in comprehending the patient's history and physical examination, and during the registry of a care plan established for the customer. In the telehealth scenario, this clinical record must contain the minimum data required for the exchange of information between health professionals and experts. To provide a data standardization of this clinical record, metadata known as archetypes were used. This study was conducted among experts in obstetrics and expert teachers from the Federal University of Pernambuco (UFPE). In order to define the sample size, the literature recommends [8] a minimum of five and a maximum of ten people to take part in the study. Additionally, the training, qualification, and availability of the necessary professionals should be taken into account. Having observed these criteria, our sample consisted of nine obstetricians who agreed to participate in this research by signing a free and informed consent term. A methodological triangulation method [9] was used, where at least two kinds of methods (i.e. a quantitative approach and a qualitative approach) were adopted. For better understanding, the methodological steps were divided into 3 tasks: 1) literature review and identification of validated instruments to monitor/evaluate prenatal care based on standards of the Brazilian Ministry of Health and those of the World Health Organization (WHO), 2) preparation of the minimum data set, which was grouped into a single instrument using the concept of archetypes for structuring the clinical record of telehealth for prenatal care, and 3) validation of clinical records with experts. The reviewing process made by specialists was initiated with the invitation of members. These were contacted by telephone and/or email, and the purpose of the study was explained to them.

Upon the acceptance to participate, an online questionnaire with medical records' data was sent for validation. A period of 15 days was given to assess/respond to the questionnaire. The evaluation was made by selecting/classifying data. These were arranged in groups according to the exams' clinical approach, such as "history of the present pregnancy" and "general physical and obstetric examination."

The experts had to judge the degree of relevance of each data item included in the first consultation record and in the subsequent consultation record. In other words, the experts had to determine whether the questionnaire's data items should remain or not in the clinical record.

This project has been approved by CAAE: 33667214.3.0000.5208, according to the resolution number 466/12 of the National Health Council in Brazil.

Data Collection, Storage And Analysis

Data collection was made by filling out an online questionnaire with the pre-selected data items for validation. As indicated in the literature [10], a brief socio-demographic characterization of these experts was included in the questionnaire alongside a list of aspects related to pregnancy monitoring. The collected data was automatically entered or transcribed into a Microsoft Excel® spreadsheet, 2010 version. For the statistical purposes of this study, the concordance percentage calculation metrics (percent concordance) and the content validity index (CVI) were used. The percent concordance method was used to calculate the percentage of concordance between judges. It is the simplest measure of interobserver agreement [7].

The formula used is described below: percent concordance = (number of participants who agreed / total number of participants) x100 [7]. For this study, we considered 80% as an acceptable rate of agreement among the evaluators [7].

The content validity index (CVI) comprises a widely used method in health [7]. It measures the proportion or percentage of judges who are in agreement about certain aspects of the instrument and its data items. This method uses a Likert scale with scores ranging from one to five.

Experts are to qualify the degree of relevance of the qustionnaire's data item being evaluated by judging them on a Likert scale of 1 to 5, classifying them into 1 "Totally Irrelevant," 2 "Irrelevant," 3 "Indifferent," 4 "Relevant," and 5 "Totally Relevant."

The formula to calculate each individual item is: IVC = number of "4" or "5" responses / total number of responses.

To evaluate the instrument as a whole, there is no consensus in the literature. Polit and Beck [8] argue that in the evaluation process of data items individually, one should consider the number of judges. In the case of six or more, a rate of no less than 0.78 [7,8] is recommeded. To verify the validity of new instruments in general, some authors have suggested a minimum agreement of 0.80 [11,12]. The data items considered "approved" were those which obtained marks above 0.78.

Results

We interviewed nine experts. With respect to socio-demographic variables to characterize the experts, five respondents were teachers from UFPE and four were obstetricians who are currently working in delivery rooms of many endorsed health institutions located in the state of Pernambuco, Brazil. The average training time was 11 years and 5.3 years of practice. The average age of respondents was 32.4 years. Regarding the titles, two were PhDs, three had Master's degrees and four were experts only. Moreover, among the respondents, five participated in a research group in obstetrics.

Validation Of Minimum Data For The Archetypes

Of the 179 evaluated pieces of data, a total of 157 items were validated to be present in archetyped records of the first prenatal consultation, while 56 data items were considered important for inclusion in the subsequent consultation record. Based on the rates of percent concordance and CVI, Table 1 shows the final validation of minimum data for the construction of archetyped clinical records of prenatal care applications in telehealth. This table lists the categories used to group the data items investigated, the total data set that was analyzed and validated, the average percent concordance for the first consultation and for the subsequent consultation and, finally, the average CVI for the group as a whole. A detailed table with the validation information of each data item can be found at: https://docs.google.com/spreadsheets/d/1YXbSXcxARR8mlewR22vUCXMAaIoPezu-PTWgt1hcxaI/pubhtml

The variables of Category 1 concerned data identification. For the first consultation, all data items validated by experts were seen as relevant, except the data item related to the SISPRENTAL code. Experts suggested adding it to the subsequent clinical record.

For Category 2, which is related to socio-demographic data, all of the data items were validated for the first consultation and no data items were relocated to the subsequent consultation. Categories 3 and 4 concerned personal and family backgrounds. For these categories, all data was considered relevant to the first consultation document, except the variables "infection with hepatitis B / C" and "infection with syphilis" from Category 4. Also, no data items were considered to fit better in the subsequent clinical record.

For Category 5, 40 data items related to gynecological and obstetric backgrounds were analyzed. Data items concerning menarche, history related to sexual practices, and even data from previous pregnancies, including the number of births and the obstetric route, were evaluated. For the first visit, 38 items were considered relevant. For the subsequent consultation, the opposite considerations were made; all data items were evaluated as being irrelevant to the clinical records, except those related to the presence, type, and treatment of sexually transmitted infections. Data items related to the number of days of the menstrual cycle and the frequency of sexual activity were considered irrelevant to be present in the two types of prenatal care records.

Category 6 contained data about the current pregnancy: date of last menstrual period (LMP), expected delivery date (EDD), calculation of gestational age by LMP, ultrasounds of the 1st quarter, vaccination schedule for hepatitis and tetanus, admissions during pregnancy, and date of the beginning of prenatal care. All of these data items were considered relevant to be in the record of the first visit, except the information about previous admissions, the admission reason, and the gestational age (GA) of early prenatal care, which were considered irrelevant.

In Category 7, data related to the physical examination was included. All of the information was considered relevant to be in the first and subsequent records, and, in fact, the values of the CVI rates collected for them were equal to 1.00. In the category of obstetric physical examination (Category 8), only seven variables, out of the 15 data items studied, were considered relevant for the first consultation, albeit all of them were considered crucial to the subsequent consultation record.

With respect to the general physical examination (Category 9), despite all information having been considered relevant to the first consultation record, none of them were deemed relevant in the subsequent visits. Regarding clinical examination (Category 10), only five elements remained associated with the first visit record, and only three of them were added to the subsequent clinical record.

Table 1 – Final validation of minimum data for archetyped telehealth clinical record for the prenatal consultation based on the percent of agreement and CVI. Recife, 2014.

Category of validated data	Analyzed data	% of concordance (1st consultation)	% of concordance (subsequent Consultation)	Average of Likert scale
1 – Data Identification	8	0.94	1.00	4.72
2 – Sociodemographic Data	10	1.00	-	4.76
3 – Clinical Personal Background	27	0.99	-	4.76
4 – Family Background	13	0.94	-	4.62
5 - Gynecological and Obstetric History	40	0.97	1.00	4.70
6 - Pregnancy History	10	0.99	1.00	4.80
7 - Physical Examination - Vital signs, weight and height	6	1.00	1.00	5.00
8- Obstetric Physical Examination	15	1.00	0.95	4.53
9 - General Physical Examination	10	1.00	-	4.62
10 – Clinical Examination	7	1.00	1.00	4.43
11 – Images and Laboratory Wxamination	23	1.00	1.00	4.62
12 – Obstetric Guidelines	10	1.00	1.00	5.00

In Category 11, which corresponds to laboratory and imaging tests, only 15 variables, from the 23 analyzed pieces of data, were included in the first consultation record, and 18 variables remained in the subsequent consultation.

In the category of obstetric guidelines (Category 12), the guidelines evaluated were related to several aspects, namely: foods, discomforts of pregnancy, feeding, delivery, vaccination, laboratory tests, pap smears, return to subsequent consultations, use of ferrous sulfate, and use of folic acid. For the first consultation, the guidelines related to childbirth and lactation were considered irrelevant, but, all of them were considered important to the subsequent consultation. All categories reviewed and approved by the experts produced VCI values greater than 0.78 and the overall average amounted to 4.7 points on the Likert scale.

Discussion

The validation of the data items of our questionnaire showed interesting results regarding the relevance and even the permanence of some variables that were previously seen as important, and many are present in the pregnancy archetypes of the openEHR's data repository. This validation may therefore give rise to some discussion regarding the actual importance of each data item studied.

Before the construction of any computer system, researchers have recognised both the importance and need for an investigation with human subjects to validate openEHR's archetyped records [13] referenced in the literature. However, there was a lack of studies with similar objectives to the work described here. With the active participation of users in the process of planning, implementation, and evaluation of computer systems, a better acceptability of such a system is achieved when it is inserted into the users' work process [13]. In the writing of this article, many gaps related to archetypes validation for the development of systems were found, especially in obstetrics in primary care, a subject on which no studies were found in international databases during the literature review performed.

Through the use of a telehealth archetyped system based on a prenatal follow-up protocol, the exchange of standardized information between systems may be increased (interoperability) and the satisfaction of health professionals with the use of these systems may be improved as well (usability).

Conclusion

Validation studies are important tools to determine which data items are relevant for EHRs according to health professionals in the scenario of caring for pregnant women.

Data validation studies are referred to as being very important in the implementation and acceptance process of EHRs by health professionals, since the validation reduces data redundancy, builds more attractive systems, and enables the management of data relevant to health care applications, hence promoting better usability.

The results of the research described here allowed for the identification of essential data from the prenatal care attendence of pregnant women in primary care, with the perspective of interaction and exchange of information with specialists (tertiary care) through telehealth.

From these results, the archetypes available in the openEHR's database will be analyzed, and comparative validation of these archetypes will be made. Moreover, an analysis of the need to review existing archetypes will be proposed.

In this sense, and based on the results of this research, the construction of an archetype that includes all the data validated for prenatal care will be designed, and this will be submitted to the openEHR's evaluation committee. Finally, as another indication of future work, there is the proposal for the construction of an archetyped clinical record for telehealth systems and the validation of its interface through usability metrics.

Abstract

In 722 cities of Minas Gerais (Brazil), primary care patients can have their ECGs remotely interpreted by cardiologists of the Telehealth Network of Minas Gerais (TNMG), a public telehealth service. As of December 2014, more than 1.9 million ECGs were interpreted. This study analyzed the database of all ECGs performed by the TNMG on primary care patients from 2009 to 2013 (n=1,101,993). Structured patient data and the results of automated ECG interpretation by the Glasgow Program are described. Mean patient age is 51 years old, 59% of them are women. The average body mass index is 25.9 kg/m², with an average increase of 0.15 kg/m² per civil year. Those patients notably have hypertension (33.2%), family history of coronary artery disease (14.5%), smoking (6.9%), diabetes (5.8%), obesity (5.8%) or Chagas Disease (3.0%). Seventy percent of ECGs are normal. This percentage is higher in women (72.3%) and decreases in average by 7.4 every 10 years of life. There are notably 12% of possible myocardial infarction, 10% of possible left ventricular hypertrophy and 8% of possible supraventricular extra systole.

Introduction

The physicians' diagnostic process in primary care is deeply impacted by the representation they form about the prevalence rates of the diseases (pre-test probabilities). Indeed, general practice "has a specific decision making process determined by the prevalence and incidence of illness in the community" [1]. Yet, this decision making process might be biased by the fact that most scientific studies focus on specific populations, especially hospital inpatients, that have increased prevalence rates of severe diseases. To support the diagnostic process in primary care, it is important to publish and discuss descriptive analysis of patients from primary care databases.

The electrocardiogram (ECG) is a widely available method that enables evaluation of the cardiovascular system, to diagnose some diseases or to exclude them. ECGs are easy to perform and available at low-cost. However, their interpretation is not that simple, and in many situations, the general practitioner (or his/her assistant) can perform the exam but is not able to interpret it. For that reason, it has been proposed to have the ECGs interpreted remotely by cardiologists [2]. The first experiment was conducted in 1905, only two years after the first electrocardiograph was ready for use.

To insure access to specialized healthcare to the Brazilian population of remote cities, the State Government of Minas Gerais (Brazil) funded in 2005 the Telehealth Network of Minas Gerais (TNMG) [3]. In this framework, a telecardiology program [4] enables the primary care physicians of remote areas of 722 cities to perform ECGs and transfer them in real time to an analysis center of the TNMG. The ECGs are analyzed by on-duty cardiologists, who send back free-text reports to the physicians the same day. Due to the high number of ECGs analysed per day (on average, 2,200 ECGs), there is a list of ECGs waiting for analysis. A nurse technician coordinates the distribution of the exams among the cardiologists on duty. Emergencies are analysed in less than 10 minutes and routine exams on average in 4 hours. The program has proven to be economically beneficial [5]. More than 1.9 million ECGs have been interpreted in December 2014 [6] but the analysis of this database has still not been published.

Only a few scientific papers provide descriptive analysis of large ECG databases, either as a main or secondary objective, and the results are informative to understand the patients' care and get reliable data about pre-test probabilities of heart diseases [7–9].

The objective of this paper is to provide the community with descriptive statistics about primary care patients and their ECGs in Brazil, by performing a descriptive analysis of the telecardiology database of the TNMG.

Methods

This retrospective observational study assessed the ECG database of the TNMG, which included all the consecutive exams performed from 2009 to 2013 (n=1,101,993).

The ECG database

The ECG database includes all exams performed in the remote health centers from 2009 to 2013, excluding emergency centers (0.2% of the sample). For each exam, the database contains:

- demographic information about the patient: gender, birth date, marital status, educational achievement, income;
- patient's symptoms: pain location (arms, neck, back, precordial, thoracic, epigastric), pain characteristics (caused by effort or emotion, relieved by rest or nitrates, pain intensity), other symptoms (dyspnea, sweating, vomiting, dizziness, syncope, palpitation);
- patient's clinical examination: height, weight, systolic and diastolic blood pressures;

- medications: diuretics, digitalis, beta-blockers, conversion enzyme inhibitors, amiodarone, calcium blockers, others;
- comorbidities or risk factors: arterial hypertension, obesity, diabetes, smoking, hyperlipidemia, personal history of myocardial infarction, personal history of coronary revascularization, family history of coronary disease, Chagas disease, chronic pulmonary disease, chronic kidney disease;
- ECGs represented by a list of time-dependent electric values available in 12 leads;
- administrative information about the ECG analysis: priority level, completion time, time of inclusion in the database, report writing start time, report sending time;
- a free-text report written by the on-duty cardiologist who interpreted remotely the ECG.

Automated computation of descriptive statements by the "Glasgow Program"

The Glasgow 12-lead ECG analysis program is computer software that can automatically interpret ECGs [10]. In this paper, it will be called "Glasgow Program," as in its technical documentation [11]. The Glasgow Program has been evaluated and has achieved very good results for signal processing, e.g., identifying waves and computing axes, durations, amplitudes and intervals [12]. It also obtained acceptable results for rhythm analysis and diagnostic interpretation [13,14]. A review paper concluded in 2001 that the output of computerized ECG processing could be used for epidemiological studies [15].

The Glasgow Program (release 28.4.1, issued on June 16th 2009) was fed with a structured description of the electric signal and a few clinical pieces of information, and was run on the total ECG dataset (n=1,101,993). It was able to output more than 900 different textual messages. We first defined a terminology according to the literature, in order to classify the ECGs the same way it is usually done in the scientific papers [8,9,16–22]. The ECG classification was performed in two steps. First, each ECG was classified into one of the following mutually-exclusive categories: normal, normal variant, abnormal, or fatal technical issue (the ECG cannot be interpreted). The "normal variant" category also contained ECGs that were normal except for rate. Secondly, only in case the ECG could be interpreted, the classification was made of several binary statements (diagnoses) that could be present (with different levels of sureness: "possible", "probable" or "certain") or not, independently from each other.

The Glasgow Program was also able to output quantitative descriptive variables, including heart rate; ventricular rate; average RR with standard deviation; heart rate variability; QRS, P, ST and T frontal axes; P, QRS, and T durations; and PR, QT and ST intervals. The corrected QT interval (QTc) was obtained using the Framingham correction. Those variables were analyzed only for "normal" ECGs, including normal variant.

Statistical analysis

Descriptive univariate statistics were computed from the whole database. For quantitative variables, the mean and standard deviation (SD) were computed. In case of non-normal distribution, quartiles were computed. A histogram was drawn, and/or a density line in case of continuous variable. For qualitative and binary variables, the proportions (prevalence rates) were computed and a bar plot was drawn.

The 95% confidence intervals of means were computed using the normal distribution when appropriate. The 95% confidence intervals of proportions were computed with the Exact Binomial Test, which can get reliable confidence intervals even when the smallest observed count is low or null [23]. The confidence intervals are not reported here when the sample size exceeds 200,000 because they are too narrow.

The Khi² test was used to test the independency between two categorical variables. Student t test or ANOVA was used to test the independency between a quantitative and a binary variable. Generalized linear model was used to test the independency between other kinds of variables. Moving average and linear regression were used to graphically represent the relation between a proportion and a quantitative variable. All the tests were double-sided and interpreted with a 5% significance threshold.

Data management and statistical computations were performed with R statistical computing software [24]. In this paper, when the p value of a test was lower than $2.2e^{-16}$, which is the computation limit of R, we simply wrote "p=0".

Variables having more than 25% missing values were excluded from the analysis. Missing values were studied.

Results

Background and clinical examination of the patients

The patients' mean age is 51 (SD=19.5; 0.5% of missing values). The distribution of the age is displayed on Figure 1. Females comprehended 59.3% of the sample, and this proportion is stable over the years. Patients' mean height is 1.61 m (SD=0.11; 23.7% of missing values). Patients' mean weight is 67.3 kg (SD=16.7; 21.4% of missing values). Patients' mean body mass index (BMI) is 25.9 kg/m² (SD=5.67; 23.5% of missing values; distribution displayed on Figure 2). The BMI is greater than 30 kg/m² in 20.3% of cases. The BMI values increase in average by 0.15 kg/m² per civil year (p=0).

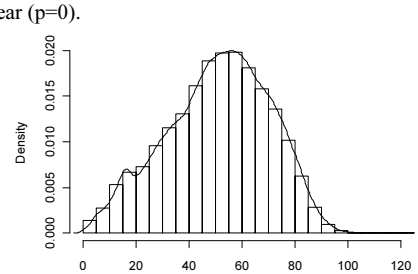

Figure 1 - Histogram of patient's age (years)

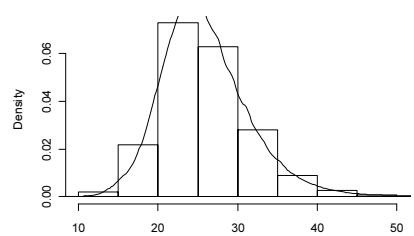

Figure 2 - Histogram of patient's body mass index (kg/m²)

Figure 3 displays the comorbidities and risk factors of the patients. Regarding the comorbidities, 33.2% of the patients have arterial hypertension, 14.5% have a family history of coronary disease, 6.9% are smokers, 5.8% have diabetes mellitus, 5.8% are obese, 3.1% have hyperlipidemia and 3.0%

have Chagas disease. Other statements have a frequency lower than 1%. However, 55.2% of patients are declared not to have any background or identified risk factor. As this part of the form is a set of checkboxes, it is not possible to know the proportion of missing values, but for instance 17.3% of patients having "no obesity" have a BMI greater than 30 kg/m².

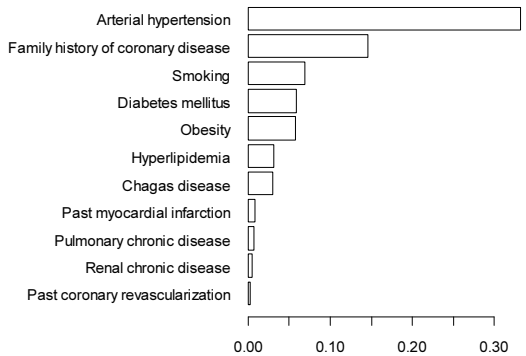

Figure 3 - Comorbidities and risk factors of the patients (prevalence rates)

Regarding the medications, 20.7% of patients take diuretics (the precise class is unknown), 7.9% beta-blockers, 2.8% digitalis, and 0.7% amiodarone. In addition, 95.7% of patients on diuretics suffer from arterial hypertension, and 59.5% of patients with arterial hypertension take diuretics. However, 68.6% of patients declared not to take any drug (see Figure 4). Another drug is taken in 11.0% of cases, but detailed information is only available as free text. As this part of the form is a set of checkboxes, it is not possible to evaluate the proportion of missing values.

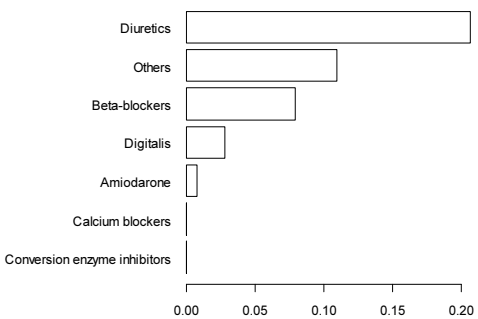

Figure 4 - Medications taken by the patients (prevalence rates)

Administrative management of the exams

At the time of the analysis, the database contains 1,101,993 different exams. The number of exams analyzed per year is displayed on Figure 5. As the year 2013 is incomplete at the time of the data extraction, the extrapolated annual value is represented using a dotted line.

Figure 6 displays the distribution of the time of the day the ECG was performed: 97.4% of them between 7:00 AM and 8:00 PM.

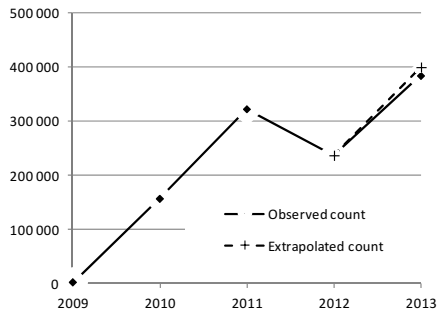

Figure 5 - Number of electrocardiograms performed per year

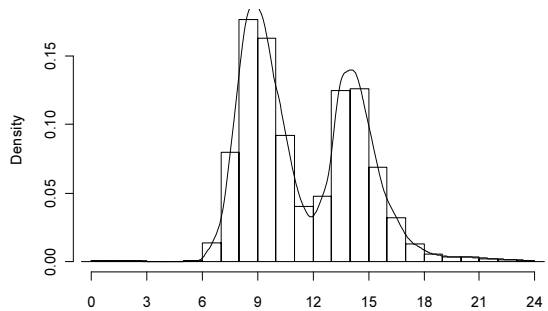

Figure 6 - Histogram of the time of the day the electrocardiogram was performed.

Prevalence rate of normal ECGs

After exclusion of fatal errors, the proportion of normal or normal variant ECGs is estimated to be 69.6%. The percentage of normal ECGs is significantly dependent on the patients' age (p=0), as illustrated on Figure 7. In average, it decreases by 7.43% every 10 years of patient life. The prevalence rate of normal ECGs is lower in men (65.8%) than in women (72.3%) (p=0). It appears to be stable over time (p=11.0%).

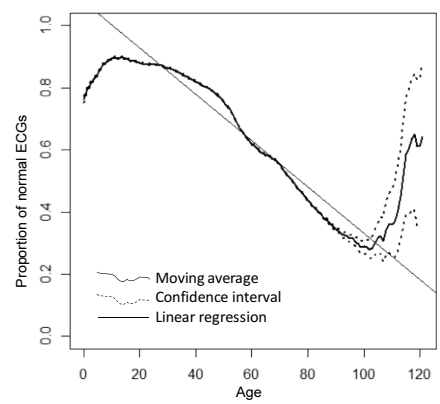

Figure 7 - Proportion of normal electrocardiograms (including normal variant) as a function of the patients' age

Electric description of normal ECGs

The electric parameters of normal ECGs (including "normal variant") are stratified according to gender, and detailed in Table 1. There are 0.00% to 0.86% of missing values for each measurement. The mean of every parameter is significantly different between men and women ($p<10^{-34}$ for each parameter).

Medical description of ECGs

The description of the final statements of the Glasgow Program is displayed in Table 2. The four statements are mutually exclusive. Then, except in case of fatal technical issue, the Glasgow Program can obtain detailed statements that are displayed in Table 3.

Table 1 - Mean (standard deviation) of automatically measured electric parameters of normal electrocardiograms

Variable	Women	Men	t test
Heart rate (BPM)	74.1 (14.8)	70.5 (16.0)	p=0
RR interval (ms)	826 (157)	876 (183)	p=0
PR interval (ms)	152 (28.0)	157 (30.5)	p=0
QRS axis (deg)	28.4 (37.5)	27.2 (44.8)	$p<1e^{-34}$
ST interval (ms)	109 (32.2)	94.0 (31.7)	p=0
QTc interval (ms)[a]	423 (22.8)	414 (24.1)	p=0

(a) with the Framingham correction

Table 2 - Final statement of the Glasgow Program

Final statement	Prevalence rate
Fatal technical issue	0.11%
Normal ECG	33.85%
Normal variant	35.78%
Abnormal ECG	30.25%

Table 3 - Prevalence rates of electrocardiographic statements ("possible", "probable" or "certain" statements)

Statement	Prevalence rate
Global statements	
Non-fatal technical issue	6.28%
Permanent pacemaker	0.45%
Sinus rhythm	93.24%
Non-exclusive ECG abnormalities	
Left ventricular hypertrophy	9.52%
Right ventricular hypertrophy	2.79%
Myocardial infarction	11.61%
Rhythm abnormalities	
Atrial fibrillation or flutter	3.59%
Multifocal or ectopic atrial rhythm	2.06%
Atrial or supraventricular extrasystole	8.21%
Sinusal bradycardia	4.98%
Sinusal or supraventricular tachycardia	3.62%
Accelerated or normal junctional rhythm	0.12%
Idioventricular rhythm	0.19%
Ventricular extrasystole	7.69%
Parasystole	0.00%
Ventricular tachycardia	0.08%
Conduction disturbances	
Sino-atrial block	0.02%
First degree atrioventricular block	5.78%
Second degree atrioventricular block	0.11%
Third degree atrioventricular block	0.15%
Wolff Parkinson White syndrome	0.68%
Left bundle branch block *	5.98%
Right bundle branch block *	4.15%
Descriptive ECG abnormalities	
Repolarization abnormality	39.36%
Bradycardia	5.29%
Tachycardia	3.55%
Short PR	1.99%
Low voltage	1.75%
QRS axis deviation	14.46%
Long QT	2.55%

**: complete, incomplete or fascicular*

Variables with too many missing values

Some variables could not be analyzed due to missing values. Demographic information about the patient included: marital status (48.0% missing), educational achievement (59.2% missing), income (68.8% missing). For those 3 variables, on average, the completeness percentage decreases by 15.4 per year (p=0).

Clinical examination of the patient: systolic and diastolic arterial pressures (respectively 89.1% and 88.7% of missing values). The completeness percentage increases by 1.2 per year (p=0).

Discussion

The objective of this paper was to analyze a million ECGs in a database and provide the community with up-to-date prevalence rates of cardiologic patient conditions in primary care population. This paper shows descriptions of the administrative management of the ECGs (number of exams, hours of performance), the patients (demographic variables, diseases, risk factors and drugs), the ECGs (medical diagnosis obtained from automated interpretation by the Glasgow Program, analysis of the proportion of normal ECGs). This information could participate in the knowledge that constitutes the base of decision-making in primary care.

The proportion of normal ECGs (around 70%) and its relation to the patients' age (it decreases by 7.4% every 10 years of life) are consistent with the literature [8]. The prevalence rates of the diseases are also consistent [8,9].

This study takes advantage of the huge database size that enables the researchers to get precise estimates of prevalence rates and means. However, the analysis raises the issue of completeness and reliability of clinical data. The last section of the results shows that many variables that may be considered secondary by the physicians have a lot of missing values. One can suppose that those values are not missing at random, and may be filled when they support the diagnostic, and left blank in other cases, but this cannot be verified. It is worth noting that the percentage of missing values increases year after year (about +15% per civil year for demographic variables), which probably illustrates the feeling for the physicians that their input is useless and time-consuming. However, this is not in contradiction with Brazilian guidelines for ECG interpretation: the ECG itself does not make the diagnosis. The cardiologist is in charge of interpreting the electric signal, but the clinician has to integrate the clinical symptoms, the risk factors, the personal history of the patient, and other exam results to make the final diagnosis. When the data are provided by the general practitioner, the absence of well shared definitions is probably harmful. In this database for instance, 17.3% of patients with "no obesity" have a BMI greater than 30 kg/m², and are then obese by definition.

The prevalence rates of electrocardiographic statements were obtained from an automated interpretation, and are not as reliable as expert analyses. Additionally, repeated exams from the same patients were not excluded.

Four distinctive characteristics of Brazilian patients can be observed in the analysis results. (1) Three percent of patients suffer from Chagas diseases. (2) Guidelines of the management of patients with arterial hypertension recommend thiazides as a possible first line treatment: 95.7% of patients under diuretics suffer from arterial hypertension, and 59.5% of patients with arterial hypertension receive diuretics (the precise class was not available). (3) The prevalence rate of obesity is high (the average BMI is 25.9 kg/m² and 20.3% of cases are over 30 kg/m²), and increases fast (the BMI values increase in average by 0.15 kg/m² per civil year). (4) Finally,

there are only a few smokers (6.9%), but this attribute could have been underreported.

Conclusion

This descriptive analysis of a huge ECG database brings informative results. The analysis may enable primary care physicians to take into account actual prevalence rates of patient conditions that play an important role in the process of medical decision making [1].

Abstract

In North Norway, no telemonitoring services for chronic heart failure (CHF) have yet been established, hence no investigations in the area have been published. However, large distances and a sparse population are causes for extra expenditure on hospital visits. In this paper, we describe the ePoint.telemed platform for home telemonitoring of CHF patients. We have reviewed the literature on home monitoring techniques, and developed two prototype platforms for remote collection of physiological data. We have refined one of the prototypes and subjected it to user testing among health professionals and their clients. Fifty patients will be involved in a randomized controlled trial aiming to establish if the home telemonitoring of CHF is clinically feasible and cost-effective. The ePoint.telemed platform is a fully automated internet based system meant for early warnings in a CHF rehabilitation program. The core of the platform is a dashboard connected to a blood pressure meter, a weight scale, and a web-based patient questionnaire. Unlike traditional systems built on dedicated medical equipment, we are applying easy-to-use components geared towards the sports market.

Chronic Heart Failure; Home Telemonitoring; Remote Monitoring Technologies; Personal Health Information Systems; Personal Health System

Introduction

In Norway, the costs for treatment of chronic heart failure (CHF) are huge, both in terms of hospital treatment and daily use of medication over years, as well as in terms of loss of quality of life for patients and their family caregivers [1]. Structured telephone systems and remote monitoring technologies (RMT) for monitoring CHF patients at home have been widely deployed in Europe over the last 20 years or so [2-7]. These systems are considered capable of increasing quality of life for the patients using them, to lower death rates, to reduce costs for medical treatment, and to decrease cases of re-hospitalization after heart surgery. However, home monitoring of patients with CHF is still in its beginnings in Norway, and little practical experience has so far been gained. In fact, to our knowledge, no routine telemonitoring services are available in Norway for C and hence no investigations in the field have yet been published, although large distances and a sparse population in N. Norway are a cause for extra public and private expenditure on travel for patients when making a visit to the hospital. These state of affairs constitute a strong motivation for home monitoring of CHF patients in Norway. But it seems that current evidence of the effectiveness and quality of CHF home monitoring systems is insufficient to recommend usage. The structure and funding streams in Norwegian health services are different from many other European countries and the outcomes of comparisons between conventional CHF services and the home monitoring systems in previous studies in Europe, may not fit well in a Norwegian context. It is thus important to further investigate the feasibility of home monitoring of patients with CHF in Norway. This paper describes a technological platform ePoint.telemed for daily monitoring of patients' weight, blood pressure, pulse, and self-declared health status directly from the patients' home. The system transmits the patient data automatically, seamlessly, and securely to a server at the University Hospital North-Norway (UNN), and allows examination of these values by a trained nurse at the hospital. An RMT system for monitoring CHF patients typically uses dedicated medical equipment to measure body weight, blood pressure, heart rate, blood oxygen saturation levels, and ECG. These systems are comparatively work intensive in terms of set-up and patient training. An RMT system provides asynchronous communication between patients and health personnel, and such systems are also remotely configurable. Compared with web-based solutions, structured telephone support requires synchronous follow-up by health-professionals and telephone systems are not remotely configurable.

The ePoint.telemed platform is a net-based system that works asynchronously with no need for interventions from health professionals, except on alarms. The platform is remotely configurable and may be individualized and set up without actually visiting the patients' home. This paper describes the technical details of the ePoint.telemed platform and the development process behind it. The platform is now being applied in a randomized trial at UNN to determine if the system is medically feasible and cost effective, if it is capable of reducing hospital re-admissions, and if it is acceptable to patients and their families as an integral part of a CHF rehabilitation program.

Methods

The prototyping of the ePoint.telemed platform was, from the start, driven by healthcare professionals at UNN. Medical doctors and nurses were involved in the design and implementation of the system from the prototyping stage until

the user trials. Moreover, early tests were performed with patients using prototypes. This may best be described as a combination of expert inspection and user-oriented design methods [8].

In 2011, we developed an alternative platform for home monitoring of CHF patients based on the dedicated medical equipment attached to a laptop in the patients' homes. The laptop was able to transmit data to our research laboratory servers using the patients' home internet connection. However, the interfacing of the medical equipment was far from trivial, and our practical experiments warned us that the maintenance of the system in the patients' homes was potentially expensive, requiring several man-hours to be set up properly. The collection of physiological data required individual adaptation of the software in each laptop due to individual needs among the patients. Since the setup of thresholds for specific biological parameters presumed programming on each laptop, our nurse had to review all of the received data manually. This was a quite laborious process and reconfiguration of our system was requested by the health professionals. We then decided to try out components geared towards the sports market for measuring physiological parameters.

Two different strategies for component integration are now implemented in the ePoint.telemed platform: the first one based on email parsing using the Representational State Transfer Application Programming Interface (REST API) [9] and a second one for pull of data based on the OAuth communication package [10]. Currently, three devices for data collection are integrated: a blood pressure meter, a weight scale, and a tablet computer. However, more and alternative types of components can easily be integrated into the platform due to its open design. At present, the platform integrates a Withings weight scale [11], facilitating push of data (weight measurements) via the easy-to-use Withings API. The BP3 blood pressure meter from iHealth [9] is also integrated, which delivers diastolic/systolic blood pressure and heart rate measurements. The tablet applied is the iPad, selected because of its compatibility with the iHealth system. Our platform is open and easily configurable for other types of equipment. The estimated effort for configuring a new device on the system is approximately one to two man-days.

All data transfer is anonymized by coding the patients' identities. In this project, confidentiality of private health information is ensured according to the Norwegian Ministry of Health and Care Service regulations [12]. All personal data which link measurements to a specific patient are removed and replaced by a code so that the information can be used alone or in combination with other health record entries. The relation between the codes and the patients' names are kept on paper in the heart polyclinic with a backup stored in a hospital PC not connected to any network.

We can collect vital physiological data according to medical needs, and set up user specific thresholds for any parameter in a fully automated fashion. The system will send mail-based alarms to users and/or health professionals for any data out of range as specified by the thresholds. In the pilot study, two patients with chronic heart failure were recruited through the Tromsø municipality home services. The patients receive their treatment at the University Hospital North-Norway, and participate in rehabilitation programs at the hospital. After being informed of the study, the patients gave written informed consent to participate in our study together with health professionals at UNN's heart polyclinic.

In 2013, after the pilot study, an application was sent to the Norwegian Regional Ethical Committee for ethical approval of a randomized controlled trial with 50 patients. After receiving the approval for the project, the final version of the ePoint.telemed platform was developed and the randomized controlled trial started in September 2014 at UNN. All patients admitted at UNNs' heart polyclinic, satisfying the inclusion criteria of the project, are randomized into an intervention arm testing the proposed telemonitoring service and a control arm with the treatment usually offered by the polyclinic. Patients assigned to the intervention arm receive a home telemonitoring kit consisting of a tablet, a wireless weight scale, and a portable blood pressure meter. All participants are given 30 minutes of instruction about the use of the equipment by a trained nurse. The patient is asked to weigh him or herself every day in the morning before breakfast. In addition, the patient also takes a measurement of the blood pressure and heart rate, and answers an online multiple-choice questionnaire about personal health conditions.

We have, through the advice from the health professionals in our project, chosen 10 questions derived from the Minnesota Living with Heart Failure Questionnaire (MLHFQ). The MLHFQ is a disease specific tool for measuring quality of life among patients living with CHF and the outcomes are according to T Hole co-releated to patients' level of functioning [13]. The MLHFQ can be divided into three categories of questions (with 8, 6, and 7 items respectively, each organized as entries on a 6 level score Likert scale).We concentrated on the questions about psychological status in the first two categories. Since the patients are expected to fill in the net-based questionnaire on a daily basis, it is necessary to keep it as short as possible. Our aim is, of course, not to assess the patients' quality of life as such but to obtain a fair estimate of any changes in psychological status. Patients assigned to the control arm receive conventional treatment.

Acceptance of the system is crucial for the successful implementation of a home monitoring service. Hence, we have included the aid of professionals as well as patients in our prototyping process. This means that the users have been involved in the project from the design of paper mock-ups and onwards. The patients participated in three design meetings together with health professionals and technologists before the installation of the prototype in the patients' home. After installation we have visited the patients at home routinely once a month, starting with instructing the patients about the use of the equipment. Later we have adjusted the system and checked the patients' operation of it. Since the fall of 2014, the system has been used on a daily basis. The cooperation with the health professionals (primarily the nurses at UNN's heart clinic) has taken the form of a continuous dialogue, involving several rounds of testing and adjustment of the running prototype. From our interactions with patients and professionals we can safely conclude that the prototype is accepted within the design team. However, a wider user acceptance of a home monitoring service presumes clinical validation and confirmed user friendliness in a larger cohort of patients.

Results

The prototype system deployed in this pilot study consists of a Withings wireless weight scale [11] and an iHealth blood pressure meter [9] that communicates with an iPad using the bluetooth protocol. Emails containing the blood pressure

measurements and the self declared health status of the patients are automatically generated by the system. These emails are then sent to a server at the hospital. The weight measurements are pulled automatically to a dashboard once per day and stored on the server. At the hospital side, the nurse receives an e-mail from the system every morning. The nurse actually has to check the incoming data only for alarms.

The dashboard may best be described as a service management system coded in XHTML and PHP. The dashboard allows for administration of system users, i.e. connecting patients and health professionals. The dashboard handles pull of weight measurements and extracts information from incoming e-posts. Individual thresholds for each biological parameter may be set. The data is stored in a MYSQL database management system. The weight measurements and the patients' health status declarations are available on the dashboard together with the blood pressure and heart rate measurements (Figure 1). The data are displayed graphically in an easy-to-read manner. After the first two months of pilot testing, the patients were satisfied with the usability of the solution. As for the hospital side, the data arrived in a timely and correct way, and the reliability of the system seems to be proven. The nurse also gave positive feedback on the system usability and functionalities.

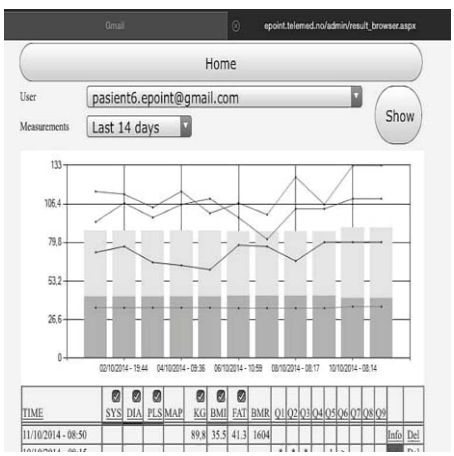

Figure 1-Snapshot of the Dashboard

The ePoint.telemed platform developed for the RCT is web-based and it follows an open strategy of component integration [14]. Patient data is accessible through a browser window. Health data are stored in a secure server. Only health professionals have access to the dashboard and the connected server. The patients can still read their data in gmail or in their Withings account. The ePoint.telemed platform applies easy-to-use Personal Health Systems (PHS) components geared towards the sports and wellness market [3]. The inbuilt internet connection of the components used in the platform implies a seamless communication with a central server placed in a local health service center or in a hospital. Vital data can be collected according to individual medical needs.

The measurements of both the blood pressure and heart rate are collected by the iHealth App on the iPad. The collected data is then sent through an email to the ePoint.telemed, back-end by a secured socket layer channel. Triggered at regular times (at the moment at 9am although these can be configured), a PHP script parses the CSV-file in the email using queries for insertion of the data into the MYSQL database. A REST API is used to parse the CSV-file. The parsed data collected by the iHealth, i.e. blood pressure and heart rate, is then presented in the dashboard.

The user is required to fill in a web-based questionnaire daily. This is accessed through a link icon in the iPad. Once the questionnaire is completed, an email is automatically composed with the answers. This is sent anonymously to the central dashboard as a CSV-file. The file is parsed in the same way as the process with iHealth, using the REST API. Weight measurements are pulled directly from the users' Withings accounts applying the OAuth communication package.

Discussion

The ePoint.telemed platform is a fully automatic internet based system meant for early warning in a CHF rehabilitation program. Unlike traditional RMT systems building on dedicated medical equipment, we are applying easy-to-use personal health systems (PHS) components geared towards the sports market. The components of the platform are fairly low cost and involve a minimum of installation efforts. The components automatically transmit the vital biological parameters to users' accounts at the vendors' internet sites. We pull the data from there, and log them into a dedicated database system. The low cost, the remote configurability, and the ease of installation and maintenance of our platform represent new features not present in conventional systems (including telephone based platforms) for home monitoring of patients with chronic heart disease.

Home monitoring of CHF potentially enhances the patients' situation during rehabilitation, and probably also means better service from the health professionals. Still, at present remote monitoring of vital symptoms is not a prioritized area in the treatment of chronic disease in Norway. For example, approximately 489 new pacemakers per million inhabitants are implanted annually in Norway (figures from 2009) [15]. But no systematic attempts have so far been made to make use of the data from these devices in CHF rehabilitation programs. However, home monitoring of COPD [16] is currently being performed in Norway, and in treatment of diabetes remote monitoring of biological parameters is at present strengthening self-management schemes as well as rehabilitation programs [17,18].

User oriented design methods have a strong position in Scandinavia, and we have emphasized including both patients and experienced health personnel in our prototyping process [19-21]. The successes of the ICT based health interventions are strongly dependent on user acceptance, both from the professional side as from the patient side. Usability issues in the ePoint.telemed platform were given careful attention. The platform is validated in a real clinical setting and follows the approved clinical procedures. The openness of the platform allows for the future inclusion of other devices (but the software used is proprietary). The platforms' applicability in connection with other pathologies such as diabetes or COPD can be supplementary tested with the inclusion of a glucose meter and a pulse oximeter, respectively.

The platform was then installed at the patients' home by a team from The Norwegian Center for Integrated Care and Telemedicine (NST). We used approximately 1 hour for installations and for instructing the patients about the basic operations of the equipment. All patients had a broadband network installed in their homes, prior to our trials. For home monitoring of heart patients in a Norwegian context, an easy-

to-install system with low maintenance costs is important. A rapid weight increase in connection with chronic heart disease (more than 1,5 kg in 2 days or more than 2,2 kg within a week) may suggest an accumulation of liquid in the body as a result of heart dysfunctions. Also, a significant and persistent weight loss over a few weeks may serve as a medical indication of problems in the heart function. We are in the process of confirming the accuracy of the collected data, but since our interest is primarily to detect changes in the parameters measured over time, we expect the precision of our data to be satisfactory.

On the hospital side, the nurse participating in the pilot study receives the patients' measurements each morning. During the pilot study, these measurements were inspected manually (in addition to the system intrinsic routines for measurement checking) and compared with baseline measurements taken at the start of the pilot study. The procedure for the patient was to turn on the weight scale and step on it, and then place the blood pressure meter on the arm to take a measurement. The patients were instructed to take a weight and blood pressure measurement every morning at approximately the same time, after visiting the toilet but before breakfast. Blood pressure values exceeding 150/110 mmHg was considered dysfunctional (but the health professionals can specify any threshold for this parameter after individual inspection of any patient).

After the first two months of pilot study testing and error corrections, the ePoint.telemed platform was considered operational both by the health professionals and the patients. As for the hospital side, the data arrived timely and correctly and the reliability of the system was accepted by the developers. Since the pilot study, we have further developed the user interface on the dashboard, and we have replaced the PC at the users' side with an iPad.

The primary outcome of the study is of administrative interest. The CHF related hospital re-admissions (calculated as the ratio between re-admissions in the intervention group compared with the re-admissions in the control arm) will be the key outcome of the study. We expect that early warning about any change in vital parameters may potentially reduce costs for interventions directed towards specific patients. Also, the economic benefit (additional costs divided by savings within the intervention group) resulting from applying the ePoint.telemed platform is of importance even if we plan to recruit only 50 patients. For the patients themselves, home monitoring of important biological parameters may imply an increased sense of security, and it may mean a decreased number of face-to-face meetings with the doctor during rehabilitation (saving time and travelling costs). In other words, we will investigate the economical benefits from applying the ePoint.telemed platform identified through a cost analysis between the intervention and control arms of the trial, and we will inquire the patients' own sense of wellbeing during rehabilitation. Measurements including weight, heart rate, blood pressure, and answers to the MLHFQ are taken at baseline, after 3 months and at study end (six months using the system).

In the practice field of healthcare, home monitoring of physiological data implies an increased focus on patients' self-management. The outcome may be reduced mortality rates for specific symptom categories and reduced costs per patient within specific rehabilitation programs [22, 23]. For the patients themselves it may mean a greater awareness about personal health and possibly an increased sense of security during rehabilitation. However, the implementation of routine home monitoring services at a heart clinic presumes organizational adaption and formalization of new working procedures among health professionals [24]. Hence, careful planning of the transitional stages is of vital importance when introducing new services in a clinical setting. Technically, more standardization of equipment and better integration with current health record systems seems to be necessary [25] to make home monitoring of CHF a common practice in Norway.

Conclusion

A platform for the home telemonitoring of patients suffering from chronic heart failure has been designed and implemented at the UNN. A user-oriented design method was applied involving both health professionals and patients. The prototype has been refined into a test version in 2014. The current version is being used in a real setting in the context of a randomized controlled trial. Approximately 50 patients will be participating in the study. The platform designated as ePoint.telemed presents innovative features that in their combination are unique to home monitoring of patients with chronic heart failure.

These features include:

- A fully anonymous transmission of data
- An open design of the platform allowing for the integration of devices from different suppliers
- A two stage patient questionnaire designed in cooperation with a hospital polyclinic
- A fully configurable set of individualized patient thresholds
- Automatic feedback to patients via e-mail
- Full user access to the clinical data collected
- A web-based dashboard with secure access for health professionals.

The success of ICT based health interventions is strongly dependent on user acceptance, both from the professional side and from the patients' side. Usability issues in the ePoint.telemed platform were given careful attention. The combinations of features of the ePoint.telemed Platform meet three fundamental requirements of electronic medical equipment in Norway: secure data transmission and storage, clinical efficacy, and a high degree of usability both for patients and professionals. The functionality of the platform was validated during real clinical testing.

Abstract

Portable Healthcare Clinic (PHC) is a mobile healthcare system comprising of medical sensors and health assessment criteria. It has been applied in Bangladesh for the last two years as a pilot program to identify non-communicable diseases. In this study, we adapted PHC to fit post-disaster conditions. The PHC health assessment criteria are redesigned to deal with emergency cases and healthcare worker insufficiency. A new algorithm makes an initial assessment of age, symptoms, and whether the person is seeing a doctor. These changes will make the turn-around time shorter and will enable reaching the most affected patients better. We tested the operability and turn-around time of the adapted system at the debris flow disaster shelters in Hiroshima, Japan. Changing the PHC health assessment criteria and other solutions such as a list of medicine preparation makes the PHC system switch into an emergency mode more smoothly following a natural disaster.

Introduction

The World Health Organization declared that 58 crisis countries, including Bangladesh, face acute Human Resources for Health (HRH) crisis [1]. Many countries experience catastrophic natural disasters. In Bangladesh, 26% of the population is affected by cyclones, and 70% live in flood-prone regions [2]. Natural disasters result in casualties and damage medical facilities and the health workforce [3]. The 2011 Tohoku Earthquake demonstrated the need for disaster management in aspects including healthcare. Although most casualties in the Tohoku Earthquake were because of drowning, the bad living environment in post-disaster shelters worsened the health condition of victims [4]. Strategies for post-disaster management are urgently required, and mobile healthcare systems may reach disaster victims quickly.

Kyushu University Hospital and Grameen Communications conducted a health management study using information communication technology. The Portable Healthcare Clinic (PHC) with medical sensors provided immediate consultation with the remote doctor over Skype for non-communicable diseases (NCDs). Following consultation, the remote doctor gives the patient an e-prescription. Data collection was conducted in 10 locations of Bangladesh between July 2012 and February 2014 [5].

However, little is known about the feasibility of introducing PHC into post-disaster areas where the healthcare conditions are different from those in non-disaster areas.

We examine the feasibility and risks of post-disaster healthcare management with a general health evaluation targeting disaster-related symptoms caused by trauma, infectious and chronic diseases, and mental disorders. After disasters, the findings of this study would be useful for developing an emergency mode of PHC to support post-disaster areas in Bangladesh, Japan, and other countries.

Methods

Logistics Classification Research

We collected data and performed a literature review on disasters in Bangladesh to understand the risks in post-disaster areas. We collected data from EM-DAT and Asian Disaster Reduction Center and used the keywords "natural disasters," "disease," "healthcare," "impact," "epidemiology," and "shelter" to collect literature through PubMed and Web of Science to classify disaster-related healthcare risks.

Revising Triage Rule for Post-Disaster Situation

The PHC has the following devices: weight scales, tape measures, blood pressure meters, glucose meters, body thermometers, pulse oximeters, urine test strips, and hemoglobin meters. Through examinations with these devices, a health assessment can be made. The health assessment logic, called Bangladesh logic (B-Logic), was introduced into all the disease management activities of PHC in Bangladesh [5].

In B-logic criteria, the results are divided into four stages (green, yellow, orange, and red), and they form a health assessment of Bangladeshis under non-disaster conditions. B-logic criteria do not address the post-disaster conditions because there is often a shortage of healthcare workers, and the unavailability of medicine is more serious in post-disaster than in non-disaster conditions. Therefore, we designed a triage protocol using B-logic and conducted a series of medical questionnaires on possible symptoms in post-disaster areas. The symptoms are assigned with risk assessment.

Operation Test

To examine the feasibility of the designed triage protocol, an operation test was conducted in chosen areas of Hiroshima City that were affected by a large debris flow in August 2014. This debris flow resulted in many casualties with 74 deaths and 44 injured [6]. Some victims were still living in disaster

shelters in October 2014. We performed an operation test in the post-disaster shelters of Hiroshima on October 25th to better understand their health conditions and to classify the operation, suitability, and efficiency of PHC performance in post-disaster areas.

Results

Logistics Classification Research Result

The investigation shows that in Bangladesh, floods and cyclones cause destructive damage during and after the disasters. They are the two disasters in the top 10 disasters that affected most people from 1985 to 2014 [7].

As the most frequent disaster in Bangladesh, flood disasters cause deaths from drowning (67.6%), physical trauma (11.7%), heart attack (5.7%), fire (3.6%), electrocution (2.8%), and other (8.6%) [8]. In addition to the direct impact of the disaster, health conditions of post-disaster populations are also affected by poor sanitary conditions of shelters, increasing tobacco abuse, and more stress.

Fever, diarrhea, respiratory problems, and abdominal pain are the most common symptoms in post-disaster Bangladesh. Approximately 20–40% of these subjects had diarrhea that mainly resulted from cholera and rotavirus infections [9-11]. For acute respiratory infections, a moderate increase in risk during the six months after the flood and the subsequent 18 months were found [12]. Chronic stress after natural disasters may also significantly affect cardiovascular risk factors [13]. People with NCDs are more vulnerable in emergencies and disasters, when emergencies exacerbate NCDs, leading to acute complications [14]. Natural disasters cause a higher prevalence rate of NCDs and negatively impact people with pre-existing conditions [15, 16].

Triage protocol using a new logic

The PHC algorithm was redesigned to target disaster situations. In the Disaster Logic (D-Logic) algorithm, the criteria for teleconsultation were adjusted for fewer people to see a doctor. This adjustment was acceptable in the short term, just after a disaster, to avoid congestion. A new assessment was added into D-logic for better coverage in disaster-related physical and mental health conditions.

D-logic was introduced to provide initial assessments of age and symptoms. Assessments based on sensor data and symptom questionnaire were created for a general examination of healthcare risks in our logistics classification of disasters. With the obtained results of D-logic, the remote doctor will make decision and instructions by Skype and e-prescription.

The D-logic triage was designed in the following steps:

1. Make an initial assessment with three questions shown in Figure 1 for the disaster patients.
2. According to the results of the initial assessment, disaster patients will be divided into five groups with different examinations (Figure 1).
3. Following check items and criteria are designed as D-logic_1 and 2, which are two examinations. D-logic_1 is based on the sensor measurements (Table 1). The red items in Table 1 are adjusted based on B-logic to fit with healthcare worker insufficiency in a post-disaster area. Referring to the index of symptoms questionnaire (Table 2), D-logic_2 (Table 3) will also perform a questionnaire examination with the criteria to decide if the subject needs a teleconsultation with a remote doctor. Symptoms in Table 2 will be checked based on the result of an initial assessment (Figure 1). From the data presented in Table 2, scores for each observation in Table 3 can be added to show if there is a minor or major abnormality. As a result, subjects with more than two scores will be required to have a teleconsultation with remote doctors.

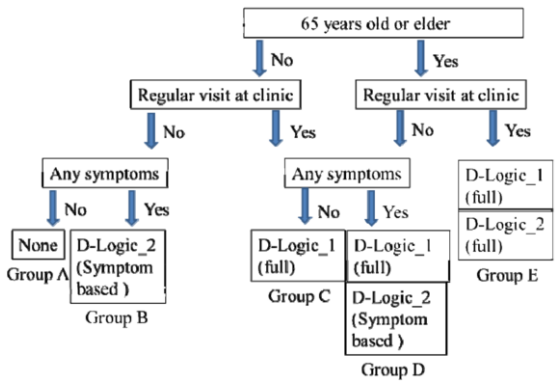

Figure 1 – Initial assessment and Flowchart of D-logic

Operation Test

To verify the operation, suitability, and turn-around time of the adapted PHC system to a post-disaster area, we tested the D-logic at the debris flow disaster shelters in Hiroshima, Japan.

We prepared the questionnaires and medical sensors to conduct the examination of two criteria, D-logic_1 and D-logic_2, to the victims who were still living in disaster shelters. Three disaster shelters and one area affected by debris flow in the city were chosen for the operation test.

We used three disaster victims as test subjects and used the medical sensors and questionnaires based on D-logic_1 and D-logic_2. Some problems and improvements to the procedure were clarified through the operation test as mentioned below.

All the subjects in our limited operation test answered that they did not feel any health problems during the initial assessment. However, through the questionnaires and examinations we found that two subjects showed some abnormalities on the examination results. Though neither of them was aware of abnormalities in their health conditions before we made the examination, one of them had a blood pressure of 158/94 mmHg, whereas the other one had a blood sugar of 150 md/dl two hours after eating. The ages of these two subjects were over 65, and this point indicates a higher risk of NCDs.

Table 1 – D-logic_1 (Red parts are the adjusted items based on B-logic, ordinal criteria)

Test	Normal	Caution	Remote medicine	Remote medicine & Encouragement to visit clinic
Body Weight Change (x kg)	x < ±1.0	±(1.0 ≤ x < 3.0) or unknown	±(3.0 ≤ x < 5.0)	±5.0 ≤ x
Blood Pressure (x mmHg systolic BP and y mmHg diastolic BP)	x < 140 (x < 130)	140 ≤ x < 160 (130 ≤ x < 140)	160 ≤ x < 200 (140 ≤ x < 180)	200 ≤ x (180 ≤ x)
	y < 90 (y < 85)	90 ≤ y < 100 (85 ≤ y < 90)	100 ≤ y < 120 (90 ≤ y < 110)	120 ≤ y (110 ≤ y)
Fasting Blood Sugar (x mg/dl)	x < 100	100 ≤ x < 126	126 ≤ x ≤ 200	200 ≤ x
Postprandial Blood Sugar (x mg/dl)	x < 140	140 ≤ x < 200	200 ≤ x ≤ 300	300 ≤ x
Urine test				
Urine Protein	- /± (-)	+ (±)	≥2+ (≥+)	
Urine Sugar	- /± (-)	≥+ (±)	(≥+)	
Urobilinogen	±		+≤ (≥+)	
Pulse Ratio	60 ≤ x < 100	50 ≤ x < 60 or 100 ≤ x < 120	X < 50 or 120 ≤ x	
Arrhythmia	None		Yes	
Number of Fresh Skin lesion	None		None	2 or more
Temperature(Celsius degree)	x < 37	37 ≤ x < 37.5	37.5 ≤ x < 38.5 (37.5 ≤ x)	38.5 ≤ x
SpO2(x %)	x ≥ 96	93 ≤ x < 96	90 ≤ x <93	x < 90
Hemoglobin (x g/dl)	x ≥ 12	10 ≤ x < 12	8 ≤ x <10	x < 8

Table 2 – Examination Item Index for D-logic_2 Check sheet

Symptom		Checksheet Number

Table 3 – D-logic_2 (Symptoms based check sheet)

D-logic2 Number	Observation	Normal (score 0)	Minor Abnormality (score 1)	Major Abnormality (score 2)
1	Confusion or loss of consciousness	No	Yes	
2	Sleep disturbance	No	Yes	
3	Flash back	No		Yes
4	Dizziness	No	Yes	
5	Thirsty	No	Yes	
6	General fatigue	No	Yes	
7	Loss of appetite	No	Yes	
8	Nausea	No	Yes	
9	Vomiting	No	Yes, only one time without bloody emesis	Yes, two times or more, or bloody emesis
10	Stomach ache	No	Yes, mild	Yes, severe
11	Abdominal pain	No	Yes, mild	Yes, severe
12	Cough	No	Yes, mild	Yes, severe
13	Nasal congestion	No	Yes	
14	Sore throat	No	Yes, mild	Yes, severe
15	Sputum	No	Yes	
16	Hemoptysis	No		Yes
17	Respiratory distress	No	Yes	
18	Headache	No	Yes, mild	Yes, severe
19	Palpitation	No	Yes	
20	Chest pain	No	Yes, mild	Yes, severe
21	Paralysis	No		Yes
22	Dysarthria	No		Yes
23	Visual disturbance	No		Yes
24	Urination	Normal	Less than normal	Anuria or oliguria (≤2/day) or much more than usual
25	Diarrhea	No	Yes, not watery	Yes, watery
26	Defecation	Normal	Less than normal	Severe (no defecation for more than 5days)
27	Surface injury	No	Yes, mild, and bleeding (-), and pus formation (-) now	Yes, severe, or bleeding or pus formation
28	Swelling	No	Yes, mild	Yes, severe
29	Joint pain	No	Yes, mild	Yes, severe
30	Pain of injury	No	Yes, tolerable without pain reliever	Yes, intolerable without pain reliever
31	Head trauma	No		Yes
32	Staying or sleeping in narrow place	No	Yes	
33	Any other symptoms	No		Yes
101	Fever (Celsius degree)	$x < 37$	$37.0 \leq x < 37.5$	$37.5 \leq x < 38.5$
102	Loss of body weight (kg)	$x < \pm 1.0$	$\pm 1.0 \leq x < 3.0$ or change is unknown	$x \geq \pm 3.0$
103	Systolic blood pressure (mmHg)	$100 \leq x < 140$	$140 \leq x < 160$ or $80 \leq x < 100$	$x < 80$ or $x \geq 160$
105	Pulse rate	$60 \leq x < 100$	$50 \leq x < 60$ or $100 \leq x < 120$	$x < 50$ or $x \geq 120$
106	Arrhythmia	No		Yes
107	Low oxygen in arterial blood (%)	$x \geq 96$	$93 \leq x < 96$	$x < 93$
108	Anemia (x g/dl by Hemoglobin meter)	$x \geq 12$	$10 \leq x < 12$	$x < 10$
109	Japanese Coma Scale	$x = 0$	$x = 1$ or 2 or 3	$x \geq 10$

During the operation test interview, some items were difficult to answer. These items are clearer to the people around the subjects. In the future, the items of the questionnaire can be divided into subjective and objective symptoms. Only the items on subjective symptoms will be questioned, and the examiner or the subjects' family can judge the items on objective symptoms. Other items such as arrhythmia or number of skin lesions were chosen as D-logic_1 and D-logic_2 components, increasing the examination turnaround time.

We conducted a full examination of D-logic and measured the turnaround time. In total, approximately 15 min on average was taken from the interview and 6 min on average was taken from the examination by medical examiners. In this operation test, the disaster ended a few months ago, which may be the reason why many victims were not fully cooperative at first. Extra time was needed to communicate with the victims for them to join the test. Months after the disaster ends, health-seeking behavior is poor. However, health-seeking behavior is prevalent earlier in post-disaster areas when possible trauma and shelter conditions are considered [17].

Among the three subjects, two had trauma due to tumbling on the second day after the debris flow. The debris flow sand deposit increased the chance of slipping. Secondary injuries in a post-disaster area should be considered when responding to the healthcare risks after disasters that cause wet and slippery conditions.

Discussion

Limitation of the System

Disaster damages may lead to a power outage and network malfunction, and this will affect the PHC consumables.

Battery backup may be too limited to cover all patients in a post-disaster area. To relieve the situation, an initial assessment can be used to screen the victims with the most health risks and relieve the pressure on consumables, resources, and healthcare worker insufficiency. However, an operation test on a large number of subjects is necessary in the future to improve the efficiency of triage by D-logic.

In Bangladesh, pharmacies and drugstores are common even in rural areas. Para-professionals, pharmacy, and drugstore sales people were the major healthcare providers to disaster-affected people after Cyclone Sidr [18]. Necessary medicine can be prepared in advance from the drugstores in Bangladesh and help the patients in the worst condition. However, treatment for PHC in Japan is limited to emergency usage. Different preparations should be planned depending on the policies of different countries and situations.

Further Improvement

Disasters have impacts on critical infrastructure leading to power outrage and network failure. PHC devices are vulnerable to post-disaster power outage and wet conditions. Backup for device consumables and waterproof measurement are necessary for future use of the post-disaster condition. During the operation test in Hiroshima, questionnaires data and examination were manually recorded. In the future, PHC will automatically switch from B-logic to D-logic by information technology, and this will result in less turnaround time and more efficiency in post-disaster settings.

Conclusion

PHC is a disease prevention program in Bangladesh and has undertaken health checkups for more than two years. It is being developed to reach the low-income people. Its mobility and agility make it easier to be carried into the rural and post-disaster areas. With widespread use in ordinary conditions, the emergency mode can become more suitable and rapidly introduced in post-disaster areas. Existing packages in disaster areas can be switched into emergency mode immediately after the disaster ends to respond rapidly to the post-disaster health risks.

Abstract

The Online Diabetes Exercise System was developed to motivate people with Type 2 diabetes to do a 25 minutes low-volume high-intensity interval training program. In a previous multi-method evaluation of the system, several usability issues were identified and corrected. Despite the thorough testing, it was unclear whether all usability problems had been identified using the multi-method evaluation. Our hypothesis was that adding the eye-tracking triangulation to the multi-method evaluation would increase the accuracy and completeness when testing the usability of the system. The study design was an Eye-tracking Triangulation; conventional eye-tracking with predefined tasks followed by The Post-Experience Eye-Tracked Protocol (PEEP). Six Areas of Interests were the basis for the PEEP-session. The eye-tracking triangulation gave objective and subjective results, which are believed to be highly relevant for designing, implementing, evaluating and optimizing systems in the field of health informatics. Future work should include testing the method on a larger and more representative group of users and apply the method on different system types.

Keywords:

Eye Tracking; Usability; Diabetes Mellitus; Post-Experienced Eye-Tracked Protocol; Consumer Health Information.

Introduction

Consumer health information technology (CHIT) is a new term in the healthcare sector, which refers to a computer-based system that facilitates access to information and behaviour changes that promote health and well-being [1]. Recently, a systematic review by Jenni Cornelly et al. examine the effectiveness of technology to promote physical activity in people with Type 2 diabetes [2]. Their findings indicate that technology-based interventions to promote physical activity are effective. Nevertheless, they demonstrate a need for evidence of the sustainability of the technology [2]. In a systematic review by Yu et al. they also identify the needs of sustainability, effectiveness, usefulness, and usability regarding CHIT and management of diabetes [3].

An example of a CHIT-system, which has been tested for usefulness and usability, is the web-browser based patient health IT system named "The Online Diabetes Exercise System". The system was developed to motivate people with Type 2 diabetes to do a 25 minutes low-volume high-intensity interval training program [4]. The development of this CHIT-system was motivated by the fact that in 2014, 387 million people worldwide had diabetes and that the number is expected to rise to more than 592 million by 2035 [5].

In a previous multi-method evaluation of the CHIT-system, several usability issues were identified and corrected [4]. Despite the thorough testing, it is unclear whether all usability problems were identified using the multi-method evaluation.

To assess the amount of usability problems that were not identified in the multi-method evaluation, we have applied an extended version of eye-tracking, named Eye-tracking Triangulation, to the CHIT-system. Eye-tracking triangulation is made of two successive sessions. The first session of conventional eye-tracking with predefined tasks followed by the second session: The Post-Experience Eye-Tracked Protocol (PEEP) [6]. Eye-tracking is a technique where eye movements are recorded while users look at a stimulus [7]. In PEEP, the users have to explain their decisions and thoughts while a retrospective replay of their eye-tracking data is shown [6]. Even though eye-tracking has been used in psychology for decades, to our knowledge, eye-tracking triangulation has not been applied to health informatics systems.

Our hypothesis is that adding the eye-tracking triangulation to the multi-method evaluation increases the accuracy and completeness when testing the usability of CHIT-systems. The objective of the present study was to assess the potential use of eye-tracking triangulation for evaluating the usability of a CHIT-system, The Online Diabetes Exercise System, which, before the present evaluation, had been optimized using multi-method evaluation.

Materials and Methods

The Patient Health IT System

As already outlined, the eye-tracking triangulation was applied to the Online Diabetes Exercise System (Figure 1). The system is a web-browser based prototype and was designed, implemented, evaluated and optimized using the iterative, systematic, and holistic multi-method evaluation, which consisted of interviews, paper prototyping, heuristic evaluation and tests with users [4]. The system contains two major functions: a 25 minute low-volume high-intensity interval training

program (HIT program), which the users in this study only looked at, but did not perform, and a glucose diary.

Figure 1 - The Menu of the Online Diabetes Exercise System

Recruitment

Eight users were recruited for the study - five women and three men. The background of the participants were diverse, ranging from having short to long educations: a biomedical laboratory technician with a master in health informatics, an occupational therapist, a global IT-manager, a nurse, a boilermaker, a shipper, an MA in Danish and Psychology, and a veterinary nurse. Their age ranged from 34 to 69 years. Six out of the eight had a Body Mass Index (BMI) of more than 25 and were per definition classified as being overweight. All the users exercised daily, they were native Danish speaking people, and they reported to use the Internet on a daily basis. Five out of the eight users wear glasses, which is not a problem while tracking their eye movements.

Equipment

The users' eye movements were tracked using a Tobii Eye-Tracker X120. The eye-tracker was placed below a Samsung Monitor 21.5 inch monitor used by the test participants, as shown in Figure 2. All eye movements were recorded using the Tobii Studio software and stored together with a screen video recording, voice input, and mouse clicks for subsequent analysis [8]. Eye-movements consist of fixations and saccades. A fixation is defined as a moment where the eyes are almost motionless and it generally has a duration of 100 ms to 500 ms. A saccade is defined as a quick movement between different fixations and on average it lasts for about 250 ms, for example while reading [6]. In this study, we were only interested in fixations periods. While the test participants sat in front of the eye-tracker, their eye movements were shown simultaneously on a separate monitor, allowing the facilitator to follow the experiment and ensuring the equipment was capturing the data at all times (to the left in Figure 2). Prior to every test session, the equipment was calibrated to each participant to ensure optimal accuracy (about 0.5 cm on a monitor placed 70 cm in front of the test participant).

Study Design and Procedure

Session 1: Eye-Tracking

Initially, each user received an introduction to the purpose of the study. They then received instructions on how to seat themselves in a comfortable position in front of the Tobii Monitor, while completing the following tasks:

1. Set up an account in the Online Diabetes Exercise System
2. Search for help due to forgotten login information
3. Login to the Online Diabetes Exercise System
4. Acquire knowledge about the Online Diabetes Exercise System through an available user guide
5. Start and finish the low volume HIT program (not performing the actual training)
6. Register and review information in the glucose diary
7. Log out from the Online Diabetes Exercise System

After assenting to the instructions and the tasks, the facilitator calibrated the Tobii eye-tracker and the users began completing the tasks.

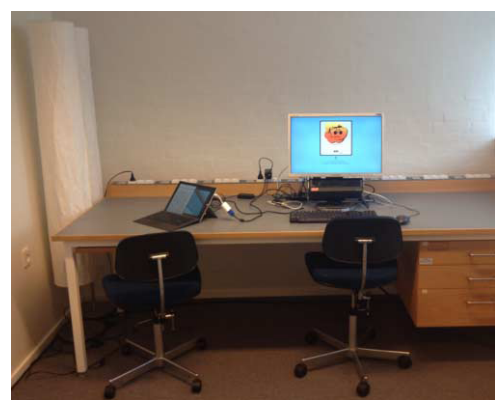

Figure 2 - The eye-tracking set up

Session 2: Post-Experience Eye-Tracking Protocol (PEEP)

A dicta-phone was turned on to collect the users' answers. The facilitator had predefined six Areas of Interests (AOIs) which would be the basis for the PEEP-session. The AOIs were: (1) *Information Text;* (2) *Forgot login/Create an Account;* (3) *Login;* (4) *Subheadings;* (5) *Colour Box;* (6) *Progress Bar.* The AOIs were spread over several different screens. The users were asked to provide retrospective protocols, meaning that while they were shown a replay of their eye-tracking data they were asked to explain their thoughts and decisions to each AOI [6]. The following details were specifically queried: long fixations; text scanning rather than reading, and failing to look at specific elements that were considered important for the task. At the end of the session, the users were asked if they had any further comments, and if not, Session 2 was complete. Session 1 took approximately 10 minutes and Session 2 took 15-20 minutes.

Data Analysis

Statistical data about the six AOIs were extracted from the eye tracking software regarding the two metrics shown in Table 1. Usability issues were identified from the statistical data. Valuable and complementary inputs to analyse the statistical data were provided by the PEEP-technique. The PEEP inputs were afterwards compared with the identified usability issues.

Table 1 – Eye-Tracking Metrics

Metric	Explanation
Time to First Fixation	The time in seconds from when the stimulus was shown until the start of the first fixation within an AOI.
Visit Count	Number of times the user fixate on an AOI.

Results

The five heatmaps shown in Figures 3 to 7 illustrate the visual behaviour of users during the eye-tracking sessions. The colour coding illustrates the total time spent looking at various areas. Green equals a shorter time, yellow medium time, and red longer time. Dashed rectangles indicate AOIs.

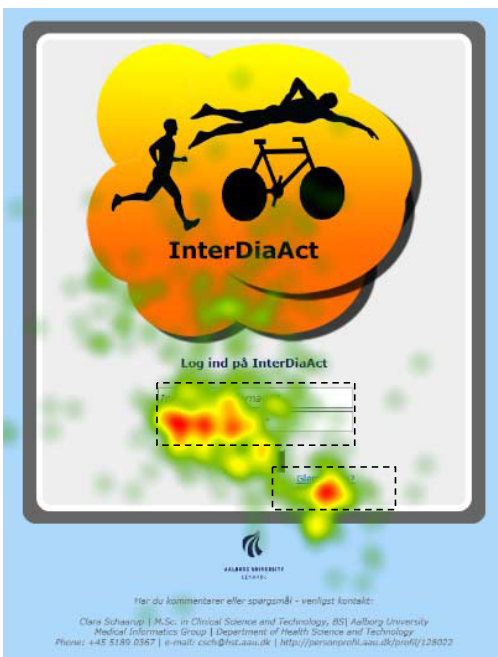

Figure 3 – The welcome screen has two AOIs: the 'Login' area and the area for 'Forgot login/Create an Account'

Figure 3 shows how the users fixated at the AOI-*Login* and the AOI-*Forgot login/Create an Account*. On average for the Login AOI, the users had 12.00 visit counts and spent 1.38 seconds before their first fixation, which can be seen in Table 2. During the PEEP session, some of the users reported that the font used was too small to identify the button 'Create an account'. Later in the session, they said that they just did not look carefully enough.

Table 2 – The six predefined areas of interest correspond to the two metrics: Visit Count & Time to First Fixation

Area of Interest; (AOI)	Visit Count; Mean(count)	Time to First Fixation; Mean(.seconds)
Information Text	10.25	17.80
Forgot login/Create an Account	5.17	10.18
Login	12.00	1.38
Subheadings	12.75	2.96
Colour Box	7.20	0.25
Progress Bar	1.00	1.33

The heatmap in Figure 4 illustrates how the users read the information about the newest research regarding low-volume high-intensity interval training. As can be seen in Table 2, the users on average had 10.25 visit counts on this AOI, the *'Information Text'*, and spent 17.80 seconds before they had their first fixation on it. In the PEEP session, the users reported that it was overwhelming with all the information on this AOI and was hard to read it all. In addition, they reported that the font size was too small. Nevertheless, some of the users mentioned that it was interesting to read. A later test of the text showed a readability index of 49, which corresponds to very difficult readings such as academic papers [9].

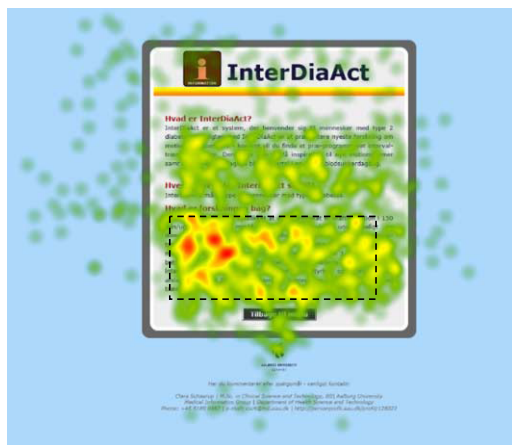

Figure 4 –AOI with the newest research regarding low-volume high-intensity interval training

Figure 5 shows the heatmap for the *Progress Bar*. On average, the users had 1 visit count and spent 1.33 seconds to identify the AOI. In the PEEP session, the users reported that the progress bar was too small and unclear.

Figure 5 – While the low-volume high-intensity interval training program was running, the users were presented to a red progress-bar placed in the top of the of the screen

Figure 6 shows the heatmap for the page where users can obtain information on how to add another training program or

switch to a different type of exercise, for example from biking to swimming. The page is divided in subheadings and one of these is defined as an AOI. On average, the users had 12.75 visit counts and 2.96 seconds to first fixation on the AOI *Subheadings*. During the PEEP session, the users reported that the subheadings helped them to get an overview of the information.

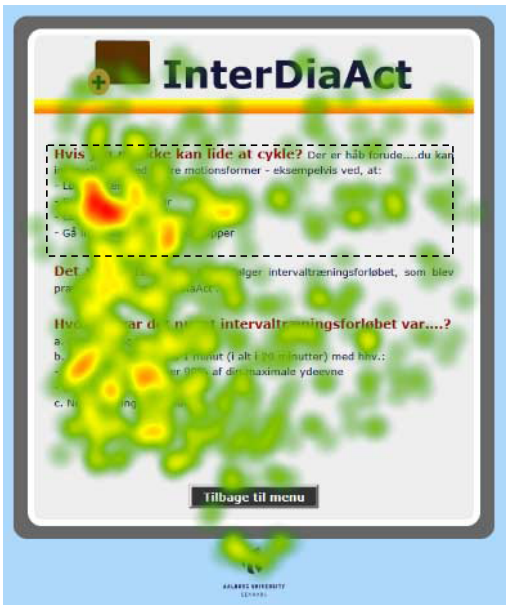

Figure 6 - The heatmap of the page where users can get information on how to add another training program or switch to a different type of exercise

Figure 7 shows the information explaining the colour scheme used during the training program – green for initial warm-up and final cool-down period, yellow for pauses between bursts of high intensity training, and red for the short periods with high intensity activity. The illustration of this at the bottom of the figure has been chosen as an AOI, the *Colour Box*. On average, the users had 7.2 visit counts and spent 0.25 seconds to first fixation at the AOI. In the PEEP session, the users reported that they preferred figures rather than text.

Figure 7 – The heatmap of the page explaining the colour scheme used during the training program

Discussion

The aim of the study was to assess the potential use of eye-tracking triangulation to evaluate the usability of the Online Diabetes Exercise System. The eye-tracking triangulation was made up of two successive sessions: The first session of conventional eye-tracking with predefined tasks followed by the second session, The Post-Experience Eye-Tracked Protocol (PEEP), the latter being based on the eye-tracking heatmaps and the six selected Areas of Interest [6].

Eye-tracking triangulation is a technique, which has been used for more than 20 years in usability studies for marketing purposes, and which is well known in cognitive psychology [7]. The technique is an attractive and powerful tool because it delivers objective results such as heatmaps and subjective results such as statements and reports that clarify potential misinterpretations of the heatmaps. The combination of objective and subjective results can be argued to make the method more valid and reliable.

In our study we saw the strength of the eye-tracking triangulation on several occasions, where the method detected usability issues that had not been found with the previously applied multi-method evaluation consisting of interviews, paper prototyping, heuristic evaluation and tests with users. For instance, we had an assumption that the participants would use the progress bar while they were looking at the low-volume high-intensity interval training program (Figure 5). However, the results showed that the users on average only had one visit count at this AOI and thus basically did not use it (Table 2). In the following PEEP session, we received an expanded explanation for this. This is an example of how eye-tracking triangulation, in our study, provided relevant information that was not provided by any of the four tests and evaluations in the multi-method evaluation.

Another example, which illustrates the strength of the triangulation, is the heatmap in Figure 4, with an AOI describing the newest research regarding low-volume high-intensity interval training. From the heatmap, we saw that the users read the information text, i.e., looked at the AOI labelled *Information Text*, but also that they looked at areas far away from the AOI several times. The heatmap did not tell us why, but the users explained this during the following PEEP session and thereby gave important information on a very relevant problem – that it was overwhelming with all the information on this AOI and that it was hard to read all. Again, this problem had not been detected by any of the four tests and evaluations in the multi-method evaluation.

The two examples illustrate how the combination of the eye-tracking and the post-experienced eye-tracked protocol can increase the accuracy and completeness of findings of usability issues in a consumer health information technology system.

From the literature, we know that it may be difficult to evaluate systems in the field of health informatics [10]. Bürkle et al. have in their study tried to assess advantages and disadvantages of different study designs, which may be potential methods to evaluate health informatics. They looked at the following designs: a randomized controlled study, a controlled study, a non-controlled study, and a simulation study and they found that evaluating health informatics depends on: the goal of the evaluation, available resources, human factors, and what type of technology that has to be examined. They concluded that a mixed approach that combines measurement of several indicators is the optimal way to evaluate health infor-

matics [10]. This conclusion is supported by the findings in the present study, which, in addition, indicates a potential added value of including eye-tracking triangulation in a mixed approach to evaluate health informatics.

Despite the promising results in our study, there were some limitations in the design. Firstly, we only used eight participants and they were probably not representative of all potential users of such a system. Secondly, the eye-tracking triangulation was only applied to one system, the Online Diabetes Exercise System, and the results may be different when applying the method to other types of consumer health information technology.

Conclusion

In conclusion, several problems, not identified previously, were found using eye-tracking – adding eye-tracking triangulation to the multi-method evaluation was found to increase the accuracy and completeness. Eye-tracking triangulation gave objective and subjective results, which are believed to be very relevant for designing, implementing, evaluating and optimizing systems in the field of health informatics.

Even though eye-tracking has been used in other areas for decades, to our knowledge, eye-tracking triangulation has not been applied to health informatics systems. Our findings suggest a future role for eye-tracking triangulation when evaluating systems in the field of health informatics.

Future work should include more studies of the potential benefits from using eye-tracking. The method should be assessed using larger and more representative groups of users and the method should be applied to a variety of different types of systems.

Acknowledgements

The authors would like to thank the users who participated in the eye-tracking triangulation sessions. The work was supported by the 7th framework EU project eWall.

Mobile App to Reduce Inactivity in Sedentary Overweight Women

Joseph Finkelstein, McKenzie Bedra, Xuan Li, Jeffrey Wood, Pamela Ouyang

Johns Hopkins University School of Medicine, Baltimore, MD, USA

Abstract

Recent studies demonstrated that the duration of inactivity (sedentary state) is independently associated with increased risk of cardiovascular disease. Our goal was to develop the technology that can measure the amount of inactivity in real time, remind a person that a preprogrammed period of inactivity has occurred and encourage a period of activity, and provide web-based feedback with tailored information to the participant and investigators. Once it was developed, we carried out a pilot study in a group of sedentary overweight women. The objective of the study was to assess potential of the mobile app to reduce inactivity in our target population. A randomized crossover design was employed with study subjects randomly assigned to a 4-week each "message-on" and "message-off" periods. Out of 30 enrolled subjects, 27 completed the study. The average age of particpants was 52±12; BMI: 37±6; 47% were white and 47% were African American. Overall, inactivity was significantly lower ($p<0.02$) during "message-on" periods (24.6%) as compared to the "message-off" periods (30.4%). We conluded that mobile app monitoring inactivity and providing a real-time notification when inactivity period exceeds healthy limits was able to significantly reduce inactivity periods in overweight sedentary women.

Introduction

Cardiovascular disease (CVD) is the leading cause of death in women in the USA. The risk factors contributing to CVD include obesity (strongly associated with insulin resistance), diabetes, inflammation, and dyslipidemia. Prevalence of CVD is lower in women than in men; however, women with diabetes carry a higher risk for CVD. Studies suggest that women with diabetes mellitus (DM) without known CVD have a greater mortality than women without DM but with known CVD.[1] Exercise reduces obesity and visceral adiposity, increases peripheral muscle glucose utilization, and increases insulin sensitivity.

The US federal guidelines recommend a daily moderate-intensity physical activity for 30 minutes. Despite these recommendations, the prevalence of obesity and diabetes continues to increase, and it is predicted that US obesity may reach 42% by 2030. In addition to the well established link between physical activity and lower CVD risk, it is now becoming evident that the duration of inactivity (sedentary state) is also associated with increased risk. The risk associated with being sedentary is independent of the amount of physical activity; i.e., the effects of too much sitting rather than too little exercise also impact CV risk.[2] Studies have generally shown that people admitting to a higher number of hours of sitting have greater risk for developing diabetes, cardiovascular disease, and all-cause mortality.[3] Thus it is plausible that reducing the amount of sedentary time may reduce CVD and diabetes risk. Furthermore, the data suggest that even active individuals would benefit from reducing their hours of inactivity. This may be particularly important in women who have greater barriers to exercise.[4]

Our goal was to develop the technology that can measure the amount of inactivity in real time, remind a person that a preprogrammed period of inactivity has occurred encourage a period of activity, and provide a web-based feedback with information tailored to the participant and investigators. Once it was developed we carried out a pilot study in a group of sedentary overweight women. The objective of the study was to assess potential of the mobile app to reduce inactivity in our target population.

Materials and Methods

For inactivity monitoring we employed a physical activity tracking device (Fitbit) and an Android smartphone with digital data plan. Fitbit uses a three-dimensional accelerometer to monitor physical activity including number of steps. Fitbit is a miniature wearable device which communicates with a smartphone via Bluetooth connection to transmit the physical activity data. The physical activity data are then relayed by a smartphone to a Fitbit database hosted by the company, which provides developers with API to access the user data by custom applications.

System Design

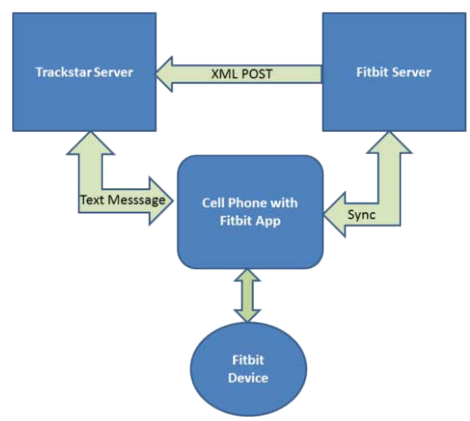

Figure 1 – Mobile App Design

The inactivity monitoring system consists of two separate programs hosted on the same server – a step monitoring app that collects data from the Fitbit users and stores it in our database, and another monitoring program that generates

tailored text messages in certain situations. Both programs were developed in C# using the Fitbit API.

The step monitoring website receives POSTed XML updates from the Fitbit server whenever the Fitbit device syncs. Each Fitbit account has a subscription service activated that tells it where to POST the XML file. The XML file is sent to our site by Fitbit automatically for each registered user account. The Fitbit device syncs every 10-15 minutes when it is in the range, which defines the maximal frequency of updates received by our server in real time. Each post provides an update on the number of steps made by a particular user in an incremental manner. The step counts starts from zero every day at 00:00am.

When the site receives the XML file it records the time and number of steps which are queried for the user using the Fitbit API. It then checks to see if there have been less than 15 steps in the past hour. If there were, and no blackout conditions apply, it will send a tailored text message to the user's phone informing that sedentary period exceeded healthy limits, and encourages the user to take a break from the sedentary position. The tailored message provides suggestions from the message library on ways to have short physical activity breaks in an office environment or at home, depending on the time of the day.

The monitoring program has four different execution modes depending on the argument(s) passed. One of those modes is the sync monitor. The sync monitoring program goes through all users and checks their last sent record, which is the last time they synced. If they have not synced for an hour or more, it should send them a text message saying so, unless such a message was sent in the past hour. This mode runs every 15 minutes. This mode addresses instances when connection between Fitbit and the cell phone is lost.

The second mode is the exercise link program, which sends a link to relevant exercise education materials from the database to every user in the database every time it is run. It should cycle through all the links in the table in order and goes back to the first one after it gets to the end. The current link is stored in the database. This program is scheduled to run at 8am every Saturday and Sunday. This mode promotes user engagement in healthy lifestyle activities by empowering the user with helpful information during weekends when users have more time to review educational messages.

The third mode is the daily report program, which sends a summary of the user's steps from the previous day. It uses the Fitbit API to query a user's total steps from the previous day. This mode provides useful feedback on a daily basis helping users monitor their activity level and adjust it when necessary.

The final mode is the no sync text. This program checks whether or not a user has synced in the last 24 hours. If not, the user is sent a text message telling them this and encouraging them to reestablish connection. This mode allows to identify potential technical issues in a timely manner.

There are blackout conditions for which no messages are sent to the patient. The first blackout condition is if the user has texted "S[X]", – where X is the number after S – so that the mobile app stops sending text messages for the next X hours. If the user texts "Okay", it does not send texts for the next 1 hour. They also do not receive texts if there are blackout times corresponding to the current time set in the database for that day. Blackout hours were entered for each patient at enrollment based on their personal preferences. This mode addresses specific user preferences in terms of their schedule when they cannot use the phone.

The design of the system has been informed by two focus groups conducted in overweight sedentary women at the beginning of the development process. The app specifications tailored participants' suggestions voiced in the focus groups.

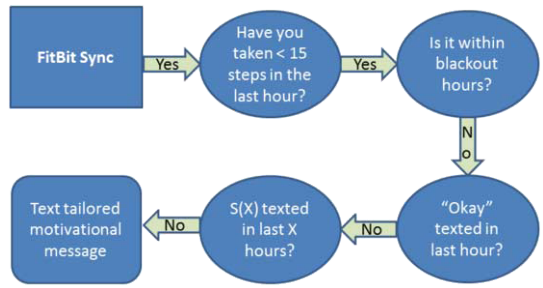

Figure 2 – Text Messaging Algorithm

Evaluation Design

A randomized crossover design was used to evaluate potential impact of the mobile app on the inactivity level (Figure 3). For this pilot we enrolled overweight sedentary women who met the following criteria.
Inclusion criteria:

- Adult women with BMI > 30 kg/m^2 who are inactive for > 3 hours on an average day

Exclusion criteria:

- Pregnant per participant's information
- Inability to walk
- Medical reasons to limit activity; e.g., unstable cardiac conditions such as angina or heart failure
- Poorly controlled hypertension, SBP >160 mm Hg, DBP >100 mg Hg (whether or not they are on antihypertensive agents)

No clinical care was provided by the research team. Participants were recruited by flyers and from previously conducted focus groups that were designed to provide feedback on the devices and messages that were used in the study. Almost all the focus group participants expressed interest in being in the study.

During the first visit the participants had their weight, height, and BP measured and blood drawn for fasting glucose and insulin. A questionnaire was administered to capture demographic and major clinical conditions to ensure that activity is possible and advisable using the American Association of Sports Medicine criteria.[5,6] Participants also completed a number of questionnaires that capture their level of activity/inactivity at work and during leisure time, as well as their readiness toward starting to increase activity. All study subjects received a Fitbit One and a smartphone. They were instructed on the use of these devices. Digital data plan and phone service were provided with the smartphone for all participants for the duration of the study. During the first 2 days (Day -2 to Day 0) participants were asked to use the devices and become comfortable with them and they were encouraged to contact the coordinator if they had any questions. The first 2 days were a regular work days and formed a baseline period of activity and inactivity. Participants were randomized to one of the two groups (Group A or B). Group A participants had the inactivity reminder system activated for time period 1 (4 weeks duration), and that function was inactivated for the second 4 weeks of the study. Group B had the inactivity reminder system inactivated for the first 4 weeks, and activated for the second 4 weeks of the

Table1 – Inactivity analysis: inactivity is expressed as fraction of the day from 8:00 am to midnight

study. At the end of the study (Day 56), the biometric measurements and questionnaires were repeated.

In addtion to tailored text messages generated by the mobile app, the participants were allowed to see all the measurements of activity that are routinely captured and displayed by the commercial Fitbit website. This includes the number of steps per day, the number of steps climbed, distance walked, and calories burned.

At the end of the study, participants were asked their views on the devices, messages, and the effect of these on their perceptions or knowledge about activity and inactivity, the impact of these technologies on their readiness to be active, and their thoughts on whether they would be willing to continue using these devices/software for longer durations. This information will be used to improve mobile app design for a larger study.

The primary outcome of interest was the number of episodes of prolonged inactivity (> 2 hours duration) per day during the time period that the inactivity reminder was active compared to not active (time Period 1 vs 2).

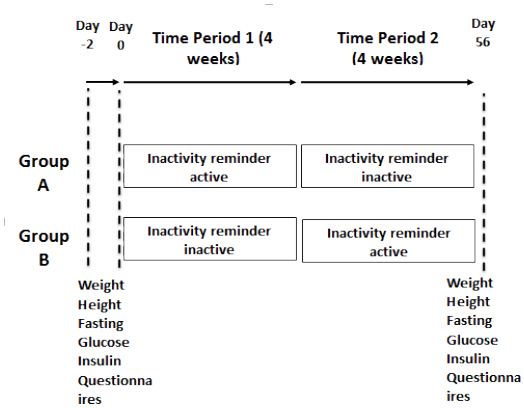

Figure 3 –Study duration and number of study visits required of research participants.

Results

Overall results were positive. Out of 30 enrolled subjects, 27 completed the study. The average age of particpants was 52±12, with average BMI of 37±6.; 47% of the participants were white and 47% were African American. There was no significant difference in baseline characteristics between Group A and B.

The inactivity was calculated as percent of consecutive 2-hour slots between 8am and midnight (total of 8 2-hr slots per day) during which the number of steps did not exceed 20 (Table 1). Overall, inactivity was significantly lower ($p<0.02$) during "message-on" periods (24.6%) as compared to the "message-off" periods (30.4%). For Group A, the mean period of inactivity as a percentage was 21.5% during the "message-on" period, and during the "message-off" period inactivity increased to 32.1% ($p<0.004$), indicating a decrease in inactivity when receiving text messages from the system. Group B, which received no tailored messaging during the first 4 weeks, showed no change when it was switched to messaging in the subsequent 4 weeks, with a mean inactivity period of 28.3% for both the "message-on" and "message-off" periods.

An analysis of the step count revealed that Group A had a higher average daily number of steps during "message-on" period (6199.1±2062.1) as compared to the "message-off" period (5614.8±1855.1). A similar but less pronounced tendency was documented in Group B with mean number of daily steps going from 5771.4±2552.4 during "message-off" period to 5699.4±2224.4 during "message-on" period.

After completion of the 8-week follow-up period, two focus groups were conducted with the study participants. A majority of the participants expressed high acceptance of the mobile app and indicated willingness to use it in the future.

Discussion

A mobile app monitoring level of inactivity in real-time has been successfully introduced in this study. The impact of tailored messaging generated by the mobile app in response to prolonged periods of inactivity has been studied in overweight sedentary women using randomized crossover design. The results of the study demonstrated a significant impact of tailored messaging on inactivity. Comparison between "message-off" and "message-on" periods showed that there was statistically significant reduction in inactivity duration when the study particpants were receiving text messages indicating that sedentary periods exceeded healthy limits and encoraging the study subjects to move. Further analysis demonstrated that significant reduction in inactivity occurred only in Group A which receved tailored messaging during the

first 4 weeks of wearing Fitbit. Participants in Group B who started receiving tailored messages only after 4 weeks of wearing Fitbit did not demonstrate decrease in inactivity after they were switched to tailored messaging. This conforms to previously described phenomenon of technological imprinting when initial patterns of new technology use are maintaned regardless of the subsequent changes in this technology.[7-9] Any change in user behavior afterward requires additonal retraining.[10,11] Our results underscore the importance of introducing fully functional mobile apps including tailored messaging from the very beginning of the intervention aimed to reduce inactivity.

Recent studies have demonstrated the importance of patient-centered delivery of the medical care tailored to individual needs, preferences, and values of the patients.[12-14] In concordance with these findings, successful implementation of the mobile app described in this study can be attributed to tailoring its specifications to preferences of the target audience and employment of participatory design principles from the beginning of the mobile app's development.[15-17] Another factor affecting high acceptance of the mobile app is that smartphones have become a ubiquitous appliance widely used in our target population.[18,19] High utility of mobile phones for health empowerment and engagement has also been demonstrated previously.[20,21]

Conclusion

A mobile app monitoring inactivity and providing a real-time notification when inactivity period exceeds healthy limits was demonstrated to significantly reduce inactivity periods in overweight sedentary women. The proposed approach is warranted for further investigation in larger group of subjects using randomized clinical trial design.

Abstract

Diabetes is a complex disease affecting 29.1 million (9.3%) US citizens [1]. It is a chronic illness that needs continual medical care and ongoing patient self-management, education, and support [2]. There is no cure for diabetes, requiring patients to conduct frequent self-monitoring of blood glucose and dosing of insulin in many cases. Evidence has shown that patients are more adherent to their diabetes management plan when they incorporate personal lifestyle choices [3]. To address the challenge of empowering patients to better manage their diabetes, we have developed a novel mobile application prototype, iDECIDE, that refines rapid-acting insulin dose calculations by incorporating two important patient variables in addition to carbohydrates consumed that are not a part of standard insulin dose calculation algorithms: exercise and alcohol intake [4, 5]. A retrospective analysis for the calibration and evaluation of iDECIDE is underway by comparing recommendations made by the application against dosing recommendations made by insulin pumps.

Keywords:

Diabetes mellitus; Insulin dosing; Clinical decision support systems Mobile application Disease self-management.

Introduction

Patient-centered care is defined as health care that respects patients' wants, needs, and preferences, supporting patient desires to make decisions and participate in their own care [6]. Too often patients must adapt to pre-existing protocols and guidelines, rather than receiving services designed to focus on their individual needs and preferences [6]. Patient-centered decision support that translates evidence-based care into health care practice in ways that account for individual preferences and goals is needed.

Many patients with chronic conditions such as diabetes can benefit greatly from self-management [7]. Self-monitoring of blood glucose can be empowering for patients, but tracking such data can be overwhelming [8]. Even patients well trained in diabetes self-management often fail to meet personal glycemic goals. Despite ongoing research to identify patient preferences, track treatments, and integrate patient data to provide personalized options, significant advances in the design and deployment of patient-centered decision aids are still to be made [9, 10].

Type 1 diabetes (T1D) is a chronic disease in which a person's pancreas does not produce insulin, a hormone required to regulate carbohydrate and fat metabolism in the body. Type 2 diabetes (T2D) results from a relative insulin deficit and can be due to a diminished insulin effect or insufficient production to maintain normal blood glucose levels. T2D patients may need insulin injections, oral medications, non-insulin injectable medications, or various combinations of these to control hyperglycemia. Patients with T1D must manage their disease by using insulin injections deliverable through syringes, insulin pens, or insulin pumps. Contemporary insulin pumps utilize a rapid acting insulin analog and deliver continuous basal insulin. Additionally, insulin pumps have bolus calculators that calculate the units of insulin needed based on settings, food intake and active insulin time. Such bolus calculators, which are designed to cover mealtime glucose excursions, do not take into account patient preferences such as alcohol intake and exercise. Evidence shows that these personal preferences can have a significant short-term impact on glucose levels, which in turn affects insulin dosing [4, 5]. Our hypothesis is that by incorporating current evidence regarding the impact of exercise and alcohol intake on insulin dosage, we can further improve postprandial glucose levels for adult individuals with diabetes, thereby empowering them to make informed, evidence-based self-management decisions. We have designed and seek to evaluate a novel, evidence-based decision support tool, iDECIDE, which customizes and refines rapid-acting insulin dosing calculations by incorporating individual preferences for exercise and alcohol. The target population of iDECIDE is adult diabetes patients with T1D or T2D.

Most of the available mobile applications are not evidence-based [11], while iDECIDE is based on the most current medical evidence.

Methods

A literature search that included diabetes pathophysiology, treatment and management options was conducted. We identified insulin dosage calculations based on glycemic levels, carbohydrate intake, exercise, and alcohol consumption.

Next, we reviewed the literature on smartphone apps for diabetes self-management and apps for healthy eating, physical activity, and personal health and wellness [11, 12]. Based on the review there is a proliferation of apps that are not evidence-based or do not align with well-established behavior change theories.

Following our literature review, we met with an endocrinologist and diabetes care team to further understand diabetes and to discuss current clinical challenges that patients encounter. We participated in a guided simulation training session with a diabetes nurse educator at the Mayo Clinic Arizona Simulation Center that included hands-on experience with insulin pumps and continuous glucose monitors. The training excluded review of existing smartphone apps for diabetes management, fitness or nutrition. Based on the trainings we created three prototypical patient cases to reflect the daily regimens and personal preferences encountered on a daily basis by diabetes patients. We learned that diabetes is not a "one size fits all" disease and

that personal management requires special consideration for each patient.

We also reviewed existing insulin pump technologies commercially available in the US. State-of-the-art insulin pumps compute mealtime insulin doses based on proprietary formulas that are approved by regulatory entities like the US Federal Food and Drug Administration (FDA). While alcohol intake and exercise can have an impact on blood glucose levels, no insulin pump takes into consideration alcohol and exercise to compute the insulin needed to correct for a meal. While insulin pumps provide bolus wizards to compute pre-meal insulin boluses, diabetes patients can manually compute pre-meal insulin bolus using an equation from Colin et al. (Equation 1) which takes into consideration important factors, except alcohol and exercise, for choosing the correct insulin dose [13].

$$U = \frac{carbs}{ICR} + \frac{cBG - tBG}{CF} - IOB \quad (1)$$

In Equation 1, the variable *U* represents units of insulin. The first fraction in the equation, "*carbs/ICR*", calculates the relationship between the grams of carbohydrates (*carbs*) intended to be consumed covered by one (1) unit of insulin (*ICR*). *ICR* is calculated as 450/TDD, where Total Daily Dose of insulin (TDD) = body weight (lbs) x 0.23. The second fraction in the equation calculates the difference between the actual blood glucose level (*cBG*) and the target blood glucose level (*tBG*) and divides this difference by the Correction Factor (*CF*). The correction factor, also called insulin sensitivity factor (ISF) is defined as how much one (1) unit of rapid acting insulin lowers an individual's blood glucose over the course of 2-4 hours during a fasting or pre-meal state. These correction doses can account for approximately 9% of the TDD by compensating for the deficits in basal rates or carbohydrate boluses. *CF* is calculated as (1700mg/dl) / TDD. The final segment of the equation subtracts the Insulin On Board (*IOB*) i.e. the theoretical amount of insulin remaining in the body after the last bolus dose.

The ADA states that regular physical activity is important for maintaining health and fitness for those diagnosed with diabetes. People with diabetes are advised to participate in at least 150 minutes of moderate-intensity physical activity per week. Regular exercise has been shown to improve blood glucose control, reduce cardiovascular risk factors, contribute to weight loss and improve well-being [14]. Evidence suggests that most forms of low-to-moderate intensity physical activity result in an increase of insulin sensitivity, which produces a drop in blood glucose levels. When glucose levels drop to abnormally low levels it is called hypoglycemia. Hypoglycemia can be averted by reducing the bolus insulin, increasing food intake, or a combination of both [5]. The evidence recommends ingestion of carbohydrates (e.g. snacks) before exercising to avoid hypoglycemic events.

Alcoholic beverages present an even more complex insulin dosing challenge. Depending on the specific content of the drink, alcoholic beverages can be a carbohydrate source and/or result in delayed hypoglycemia. It is difficult for patients to factor alcoholic drinks into their insulin dosing calculations. Also, they frequently are not aware that more than 2 alcoholic drinks can increase the probability of hypoglycemia a few hours after alcohol consumption [15].

We therefore propose a new insulin dosing equation (patent pending) that accounts for the intensity and duration of physical exercise as well as the alcohol load and related carbohydrates from alcoholic beverages. We have added to the standard equation (Equation 1) parameters to account for patient preferences for exercise and alcohol consumption. As we noted previously, insulin pump calcuators do not consider exercise when calculating insulin dosage, neither do they factor in the effects of alcohol on insulin sensitivity. iDECIDE incorporates these factors to suggest the dosage of rapid acting insulin and sets an alarm to recommend glucose level monitoring in certain circumstances related to alcohol consumption.

Results

Several prototyping platforms such as WireframeSketcher, POP, and Proto.io™ were compared. Proto.io™ emerged as the best choice due to its drag-and-drop intuitive interface for building interfaces. Figure 1 depicts screenshots of the resulting iDECIDE prototype built with Proto.io™.

To exemplify the use of iDECIDE, Figure 1 demonstrates a T2D patient using the app to decide if insulin should be taken before starting a 30 minute, medium-intensity bike ride. Based on the exercise plan and his current blood glucose level of 150 mg/dl, (cBG=150) iDECIDE recommends no insulin and suggests consuption of an additional 10 g of carbohydrates before starting the exercise to achieve a target glucose level of 130 mg/dl (tBG=130) and to avoid hypoglycemia. iDECIDE is using the ICR=10 and CF=20, based on input from the patient's endocrinologist. The IOB=0.75 because the previous insulin dose was 1.25 units from 2 hours prior [16]. To account for exercise (Ex), 0.25 is subtracted off given the short duration (30 minutes) to be completed [17]. The suggested carbohydrates (10 g) were derived from the evidence regarding the patients weight of 150 pounds and the choice of performing 30 minutes of moderate exercise [5].

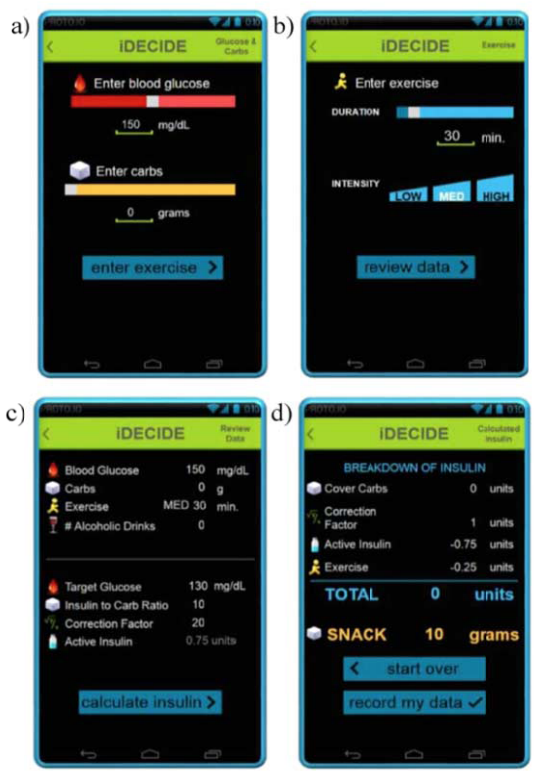

Figure 1- Screenshots of the iDECIDE: a) the patient inputs 150 mg/dl as current blood glucose and that no carbs will be consumed, b) he also inputs that he will be performing 30 minutes of medium intensity exercise; then c) iDECIDE summarizes the input data, the parameters set up by the patient's endocrinologist (e.g. target glucose), and the computed active insulin or IOB; finally d) iDECIDE generates

recommendations (take 0 U of insulin and consume a snack with 10 grams of carbohydrates) and a breakdown of how the suggested insulin dosage was computed (0 U= 0 U to cover carbs + 1 U for correction factor -0.75 U of active insulin – 0.25 U for planned exercise)

Figure 2 exemplifies another use case scenario showing how iDECIDE can set up an alarm if the patient chooses to consume more than 2 alcoholic drinks. The alarm is to remind the patient to monitor blood glucose levels to help avoid hypoglycemic events.

Both Figures 1 and 2 assume that the user enters information immediately before eating, drinking or exercise in order to compute the insulin bolus. It is not uncommon for diabetes patients to input data after they eat or drink to account for last-minute changes.

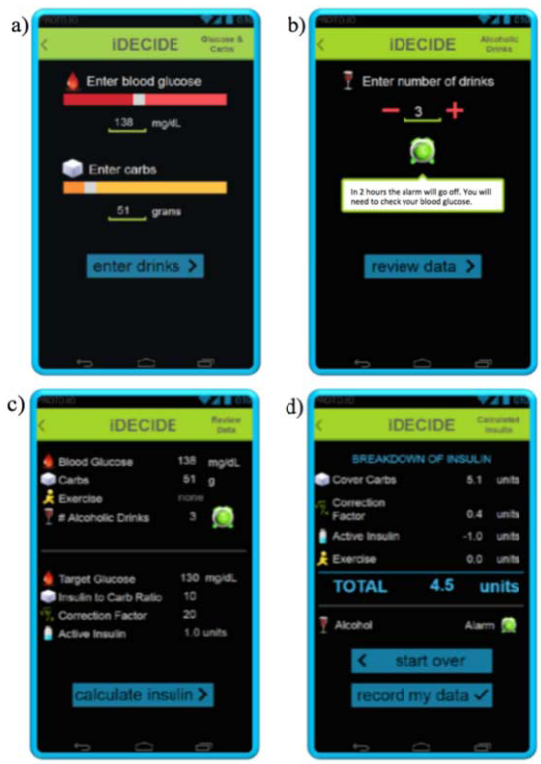

Figure 2- Screenshots of the iDECIDE prototype: a) the patient inputs 138 mg/dl as current blood glucose and that 51 grams of carbs will be consumed, b) he also inputs that he will be drinking 3 alcoholic drinks, to what iDECIDE reacts by setting an alarm to remind checking blood glucose levels to avoid hypoglycemia; then c) iDECIDE summarizes the input data, the parameters set up by the patient's endocrinologist, the computed IOB and indicates that it has setup un alarm; finally d) iDECIDE generates recommendations (take 4.5 U of insulin and check the blood glucose levels in 2 hours when the alarm rings) and a breakdown of how the suggested insulin dosage was computed

We incorporated feedback on this mobile application and on the iDECIDE evidenced-based insulin dosing equation from domain experts in clinical decision support systems and usability, as well as fellow biomedical informatics graduate students. The iDECIDE prototype displayed in Figures 1 and 2 resulted from these recommendations. Then, we deployed the resulting improved interfaces and functionalities as an Android app and we performed a usability study. We secured IRB approval from Arizona State University to recruit 5 students to participate in the study. Participants were given 7 tasks to complete after a 5 minute period of self-guided exploration of the tool. Afterwards they were given a usability survey to complete. A total of 7 usability issues were identified. The exploratory task resulted in the most issues, 5.8, with the final two tasks resulting in no reportable issues. This may suggest that users were able to learn to use the system over time.

The class diagram in Figure 3 shows the main classes (domain concepts) and relationships used for designing iDECIDE. When possible, the domain knowledge of iDECIDE was mapped into terminologies and thesaurus like the Current Procedural Terminology (CPT), the SNOMED Clinical Terms, the National Cancer Institute thesaurus (NCI) and RXNORM. For instance, the concept *currentBG* was mapped to the NCI with the code C0392201.The *Diabetes Patient* using *iDECIDE* takes daily multiple measurements of blood glucose *(currentBG),* which is a type of *Endocrine Finding*. We are also modeling that, for example, a patient can use iDECIDE to set up clinical goals (*hasDesiredState*) related to *Target Glucose, Target Carbs, Target Exercise,* and *Target Alcohol*. For instance, one goal could be to have no more than 2 alcoholic drinks per day during weekends. Every time the patient interacts with iDECIDE he is requested to input his daily preferences (*hasPreferences)* on *Carbs Plan, Alcohol Plan, Exercise Plan,* and *Insulin Plan*. For example, the patient plans to have 3 alcoholic drinks and a dinner, which account for 51 grams of carbs. Based on the input, iDECIDE triggers recommendation messages to remind the patient that his goal was to consume less than 3 drinks, and can also remind the patient the ADA guidelines on alcohol consumption. The patient can decide to follow iDECIDE's recommendations (*makesRecommendations*) or can decide to stick to the original plan, committing to a plan (*hasCommitedTo*). Patients with chronic illnesses, such as diabetes, frequently encounter *Obstacles* when trying to achieve goals or follow treatment recommendations; they are more likely to be successful if back up plans are identified in advance (*hasBackUpState*) and suggested to the patient when obstacles are encountered.

Also, we are incorporating patient Specific, Measurable, Attainable, Realistic and Timely (SMART) goals related to diabetes management, fitness and nutrition to attempt to further *empower patients* to achieve a healthier lifestyle. For instance, "walk more" is too general as a goal. Instead, "I will walk three times a week for 20 minutes" can be measured, is action oriented, can be chosen based on clinician assessment of the patient's clinical state and self-motivation to change behavior, and has a time frame. Patients can understand SMART goals, and the achievement of SMART goals can be assessed and tracked by decision support systems. Therefore, we are currently working on decision mechanisms to provide suggestions to help patients achieve their chosen goals. For instance, in the example case-scenario described above, the patient has a fitness SMART goal of daily lunchtime exercise for 30 minutes at medium intensity. An obstacle arises for the patient: rain. The model incorporates a back-up plan for inclement weather, and suggests an exercise at home (e.g. a 30 minute WiiFit activity) that will achieve his goal. The proposed decision mechanism is inspired by the goal-based clinical decision support planning framework proposed and implemented by Grando, et al. [18, 19] to detect and recover from deviations to standard clinical care plans. In order to specify and reason on SMART goals we have built an ontology using the Ontology Web Language (OWL) using the Protégé tool. Figure 4 depicts a screenshot of the Protégé tool, demonstrating how we model a SMART goal for exercising and the encountered obstacle. The resulting ontology will support the

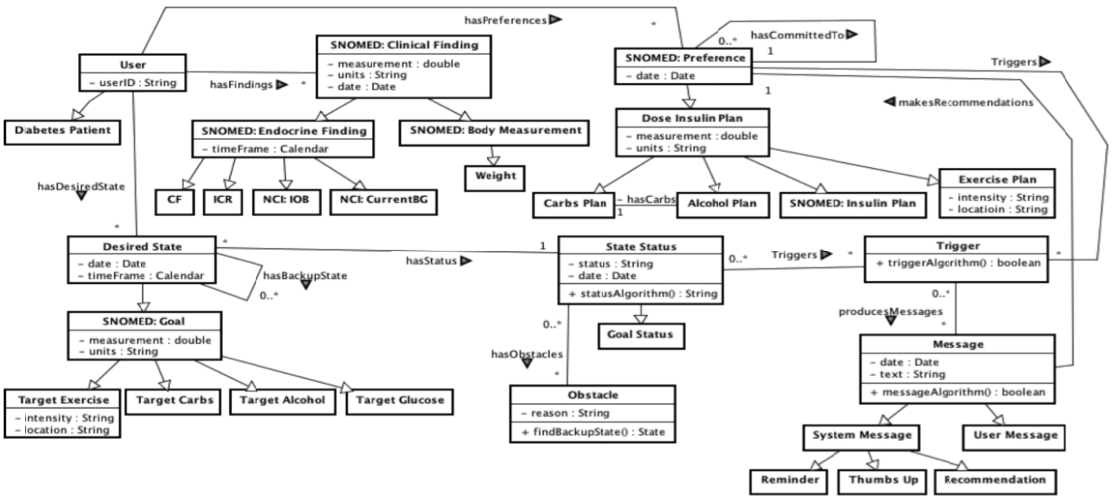

Figure 3- Class diagram depicting iDECIDE's main classes and relationships

decision rules that recommend behavioral changes, such as a specific, pre-identified home exercise option to use when there is inclement weather. Furthermore, using the ontology's goal achievement status (full, partial and none) the achievement status will be automatically determined and tracked. In our example above, the suggested back-up plan, WiiFit, is considered equivalent to the initial outdoor plan, so our patient achieves the prescribed exercise goal.

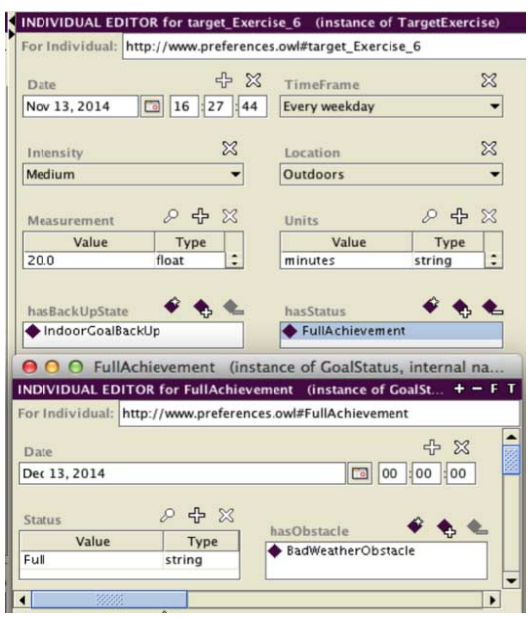

Figure 4- Screenshot from Protégé, displaying the use case scenario of a patient who chooses the goal of walking outdoors every weekday for 30 minutes with medium intensity. In case of in-clement weather, the back-up plan is to exercise at home. The status of the goal achievement (full, partial, none) can be monitored and tracked

Discussion

Future plans include providing reminders, encouragement messages and alternatives to help patients achieve their SMART goals. For our previous example, iDECIDE could remind at lunchtime the patient to exercise with the personalized message, "Time for your lunchtime break exercise. It feels good to be in shape!" The patient can choose to answer the reminder selecting from a set of predefined options including "I cannot exercise today, the weather is bad." Based on the patient's feedback and back up plans iDECIDE can provide suggestions, I see … do you feel like trying some WiiFit tonight instead? I can send you a reminder if you want."

We are recruiting twenty Arizona Mayo Clinic adult patients with T1D who currently use Medtronic™ insulin pumps to begin a retrospective calibration of the evidenced-based formula used by iDECIDE. We are limiting this study to users of Medtronic™ pumps to streamline the data analysis. Participants will be asked to keep records for one month, including alcohol intake and performed exercise (see Tables 1 and 2). The study was approved by the Mayo Clinic IRB.

Initially, we tried to reuse existing retrospective data repositories generated from insulin pumps and patients' diabetes dairies, but the available repositories lacked information on alcohol consumption or they could not be shared due to human subject protection constraints. Following the completion of the study, all participants will provide the data generated during the study period by their insulin pumps and their daily records on alcohol intake and performed exercise. We will input the provided data into iDECIDE. As part of the projected retrospective calibration, domain experts will compare the insulin recommendations generated by iDECIDE against those generated by insulin pumps. We will consider that a recommendation from iDECIDE is as good as the one from the insulin pump when the recommendations are close in range and the postprandial glucose target is achieved. We say that a recommendation from iDECIDE is better than the one from the insulin pump if iDECIDE recommends a higher (lower) dose and the postprandial reading is higher (lower) than target.

We are adopting a user-centered design approach for iDECIDE. Numerous otherwise well-conceived applications that target patients and health consumers have failed to achieve their desired effect because they have not involved users in the development process. Usability issues identified from the completed usability study will be considered to make appropriate design changes. We also plan to conduct another usability study with diabetes patients at the Arizona Mayo Clinic to fur-

ther improve the interfaces and functionalities of the mobile app.

iDECIDE does not communicate with continuous glucose monitors or insulin pumps via wireless or Bluetooth technologies because insulin pump and glucose reader manufacturers do not share the application programming interfaces (APIs) that could facilitate such interactions. iDECIDE currently requires patients to manually input first their glucose reading, meal carbohydrates, alcohol intake and exercise. iDECIDE recommends an insulin dosage to be injected using an insulin pump or syringe. The current study utilizes patients on insulin pumps as a model to test and refine the iDECIDE methodology. Insulin pumps utilize only rapid acting insulin. Future refinement of the system to account for differences in insulin pharmacokinetics will be needed. There are situations where the actions of diabetes patients digress from what was previously entered into the pump's bolus wizard. In these situations there is no technology to account for such behavior. Most patients who use insulin pumps are fairly disciplined and adhere to an established routine, in such cases iDECIDE would be a useful tool.

Table 1– My Diabetic Diary: Tracking alcohol intake

DATE (m/d/y)	TIME (Hour: Min)	TYPE OF DRINK (Beer, wine, etc)	# OF DRINKS	MEASURE (small glass, pint, can, etc)	Did You Input Drink's Carbs Into Insulin Pump?

DATE (m/d/y)	TIME (Hour: Min)	INTENSITTY – check one			DURATION (minutes)
__/_ /_	__ : __	LIGHT	MODERATE	VIGOROUS	

Conclusion

iDECIDE is a novel mobile application prototype that personalizes insulin dose calculations by incorporating two important patient variables that are not currently a part of standard insulin dose calculation algorithms: exercise and alcohol intake. Unlike the proprietary algorithms currently employed by insulin pump manufacturers to calculate insulin dose recommendations, iDECIDE is based on available clinical evidence that can be reviewed and discussed by the patient with the endocrinologist and care team. Also, iDECIDE will empower patients to improve disease management, fitness and nutrition by incorporating SMART goals. The app will help to track the achievement of SMART goals, but also provide reminders, encouragement messages and alternatives to help patients achieve their goals.

Reconfigurable Embedded System for Electrocardiogram Acquisition

Marcel Seiji Kay[a], Fábio Iaione[a]

[a] *Faculty of Computing, Federal University of Mato Grosso do Sul, Brazil*

Abstract

Smartphones include features that offers the chance to develop mobile systems in medical field, resulting in an area called mobile-health. One of the most common medical examinations is the electrocardiogram (ECG), which allows the diagnosis of various heart diseases, leading to preventative measures and preventing more serious problems. The objective of this study was to develop a wireless reconfigurable embedded system using a FPAA (Field Programmable Analog Array), for the acquisition of ECG signals, and an application showing and storing these signals on Android smartphones. The application also performs the partial FPAA reconfiguration in real time (adjustable gain). Previous studies using FPAA usually use the development boards provided by the manufacturer (high cost), do not allow the reconfiguration in real time, use no smartphone and communicate via cables. The parameters tested in the acquisition circuit and the quality of ECGs registered in an individual were satisfactory.

Keywords:
M-health, Electrocardiogram, Embedded systems, Field Programmable Analog Array.

Introduction

The smartphones popularization and the growth of available resources on these devices, as well as higher life expectancy, resulted in the development of mobile systems to be used in the medical field, resulting in an area called Mobile Health (m-Health). Nowadays, this area has generated significant breakthroughs and contributions in health-related research [1]. Studies undertaken by the World Health Organization (WHO) estimates that in 2030, about 23.3 million people will be fatal victims of cardiovascular disease [2]. One possibile solution to reducing these estimates is to increase the use of portable electronic systems to diagnose various heart diseases. These systems easily and comfortably perform tests with mobility, enabling preventative care and avoiding more serious problems [3].

Electronic systems that perform the acquisition of the electrocardiogram (ECG) consist of an analog stage (signal amplification and filtering) and a digital stage (signal digitizing). It's important to emphasize that for the acquisition of bioelectric signals such as ECG, an analog stage will always be necessary due to the necessity of amplifying and filtering the signal before its digitization, eliminating the electrode half-cell potential and avoiding aliasing. Therefore, the Field Programmable Analog Array (FPAA) is an analog stage option. The FPAA is a semiconductor device consisting of several internal configurable analog circuits (switched-capacitor filters, multiplexers, operational amplifiers, and others). The use of FPAA offers the following advantages: easy and fast prototyping circuits, low cost, reduction of the dimensions of the printed circuit board, increased system reliability, high precision and flexibility [4].

There are a few studies designed to use FPAA for the acquisition of ECG signals [3, 5, 6, 7]. In was observed the following limitations in common in these studies: a desktop computer used to view and store ECG signals in real time; usually require a Field Programmable Gate Array (FPGA) and a FPAA contained in their development boards provided by the manufacturer (high cost); the FPAA settings are pre-generated on a computer and stored in the FPGA or an auxiliary memory; the FPAA sends the ECG signal to the computer via cable (USB or EIA-232); and the recording tests are performed using only ECG simulators.

The lack of FPAA studies in literature added to the growing demand for this subject, motivated the goal of this paper to develop a Reconfigurable Embedded System for ECG Signal Acquisition (RES-ESA), and a software to display and store these signals on a smartphone with the operational system (OS) Android. Thus, we seek to explore the advantages provided by FPAA outdoing the limitations of other papers.

Materials and Methods

The microcontroller (MCU) selected was the C8051F320 [8] which is an 8-bit device with a core compatible with the MCS-51 family instruction set. This core has a pipeline that allows the execution of 70% of instructions in 1 or 2 clock cycles, providing an acceleration of approximately 12 times greater compared to the original MCS-51 core using the same clock. In addition to the resources available in the MCUs from the family MCS-51, the C8051F320 also includes: 24.5 MHz oscillator, 2304 bytes data memory (RAM) (256 bytes original, 1 extra kB and 1 kB USB FIFO), 16 kB program memory (FLASH) programmable in the system, SPI serial port, USB 2.0 transceiver/controller, A/D converter (10-bit SAR, 200 ksps, 17 multiplexed inputs), 2.44 V voltage reference to the A/D converter, 3.3 V voltage regulator, crossbar that allows to configure each MCU I/O pin function, among others. The MCU package is a kind of 32-pin SMD (LQFP) and was welded in a DIL adapter card (2.54 mm pitch) allowing its use in the breadboard.

The FPAA used in the study was the AN221E04 [4], which internally has: four configurable analog blocks (CAB), six E/S configurable cells (two output specific), 256 byte Look up table (LUT), voltage references, oscillator and configurable frequency dividers, configuration interface, configuration RAM memory (stores the current FPAA configuration), shadow RAM memory (stores the new FPAA configuration), and analog switches (connect any CAB in any I/O cell). There are internally in each CAB the following analog devices: two operational amplifiers, a voltage comparator and eight capacitors, in addition to analog switches that connect these devices. The two RAM memories allows on-the-fly reconfiguration, in which a new configuration may be sent to the FPAA while the current is in operation, and the new one takes place with no FPAA restart required. The AN221E04 has a 44-pin SMD

(QFP) package and was also welded into an adapter to be used in the breadboard.

The FPAA configuration was performed using the AnadigmDesigner2 software tool that provides the analog circuits implemention graphically generating the data file configurations as needed. The circuit creation used the denominated CAM modules, which can implement analog functions such as filters, amplifiers, multipliers, adders, peak detectors, comparators, rectifiers, among others.

The AN221E04 supports two methods to dynamically change the analog circuits configured parameters (gain, cut-off frequency, among others): the algorithmic method and the state-driven method. The algorithmic method uses functions in C (previously generated by AnadigmDesigner2) to create the FPAA data reconfiguration. The state-driven method, previously is generated by the AnadigmDesigner2 a primary configuration file and secondary configuration files. The latter serve to reconfigure only the parameters of the analog circuit defined by the primary configuration.

The wireless communication was implemented using HC-05 module, which is compatible with the 2.0 Bluetooth standard. The MCU and module communication uses a serial interface EIA-232 (TTL levels), set to 9600 bits/s, eight data bits, no parity bit and a stop bit. The module has an integrated antenna and requires a voltage from 3.3V to 6V.

The Smartphone used was the Samsung Galaxy Nexus I9250, which offers the following specifications: dual-core ARM Cortex-A9 CPU with 1.2 GHz clock, 1GB of RAM, 16GB of flash memory, 3.0 Bluetooth compatible with previous versions, Android 4.2.1, among others.

The integrated development environment (IDE) Silicon Laboratories 4.50 was used in MCU programming in C, installed on Windows 8. This IDE allows creating MCU programs for the MCS-51 family using the open-source Small Device C Compiler [9]. The Smartphone application program was held at Juno Eclipse IDE using the Android SDK (Software Development Kit) 4.2.2 (API 17) installed. It is worth highlighting that the Google USB Driver package (Galaxy Nexus compatible) was installed on Eclipse. This package allows applications to be tested directly on the Smartphone via USB cable. It allows the tests using Bluetooth, because the simulator does not originally support this resource.

Figure 1 shows the system constructed block diagram for the ECG signals acquisition, which was first mounted on a breadboard. It can be observed that the system receives the individual signals by 3 electrodes, whereas all the electronic circuit required for conditioning the ECG signal was constructed in FPAA. Through the SPI bus, the MCU performs the FPAA configuration (MCU acts as the master device and FPAA as a slave device), from the data configuration received from the smartphone via Bluetooth. It is worth pointing that the clock signal (100 kHz) the FPAA requires to work was generated by the MCU, using the programmable couter array (frequency output mode).

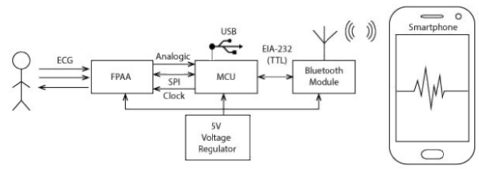

Figure 1 – System block diagram for acquiring ECG signals.

The FPAA amplified and filtered signal is digitized by the MCU A/D converter (8 bits, 480 samples/s, V_{FS} = 3.3V) which transmits the signal to the smartphone via the Bluetooth module. The system works using a 5V source.

The firmware transfer to the MCU used a bootloader, which occupies 5 kB MCU FLASH memory and allows the firmware upload using the computer's USB port and the USBbootloader application installed on an IBM-PC (Windows 8), both provided by the MCU manufacturer. The bootloader firmware was previously recorded on the MCU using the serial EC2 adapter/recorder.

Figure 2 shows the CAMs used and the FPAA internal configuration performed in the AnadigmDesigner2 software.

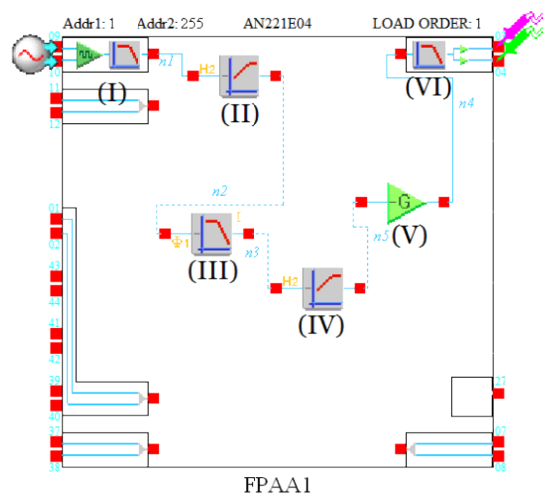

Figure 2 – (I) Input Cell: differential amplifier with low offset (G = 16), bilinear low-pass filter (Fc = 76 kHz); (II and IV) bilinear filter: high-pass filter (Fc = 0.781 Hz), G = 1; (III) biquadratic filter: low-pass filter inverter (Fc = 40 Hz), G = 32.5; (V) Inverter Amplifier: G = -1; (VI) Output Cell: differential output and bilinear low-pass filter (Fc = 76 kHz).

The CAMs (II) and (IV) function is to eliminate the electrodes half-cell potential and OPAMPs offset voltages. The CAM (III) function is to act as anti-aliasing filter. The CAMs (I) and (VI) cut-off frequency was set to the lowest value allowed by the FPAA (76 kHz). The gain is provided by CAMs (I), (III) and (V), the last one can be reconfigured by the smartphone to change the total system gain.

Figure 3 illustrates the developed Android application flow chart.

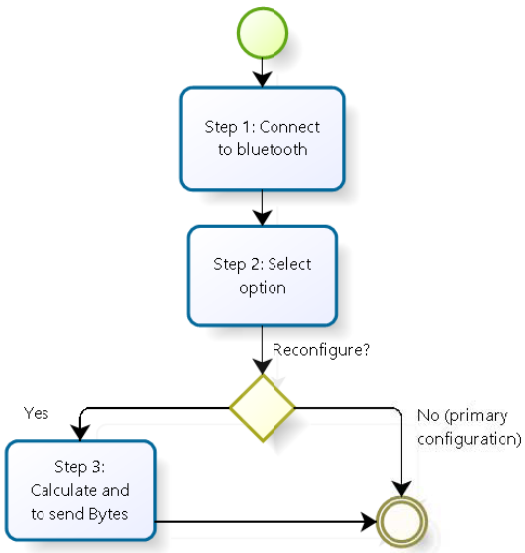

Figure 3 - Initially (step 1), RES-ESA bluetooth pairing. Step 2, the user select on the application if desires to use the primary configuration or reconfigure the FPAA gain. If the reconfiguration is chosen, an algorithm calculates and sends the bytes that change the gain setting of the FPAA. Subsequently, the received data is plotted in real time on the screen.

Results and Discussion

The circuit tests conducted to acquire ECG signals were based on the ANSI/AAMI EC13:2002 [10] recommendations and used the test circuits shown in Figures 4 and 5. The respective tests and results are described below.

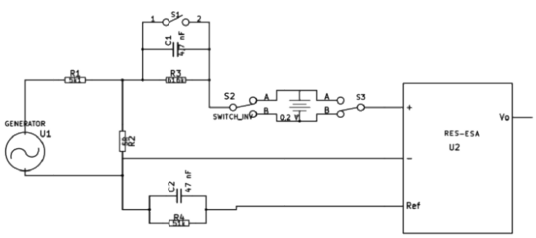

Figure 4 - Diagrammatic model of one of the test circuits used (taken from [10]). The signal from the generator passes through a resistive voltage divider that reduces the amplitude in approximately 1000 times. R4 and C2 simulate the impedance skin-electrode. R3 and C1 are used to estimate circuit input impedance. The 0.2V voltage was generated using a CR2032 battery (3.0 V) and a resistive voltage divider.

Input range and half-cell potential rejection

In this test, the standard specifies that a device must be capable to respond and display voltages ranging from -5 mV to +5 mV. In addition, a +200 mV and a -200 mV tension was injected (simulating the half-cell potential - HCP) in series with the ± 5 mV signal, and a variation in the recorded signal amplitude was registered, which should vary no more than ± 10%. In this test, the signal generator was set to generate a 16 Hz sinusoidal wave and the following settings were used on the Figure 4 circuit, S1 always closed: S2 and S3 in position A (no HCP); S2 in A and S3 in B (with HCP); and S2 in B and S3 in A (with HCP and reversed polarity). It should be observed that it was not possible to use the values specified in the standard to simulate the HCP (± 300 mV), because they saturate the output of the input cell, as its minimum gain is 16 and the output swing is ± 4 V. This was a limitation of the input cell used; however, good Ag-AgCl electrodes present potential around the value used in the test.

Using the data obtained, there were no recorded signal distortions/saturation when the applied sinusoidal wave amplitude was 5 mVp. Furthermore, with HCP, the recorded signal amplitude did not overstepped the acceptable limit of ± 10%. The records average difference with and with no HCP was 0.41 ± 0.19% (α = 99%).

Frequency Response

The frequency response test was performed using two methods, as shown in [10]. In method A, 1 mVpp sinusoid with frequency of 0.67 Hz, 5 Hz, 10 Hz, 20 Hz and 40 Hz were used. The standard requires that the amplitude of the recorded sinusoids come from 0.7A5 to 1.1A5 (A5 is the amplitude of the 5 Hz sinusoidal wave). It was observed, that the amplitudes of the signals recorded in 30 repetitions reached 1.015A5; however, the lower limit was exceeded by the 0.67 Hz frequency reaching 0.63A5, caused by the fact that the high-pass filter has a Fc = 0.781 Hz (minimum possible value), that is, a limitation of FPAA.

Method B used a triangular 1.5 mVpp and 1 Hz signal. For every 10 consecutive cycles with triangle base width of 200 ms, it generated 10 cycles with base width of 20 ms. The standard requires that the recorded signal, the peaks of the 20 ms base triangles must have a minimum range of 75% of amplitude of the 200 ms base peaks. It was found that the 20 ms triangles peaks did not exceed the acceptable lower limit and yielded an average value of 88.6 ± 1.6% (α = 99%).

Noise

According to the standard, the recorded signal noise measurement must not exceed 30 uVpp, when referenced to the input (RTi). To perform this test it was used in a circuit suggested by [10] in which each of the three module terminals was attached to a parallel RC circuit (51 kohms and 47 nF) and connected to a common point (short circuit). It was recorded 10 segments with 10 seconds duration each, and the noise limit must be respected in at least 9 of the 10 segments.

A noise of 67 ± 3 uVpp (α = 99%) was obtained from the tests. However, it should be noted that the circuit was mounted on a breadboard, which is more susceptible to noises due to the length of the wiring connections. Moreover, it was not carried out any detailed analysis of the internal FPAA configuration with the goal to improve this parameter.

Common Mode Rejection

The common mode rejection ratio (CMRR) test, presented the system's ability to reject signals in common mode, as the 60 Hz power grid noise that reaches the body and appears on both system inputs (input+ and input-). The 60 Hz CMRR measurements were applied and recorded two signals: 1.0 mVpp/60 Hz/ differential mode, using the Figure 4 circuit; and 0.4 Vpp/60 Hz/common mode using the Figure 5 circuit. Each record held lasted 60 seconds, the second one was registered with S1 and S2 closed, S1 opened and S2 closed, and S1 closed and S2 opened, in order to simulate an imbalance in the skin-electrode impedance (Figure 5).

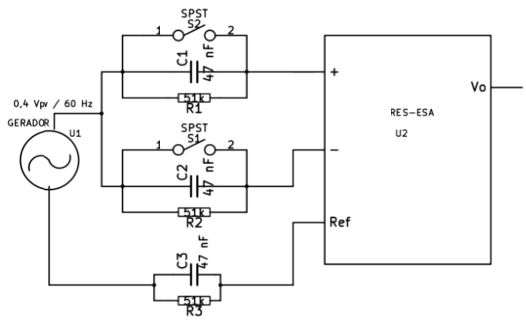

Figure 5 - Schematic diagram of the test circuit used for measuring the CMRR (based on [10]).

Through the analysis of the recorded signals, it obtained the peak to peak voltage for each record and calculated the differential mode gain (G_{md}), common mode (G_{mc}) and the CMRR (CMRR = 20 $\log_{10}$ (G_{md} / G_{mc}). The results were 79.9 dB (S1 and S2 on), 59.4 dB (S1 off, S2 on) and 61.8 dB (S1 on, S2 off).

The standard [10] does not specify values in dB, but the value obtained approximately 60 dB, with unbalance in skin electrode impedance is acceptable, because it indicates that the G_{mc} is 1000 times smaller than G_{md}.

Input Impedance

The input impedance test simulated a skin electrode impedance increase through a 616 kilohms resistor in parallel with a 4.7 nF capacitor connected in series with the positive input (Figure 4). In this test, the recorded signals with S1 opened (Figure 4) should not present an amplitude reduction greater than 20% compared to that obtained without the simulated impedance (S1 closed) within the frequency range from 0.67 to 40 Hz. There was no record that exceeded the 20% limit, with an average reduction of 12.2 ± 2.9% (α = 99%).

Power consumption

The power consumption was measured, disregarding the LEDS electrical currents, using a digital ammeter. The electric current measurement was 88.6 ± 0.6 mA (α = 99%), resulting in an power of 443 ± 3 mW (α = 99%). It should be observed that the FPAA internal circuit configuration optimizations were not performed aiming to reduce consumption. Nevertheless, the consumption obtained was lower in comparison to some other studies using FPAA to acquire bioelectric signals. In study by Mou [3] the system consumption was approximately 12 W (composed of a FPGA development board, a FPAA development board and an LCD screen), whereas in study by Sanches[11], the simulated consumption for electromyogram signal conditioning, FPAA only, was 700 mW. It should be observed that multiple studies [5, 6, 7] did not mention the power consumption.

ECG real signals registration

The test with real ECG signals involved the acquisition of signals in an individual and the DI derivation was used for this (left arm with the positive input and the right arm with the negative input of the system). Figure 6 shows the displayed and stored signal on the Smartphone.

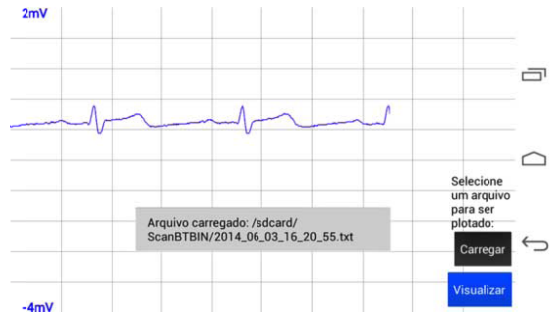

Figure 6 - Real ECG signal recorded in an individual and displayed on the smartphone. This record used the minimum configurable FPAA gain (Total gain = 260).

The signals displayed on the smartphone had a satisfactory reproduction of the real signal captured in an individual, especially considering that the circuit was mounted on a breadboard, a situation that makes it more susceptible to external electromagnetic noise and those generated by the circuit itself (digital part).

Regarding the use of internal FPAA AN221E04 resources, 27 elements were used (56.3%) out of 48 (5 of 8 opamps, 22 of 32 capacitors, none of the 4 comparators and none of the 4 SARs).

Similar smartphone-based systems

The Table 1 shows several existing contemporary systems, displaying the main features of the other smartphone-based systems and the proposed one (RES-ESA).

Table 1– Main Features of the Systems

Name	Description	Price (USD)
AliveCor ECG [12]	Heart monitor with 1-lead (approved by Food and Drug Administration (FDA))	199.00
ECG Check [13]	1-lead, works only on Apple devices (iPhone 4S or newer, iPad 3 or newer, and iPod 5) and approved by FDA.	129.00
Galaxy S5 [14]	Built-in sensor for the heart rate measurement by photoplethysmography.	600.00
RES-ESA	Reconfigurable, 1-lead and low cost.	22.61

Conclusion

In light of the foregoing, it can be noticed that this work successfully used a reconfigurable analog device (FPAA) to capture low amplitude (about 3 mV) ECG signals. The great flexibility offered by the FPAA can be verified with the possibility to reconfigure the amplifiers gain, filter frequency cut-off, filter approximation function and even the signal conditioning circuit. Despite the FPAA advantages, a few studies using FPAA are found about this subject.

The parameters measured in tests (input range, immunity to half-cell potential, frequency response, noise, CMRR, input impedance and power consumption) and the ECG signals quality recorded in an individual were satisfactory. Note that all measured parameters, including the system noise that did not meet the standard, can be improved by optimizing the configured circuit and mounting the entire system on a printed

circuit board. The board has not been manufactured yet, but the layout has already been prepared.

It is possible to view and store the ECG signals in real time on the smartphone Android application and change the total circuit gain, enabling send the data via the Internet to a doctor to examine them later (telemedicine).

The main contributions of this work was the development of a system for acquisition of ECG signals using a smartphone, the development of a reconfigurable system for the acquisition of analog signals, and the creation of Java methods for the Android application to reconfigure the gain of the FPAA via Bluetooth. Comparing this work with others that used FPAAs for the acquisition of bioelectric signals, it can be noticed the following differences: the system developed displays and stores the signals on a smartphone and not only on a desktop computer; the system developed did not use the development board provided by the FPAA manufacturer (high cost); the developed system allows to set the FPAA gain via smartphone in real time; the system sends the recorded data via bluetooth and not only through cables; and the developed system was tested in an individual in real ECG acquisition. It should be noted that no work found allows to view the signals and reconfigure the FPAA on a smartphone.

Some suggestions for future works are: manufacturing the printed circuit board to improve various system characteristics (noise, CMRR, and others); development of a home care system using RES-ESA; analysis of the possible applications and the potential impact on the care delivery loop; use of signal processing algorithms and artificial intelligence on the Android application for QRS detection and heart problems; development and testing new FPAA configurations for other bioelectrical signals acquisition, such as electroencephalogram (EEG) and electromyogram (EMG); use of algorithms for estimation of sleep stages, epilepsy detection, among others; and the development of human-machine interfaces based on bioelectric signals, an area with a lot of attention nowadays.

Availability Communication: Requirements for an Awareness System to Support Nurses' Handling of Nurse Calls

Joakim Klemets[a,b], Pieter Toussaint[a,c]

Abstract

The recent development of mobile technologies allows nurses to receive different types of requests anywhere. However, the interruptions generated by these devices often presents a challenge for nurses in their daily work in a hospital department. In previous inquires we have investigated nurses' strategies to managing technology-mediated interruptions in the form of nurse calls. This study reports on an effort to co-design a system that supports an important strategy employed by nurses. Through the involvement of domain experts, the study elicits requirements for an awareness system to support nurses' collaborative effort in handling nurse calls.

Keywords:

Awareness; Interruptions; Collaboration; Nurse Calls.

Introduction

Nursing work in a hospital department is characterized by complex cognitive work that involves continuous organisation, prioritisation and decision making [1]. Nurses can have multiple clinical and administrative tasks that simultaneously compete for their attention. To manage these challenges in order to provide high quality care, communication among nurses is fundamental [2, 3].

One important aspect of nurses' work is responding to nurse calls. Nurse call systems provide a means for patients to communicate their need of assistance to a nurse. Regardless of how the nurse calls are communicated to the nurse, they are likely to interrupt an ongoing task. This requires the called nurse to assess her availability for the nurse call and perhaps yet again re-prioritise and re-organise work. Therefore, nurse call systems have often been accused to be a source of interruptions that not always are appreciated, as they often disturb ongoing work [4-6]. Interruptions in these environments are also associated with reduced quality of care [7] and patient safety [8].

The intentions behind a nurse call can vary greatly, from toileting assistance or pain medication to information requests [9]. As most nurse call systems do not provide urgency clues, nurses need to decide, with sometimes limited information, whether they should abort an activity to respond to the nurse call or not. A decision that often is regarded as stressful [4, 6].

To date, limited literature exists that describes nurses' handling of nurse calls. Instead, previous research on nurse call systems investigated aspects such as patient satisfaction [10], reasons behind nurse calls [11], and attempts to limit nurse calls [9, 11]. Through ethnographical fieldwork, we previously investigated nurses' strategies in managing interruptions in the form of nurse calls [6, 12]. As a next step, the aim is to discover how a system could be designed to support these strategies.

Nurses assess their availability towards a nurse call based on a number of contextual factors, including their current activity, the relationship to the calling patient and the patient's condition [6]. A strategy employed by nurses to handle nurse calls is to hand over their patient responsibility in certain situations [12]. However, another important strategy identified in our previous studies is maintaining an awareness of colleagues' activities. The decision of whether to respond to a nurse call is highly influenced by this awareness [6].

Therefore, the main objectives in this study were to (1) co-design a system with end-users that supports nurses in maintaining awareness of colleagues' availability, and (2) to analyse the possible effects the proposed system could have on current work. Based on data from our previous studies, we developed a prototype system. The prototype was used as a trigger for further requirement elicitation and analysis in participatory design workshops [13] to achieve the study objectives.

Background

Awareness

Awareness is a central concept within the field of computer-supported cooperative work (CSCW) that is essential when one aims to support efficient coordination and collaboration among team members [14]. The perhaps most commonly used definition of awareness within CSCW is *"...an understanding of the activities of others, which provides a context for your own activity"* [15]. Schmidt discusses the problem that the notion of awareness is indeed ambiguous and that it needs to be understood as a person's awareness of *something* [16]. One relevant example would be activity awareness that is an essential part of collaboration between medical personnel in a hospital. Here, the awareness of colleagues' activities has direct influence on their own activity [17]. Further, Heath et al. discuss how awareness is achieved and sustained through social interaction that involves participants' sensitive monitoring and displaying of actions and activities [16, 18]. A key aspect is that the monitoring and displaying process can occur simultaneously as its own activity, requiring very little effort [19].

There has been extensive research into how technology could support awareness [14]. Within the healthcare domain, one

example is the AwarePhone approach that seeks to minimize interruptions by mediating context cues about the callee to the caller through the phone's address book [20]. The main focus in their study is how the mediated social awareness can enhance collaboration among health care workers who are not co-located. For example, allowing a nurse to consult a doctor more easily. Our focus, however, is to investigate how such an awareness system could be designed to support the handling of a specific type of interruption, that is nurse calls. Nurse calls differ from information requests in the form of phone calls in that the former is expected to be responded to more or less immediately, while that is not always the case for the latter.

Activity Awareness to Support Nurse Call Handling

A few years ago a new, wireless nurse call system was deployed at a Norwegian university hospital. The system allows patients to issue a nurse call by using a draw-string mounted inside each patient room. The signal is then delivered to nurses on both public displays and on wireless phones carried by the nurses. A call plan allows nurses to configure to which nurse a nurse call should be delivered first. If the primary nurse is not able to respond to the call, it can be forwarded to the next nurse. Nurses usually configure the call plan according to agreed patient responsibility. By doing so nurses' receive nurse calls on the wireless phone from patients they have the primary responsibility for first [12].

Through observations and workshops, we investigated nurses' strategies to handle nurse calls at the hospital where the above system was deployed [6]. The findings report a number of contextual factors that play a role in nurses' decision whether to respond to a nurse call in a busy situation. An important factor, however, is their awareness of colleagues' activities.

Nurses continuously monitor colleagues' activities as well as their own, in order to know who is available. Knowing that someone is available when, for example, situated in a patient room talking to an anxious patient, allows the nurse to remain focused on the task at hand, trusting that a colleague will take care of the call. Similarly, nurses prioritize their own activities based on their awareness of colleagues' activities. For example, if a nurse is aware of that his or her colleagues are busy and unable to respond to nurse calls, the nurse may not undertake an activity that will make him or her unavailable as well. Rather, the nurse chooses to remain available in order to act as a backup in responding to nurse calls for the other nurses [6].

However, it is not always the case that nurses are able to monitor colleagues or display their own activities. Nurses report that sometimes a patient visit can take an unexpected turn. In these cases, when nurses normally have not told anyone about the prolonged stay, it might be that no one is able to respond to nurse calls [6].

Methods

Research Design

To meet the first objective, to co-design a system with domain experts, participatory design workshops were held. To trigger discussion, and to demonstrate to the participants technological possibilities, a prototype was developed [21]. The prototype system allowed nurses to communicate their availability status through the wireless phone, as well as, become aware of colleagues availability when a nurse call was issued.

Mogensen and Trigg discuss how artefacts can be used to foster analysis of both current and future practice in participatory design workshops [13]. Scenarios were designed for the workshop where the prototype was used to address the second objective, to analyse possible effects of the designed technology.

Two workshops were held with nine female student nurses from five different hospital departments. All participants had at least one month of experience working at the hospital and using the wireless nurse call system. The workshops were held in a usability lab furnished as a hospital ward and videotaped to facilitate detailed data analysis afterwards. Each workshop lasted for about three hours. After an initial focus group interview, the workshops also included a role-play session, before allowing participants to reflect on their experience with the prototype in another focus group interview.

The scenarios for the role-play session were based on our previous observational studies of the system at the hospital. The scenarios aimed to replicate tricky situations where the acting nurse had to decide whether or not to abort the current activity in order to respond to a nurse call. Participants were instructed to use the prototype in the scenarios. The methodology applied was also influenced by scenario-based design, often employed in the design of collaborative systems [22], and the use of role-play in the design of mobile systems [23].

Prototype

The prototype was developed using a conceptual user interface design tool. The prototype was deployed on an iPhone and allowed users to interact with the application's different screens and menus. However, as the prototype only implemented the user interface, it was not possible to send messages between the phones. Additionally, the application did not receive nurse calls. Therefore, we configured the phones to display a nurse call before the scenario (Figure 1). Then, during the scenario, one of the researchers would play a sound that indicated that the acting nurse received a nurse call.

Figure 1 - Colleagues' statuses are displayed on the phone when a nurse receives a nurse call

In addition to displaying the room number from where the call was initiated, the prototype also displays the availability status for each colleague in the ward. The nurse can then use this information in deciding whether to reject ("avvis") or accept the nurse call ("ok"). Through the user interface, nurses can set their availability status to: available (green), busy (yellow), or unavailable (red), as illustrated in Figure 2. The idea was that a nurse could use the green indication when not occupied with anything important and is able to respond to nurse calls. Yellow indicates that the nurse is busy, but that the task is not of the highest importance. The red indicator communicates that the nurse is undertaking an important task that the nurse would not like to forsake.

Figure 2 - Nurses can be choose from three different availability statuses

Results

Availability Monitoring

When presented with the prototype, nurses' initial reactions were very positive. A nurse reflected: *"That's clever, then you see whether someone can respond to it or not, or if you have to assess responding to it yourself"*. The nurses explained that in a situation where they are occupied with another task, it relives the decision making process if they know that there are other colleagues who can respond to the call, but also that this enhanced awareness of their colleagues' availability could alter their decision to engage in an activity in order to remain an available resource. A nurse explained: *"if I see that many have set themselves to busy I would have waited, it would have been great to have an overview really"*.

This resonates with nurses' current practice of monitoring their colleagues' activities and availability [6]. The nurses reported trying to keep each other informed about activities they undertake. However, as a nurse stated, it is impossible to know where everyone is all the time. For example, nurses said if they are just bringing something from a different floor they do not tell anyone about it. They also admit that it is more difficult to keep track of colleagues' activities while inside a patient room.

Availability Displaying

Being able to display ones' availability through the system to colleagues in times where it would have otherwise been tricky to do so, was seen as a benefit. According to the nurses, this would allow them a higher degree of focus on the task they are performing. A nurse said: *"It would have been useful to be able to give a notice (.), or to lock ones phone (.), so that when you're in a situation that is difficult to leave (.), that some of your responsibility of responding to nurse calls is taken away if there are others who are able to respond during that time"*.

In the focus group discussions, nurses expressed uncertainty in how to set ones' availability status in different situations. The prototype allowed nurses to set their availability to green, yellow, or red. But, it was far from clear in what situation a nurse's availability would be set, for example, to yellow or red. When discussing how the system should behave when different statuses were set, no nurse wished to make themselves completely unavailable (or unreachable) in any situation. They rather wished to indicate that they are occupied at the moment but not completely block incoming requests. While discussing a scenario where the acting nurse was visiting an anxious patient, a nurse said: *"I would never had set myself as unavailable – that is completely unavailable, no, because if the others are busy with various things that they can't leave, then I'm able to leave a patient who is a bit anxious if I explain myself and ask if I can leave for just two minutes"*. Hence, nurses wished to remain in the "loop" even when occupied to remain aware of what was going on outside. As a nurse told: *"You can't remain an overview [of what is happening] if you're completely unavailable or blocked"*. Especially at night shifts, were there are fewer nurses working, it important that nurses are notified about a nurse call even while "unavailable". A nurse explained: *"during the night for example (.), it isn't possible (.), then you are usually alone at the bed area (.), perhaps together with an assistance nurse"*.

One concern the nurses voiced was the extra work maintaining their status would require. Although they saw the benefit, they were afraid it would not be used or that they would forget to change their statuses. Therefore, they suggested the status of a nurse should be changed automatically whenever he or she enters and leaves a patient room. Further, it was proposed that there should be a timer, which would remind the nurses to change their availability back to green after some time.

Adaptive Notification Profile

In the deployed system at the hospital, when a nurse call is issued, nurses are notified through wall panels and the wireless phone. The wall panel where a nurse has marked his or her presence displays the room number and makes an alarming sound. The wireless phone also plays a ringtone when a nurse call is received. The wireless phone at the hospital is configured so that nurses are not able to turn the volume of the ring signal below a certain level.

In the focus group discussions it was evident that the nurses did not appreciate the rigid notification scheme. Nurses felt the ringing was too excessive, especially inside a patient room. A nurse said: *"Inside the room it is quite quiet so you don't need to have such a severe sound"*. Similarly, a nurse expressed that *"there is no point in having alarms both on the phone and on the wall"* inside a patient room. Nurses said the many alarms made it more difficult to focus on the patient they were caring for.

Instead nurses propose that the notification should be modified according to their availability status. A vibration, they explain, would be enough to make them aware of a nurse call in situations where they, for example, are busy with another patient. However, if a nurse call is not responded to by anyone after some time, nurses suggested the notification could become more persuasive. Another nurse proposed that the time the calling patient had waited for a response could be displayed together with the notification.

System Interaction and Feedback

After having forwarded a nurse call, nurses explained that the calling patients do their thoughts, making them wonder whether the patient received help or not. As this further takes some of their attention away from their current task, they said that they would wish to receive feedback, after having dismissed a nurse call, as to whether someone else responded. A nurse proposed that the room number displayed on the wall panel could change colour when a nurse confirmed that he or she will respond to the call. Another nurse confirmed: *"Yes, a type of confirmation that tells you that the nurse call you forwarded has been responded to"*.

Further, the nurses proposed that feedback should be provided to the patient that someone is on their way. The current system does not provide any information to the patient about whether a nurse has noticed their request.

During the focus group interview the nurses explained that the phones are badly suited for sterile environments and the phones should not be exposed in these situations. A badly designed user interface, which required too much attention, was also mentioned as a reason why the phones were not used. The nurses felt that interacting with the phones took too

much focus away from, for example, a visited patient. When asked how they would like to be notified about a nurse call, a nurse explained: *"To have a look at the wall-panel is not as disruptive as to pick up and look at the phone"*. Instead nurses preferred to use the wall-mounted displays to learn about a nurse call and to respond to them. It was suggested that colleagues' availability status should be displayed on public displays, to make the information accessible "at-a-glance". A nurse said: *"I think that the proposal made was very good, that the sound is turned off, and that you instead see it on the wall-panel"*.

Expected Effects

One expected effect of the new functionality the nurses discussed was that it would allow them to more fully focus on the patient they are nursing if they knew there were others available to care for a calling patient. The nurses explained that if they are aware a colleague is able to respond to a nurse call, they then do not rush away from the patient as quickly as they would otherwise.

Further, they expected the availability awareness to reduce the wait-time for patients. Although the nurses said the current system works as it is, the proposed functionality would make it more effective. A nurse explained: *"With the new functionality it would probably be more efficient and faster, five minutes for us seems like nothing, but for the patients it probably feels like forever"*. If the nurses know their colleagues are unavailable, there is no need to let the nurse call keep calling to find out whether someone is able to respond.

Similarly, nurses revealed that, even if they are not busy with something, they sometime hesitate to respond to a nurse call from a patient that is not their assigned responsibility. A nurse explains: *"It is best for the patient to be [in] contact with the same nurse as much as possible, so if she isn't busy there is no reason for me to go in there, otherwise you could just enter any room at any time"*. However, if the primary nurse for the patient is not responding and cannot be seen, nurses said they do respond to the call. Providing quick access to information about the primary nurse's availability status could therefore also reduce response times to nurse calls.

Summary of Proposed Functionalies

The following list summarizes the additional functionalities to the proposed awarenss system that were suggested by the nurses during the workshops.

- Nurse calls should not be blocked even if status is set to yellow or red so nurses can remain aware of what is going on in the department
- The notification for nurse calls should be modified according to set availability status and for how long the calling patient has waited
- Status should be set automatically when entering or leaving a patient room
- A timer should remind the nurses to update their status if it has been set to yellow or red
- Allow nurses to interact with wall mounted displays instead of the phone (monitoring and displaying availability)

Discussion

A concern raised during the workshop was the extra work required in maintaining ones' status, which also was mentioned as an issue in [20]. While the proposed solution to update the status automatically based on location is appealing, there is reason to be cautious when building context-aware applications [24]. Brown and Randell argue for a defensive use of context that allows users to easily correct the system when it makes an erroneous inference [25]. The system could well infer a nurse's availability based on the location, but make this inference flexible. For example, the system could automatically set the nurses status to busy (yellow) when entering a patient room. At the same time, this selection could be displayed on the wall panel inside the room and allow the nurse to change the status by pressing either a green or red button on the wall panel.

As both monitoring and displaying of co-located colleagues requires barely any effort [18, 19], the difficulty is to achieve the same awareness when designing a system to support spatially distributed team members [14]. Some degree of automatic inference of availability helps at the displayer's side, but it is important to not overload monitor with too much information, as Gross discusses [14]. In their paper, Avrahami et al., demonstrate how people often over- and under-estimate the significance of various cues when estimating the interruptibility of a person. In their study, contextual variables such as whether a person was on the phone, drinking, reading, or socially engaged were included. Similarly, another study found that people use contextual cues to merely find out whether a person is present, rather than assessing whether the person can be interrupted or not [26]. While the cues included in these two studies were more related to typical office work, it does raise the question whether such cues are beneficial when estimating whether a person can be interrupted or not? The main rationale to merely display a colour code is to lessen the effort required by the one monitoring. However, whether such an indication is correctly estimated is not addressed in this study.

With regard to system interaction, the results hint that the nurses do not prefer to pick up the phone when a nurse call is issued. Therefore, one alternative could be to present the number of available nurses along with the nurse call on a wall panel. Further, the availability information could be made easily accessible on a big screen in the hallway. Allowing nurses to change their status on the publicly available screen might also provide advantages over doing so through the wireless phone in form of reduced effort.

Scholars have argued for the need of user-centred design approaches in the development of technological systems within the healthcare domain [27, 28]. Participatory design has previously been used in the design of nursing tools [29], and a similar method was adopted in this study. The approach, which combined artefacts in the form of scenarios and a prototype, was found to stimulate participants to come up with ideas on how to design the system; system features that maybe participants would not have been able to envisage otherwise. The prototype, although an early version, allowed the participating nurses to widen their technological frame of reference [30].

The artefacts also trigged analytical discussions on the expected effects of the proposed awareness system. A short summary of these would include; faster response times to nurse calls, less noise, and allow the nurse to remain more focused on the patient. Both the reduced response time and the notification modification based on status, contributes to less noise in a department. Less noise means that nurses can better focus on their work. Also, knowing that someone else is able to respond to an issued nurse call allows nurses to more fully remain focused on the current task.

A study limitation is that all participants were nurse students with limited experience. However, the initial prototype was designed based on a thorough study of nurses work practices that included both observations and workshops with experienced nurses [6]. Another limitation is the relatively small sample size. Yet, in usability studies, for example, there is no consensus of an optimal number of participants [31]. Some advocate that five is enough, while others suggest around ten participants [32], or even more [31].

Conclusion

Through a particpatory design approach, this study has investigated how an awareness system could be designed to support nurses' handling of nurse calls in a hospital setting. Requirements for a system that is sensitive to and communicates availability information of nurses has been elicted. Further, through co-analysis with domain experts, expected effects of the co-desiged system hints at increased focus on current tasks, reduced noise, and faster response times to nurse calls.

Acknowledgement

The authors would like to thank Monika Grimstad Hafredal and Veronica Sund for their help in planning and conducting the workshops, as well as making the prototype.

Abstract

The Tailored Lifestyle Change Decision Aid (TLC DA) system was designed to provide support for a person to make an informed choice about which behavior change to work on when multiple unhealthy behaviors are present. TLC DA can be delivered via web, smartphones and tablets. The system collects a significant amount of information that is used to generate tailored messages to consumers to persuade them in certain healthy lifestyles. One limitation is the necessity to collect vast amounts of information from users who manually enter. By identifying an optimal set of self-reported parameters we will be able to minimize the data entry burden of the app users. The study was to identify primary determinants of health behavior choices made by patients after using the system. Using discriminant analysis an optimal set of predictors was identified. The resulting set included smoking status, smoking cessation success estimate, self-efficacy, body mass index and diet status. Predicting smoking cessation choice was the most accurate, followed by weight management. Physical activity and diet choices were better identified in a combined cluster.

Keywords:

Decision Support Systems; Self-Management, Statistical Analysis; Consumer Behaviour.

Introduction

Health behaviors play a significant role in maintaining optimal health and preventing chronic health conditions. Information technology has great potential in promoting healthy behaviors in the general population [1-2] and for people with chronic conditions [3-4]. A variety of mobile applications have been introduced to modify health behaviors [5] including mobile smartphone applications [6] and web-based platforms [7].

Decision-aids designed to incorporate patient preferences into health decisions have been shown to facilitate patient-centered care [1]. We designed the Tailored Lifestyle Change Decision Aid (TLC DA) system to provide support for a person to make an informed choice about which behavior change to work on when multiple unhealthy behaviors are present [8]. TLC DA can be delivered via multiple health communication channels including web, smartphones and tablets. The system collects a significant amount of information, which is used to generate tailored outputs to consumers in order to assist them in choosing a health behavior to modify.

One of the current limitations of the system is the necessity to collect vast amounts of information from users who have to manually enter all required data. The acceptance, scalability, and ease of use of the mobile app can be significantly improved if we were able to minimize the number of self-reported parameters collected from users at the initial introduction of the app. In this project we aimed at identifying the most important parameters defining health behavior choice in users of the TLC DA using discriminant analysis. By identifying an optimal set of self-reported parameters we will be able to minimize the data entry burden of the app users. Decision support based on a model that can forecast health behavior choice can help further minimize the amount of self-reported data collected. Currently, factors that determine behavior choices by TLC DA users are unknown. The main goal of this study was to identify primary determinants of health behavior choices made by patients after using the TLC DA system.

Methods

System Design and Data Collection

TLC integrates clinical data elements (height, weight, waist circumference, total cholesterol, HDL cholesterol, systolic and diastolic blood pressure, diabetes diagnosis) with patient assessment data to run its decision logic for the tailored outputs [9]. Patient assessment consists of five standardized questionnaires pertaining to 1) diet, 2) weight 3) physical activity 4) tobacco use and 5) psychosocial issues. For each of the four behaviors, we also assess the level of engagement in the unhealthy behavior (i.e., number of cigarettes smoked and level of nicotine dependence) as well as the patient's transtheoretical stage of change for improving the behavior and self-efficacy in their ability to sustain the behavior change. The patient output report contains four components: 1) behavioral risk and clinical risk; 2) readiness and confidence scores for changing each of the four behaviors; 3) qualitative equations to elicit patient priorities for change and 4) an action plan to affirm their behavior change priorities and goals. The readiness and confidence of the individual for each behavior is combined to present chance of success for each behavior. This allows the patient to contrast chance of success (readiness + confidence) against the level of health benefit the patient would achieve if they elect to work on that specific behavior. For example, whereas quitting smoking would produce the highest health benefit, the patient would also have a lower chance of success in quitting at this point in time (Figure 1). On the other hand, although physical activity would produce a lower benefit, the patient would also have the highest chance of success of including physical activity into their lives. Patients are asked to choose a behavior to work on as they consider level of risk and chance of success for each of the unhealthy behaviors they engage in.

Eighty consecutive adults (45 females and 35 males) participated in the study. Participants were recruited via telephone and at community centers, fairs, and other public places and were eligible if they where English speaking, between the ages of 18 and 70 and had no counterindications for engaging in a lifestyle modification progam.

Analysis

Baseline patient characteristics were represented by 45 variables reflecting their age, blood pressure, body mass index (BMI), smoking status and behavioral characteristics associated with behaviors of choice.

The study subjects were grouped based on their choice of health behavior after using the decision aid to corresponding categories including "Physical Activity," "Diet," "Weight Management," and "Smoking". Detailed characteristics of these variables were described previously [10]. Stratified analysis based on patient choice has been performed.

All statistical analyses were performed using IBM SPSS Statistics 22. Group statistics were conducted to examine the overall means and standard deviations of 45 independent variables for four patient's behavior categories. Cross-correlations of group variables were investigated by bivariate correlation analyses. Discriminant analysis was conducted 1) to find the best variable set that determines choice of health behavior; 2) to compose discriminant functions based on linear parameter combinations; and 3) to build a predictive model determining most likely choice of health behavior patients decide to adapt after using a computer-mediated decision aid. To achieve this, a stepwise analysis was carried out, specifically Wiks' lambda method was used.

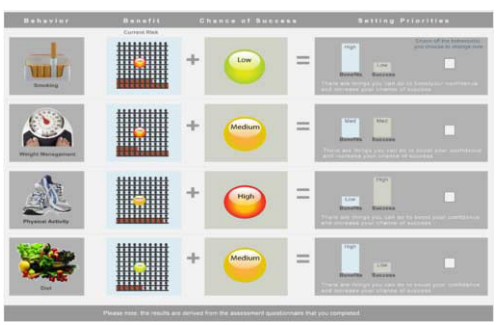

Figure 1 – Tailored Lifestyle Counseling (TLC) System

Results

Group Statistics and Correlations

The means and standard deviations of 45 baseline variables were calculated for each of the four patient behaviors. All nominal variables were converted into ordinal variables for the purpose of this analysis. The study subjects were grouped based on their choice of health behavior after using TLC to corresponding categories including "Physical Activity," "Diet," "Weight Management," and "Smoking". For each group average characteristics were calculated as presented in Table 1.

Bivariate correlations between each "Physical Activity" group variables ranged from -0.236 to 1.000 as can be seen in Table 2. "Diet," "Weight Management," "Smoking" group variables correlations were ranged from -0.620 to 1.000, from 0.290 to 1.000, and from -0.566 to 0.961 respectively as shown in Tables 3, 4 and 5.

Canonical Discriminant Functions

To discriminate a priori defined categorical groups ("Physical Activity," "Diet," "Weight Management," and "Smoking"), a stepwise discriminant analysis was performed. At each step, the parameters that minimized the overall Wilks' Lambda were entered. The maximum number of steps was 90, entered

independent variables were S Status, BMI, S Success, S Soc and D Status, and the other 40 independents were eventually removed. In the resulting model, S Status had 0.744 of tolerance, 55.536 of F to Remove and 0.583 of Wilks' Labda, BMI had 0.808 of tolerance, 9.481 of F to Remove and 0.246 of Wilks' Lambda, S Success had 0.069 of tolerance, 9.578 of F to Remove and 0.246 of Wilks' Labda, S SoC had 0.075 of tolerance, 7.188 of F to Remove and 0.229 of Wilks' Lambda, D Status had 0.932 of tolerance, 4.322 of F to Remove and 0.208 of Wilks' Labda, and the model made by these 5 parameters had 11.632 of F to Remove and 0.176 of Wilks' Lambda as shown in Table 6.

As the result of this analysis, three canonical linear discriminant functions were generated to calculate Function 1, Function 2 and Function 3:

Function 1 = 1.060 S Status – 0.085 BMI + 4.779 S Success - 0.893 S SoC + 0.057 D Status – 8.131

Function 2 = 0.288 S Status + 0.094 BMI – 1.335 S Success + 0.488 S SoC - 0.256 D Status + 0.641

Function 3 = 0.145 S Status + 0.095 BMI - 3.184 S Success + 0.437 S SoC + 0.147 D Status + 2.815

The eigenvalues of Function 1, 2 and 3 were 2.989, 0.300 and 0.095 respectively. The proportion of discriminating abilities of the Function 1, 2 and 3 were 88.3%, 8.9% and 2.8% respectively. The canonical correlations of Function 1, Function 2 and 3 were 0.866, 0.480 and 0.295 respectively as shown in Table 7.

Classification Statistics

The classification was processed for all 82 patient variable sets, that included 25 sets of "Physical Activity," 23 sets of "Diet," 21 sets of "Weight Management," and 11 sets of "Smoking," and the prior probabilities were set for all groups equal. As shown in Figure 2, the group centroids (Function 1, Function 2) of "Physical Activity," "Diet," "Weight Management," and "Smoking" were (-0.968, 0.395, 0.346), (-0.726, 0.278, -0.428), (-0.232, -0.889, 0.040) and (4.162, 0.216, 0.031) respectively.

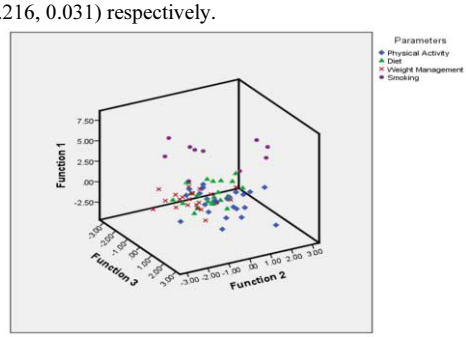

Figure 2- Canonical Discriminant Functions

The classification results are shown in Table 8. The classification success was assessed using original and cross-validated modes in case of our data sets did not differ. Percentage of correct and incorrect classifications was based on the generated Function 1, 2 and 3. Sixty-four percent of "Physical Activity" observations were classified correctly as "Physical Activity", but the remaining cases were incorrectly classified as "Diet" (24%) and "Weight Management" (12%). "Diet" observations were correctly identified 56.5% of the time as "Diet" but 26.1% were misclassified as "Physical Activity" and 17.4% as "Weight Management." "Weight Management" observations were correctly classified 85.7% as "Weight Management" but 4.8% were misidentified as the other behaviors. In cross-validation each case was classified by the functions derived from all cases using the leave-one-out method. There was difference in predicting patient's behavior between the original validation and the cross-validation (Table 8). Original classification estimates yielded overall 71.3% of correctly classified cases using Function 1, 2 and 3 generated by discriminant analysis. Cross-validation resulted in 72.7% correct classification results for the "Smoking" category, 66.7% - for the "Weight Management" category, and 75.5-86.6% - for a combined group of "Physical Activity" and "Diet."

Correlation is significant at the 0.01 level (2-tailed).

Discussion

Using discriminant analysis an optimal set of independent predictors was identified that determined behavioral choice of users of a computer-mediated decision aid. The resulting set included smoking status (S Status), success estimate in smoking cessation (S Success), smoking self-efficacy (S SoC), body mass index (BMI) and diet status (D Status). Prediction of smoking cessation choice was the most accurate, followed by weight management choice. Physical activity and

diet choices were much better identified in a combined cluster (76%-87%) indicating decisions about these two behaviors were identified by the same variables and the variables that could separate them may have been missing from the dataset. Presence of variables related to individual risks and levels of success in accepting certain health behaviors in the final set of predictors confirmed significance of the computer-mediated decision aid that presented these very variables for user consideration via the TLC DA system. The TLC DA system was instrumental in assisting patients in making informed heath choices. The resulting minimized parameter set can significantly improve user experience by minimizing the amount of information they must manually enter.

Conclusions

Unhealthy behaviors are the most prevalent, preventable and reversible causes of death in the United States [14,15]. They are leading causes of death from cardiovascular disease, cancer and stroke [14]. Physical inactivity and poor diet may have overtaken smoking as the chief preventable mortality risk [12, 13]. Modifiable non-tobacco risk behaviors account for roughly one-third of cancer deaths [16,17]. Additionally, fruit and vegetable intake and physical activity are thought to be independently protective of heart disease [18,19].

The TLC DA differs from previous technologies designed to modify health behaviors. It provides the *opportunity* for choice, rather than an *obligation* to adhere to an assigned regimen. When people perform tasks out of obligation, they subsequently show poorer self-regulation as compared to people who performed comparable tasks that they had chosen themselves [11]. Based on self-determination theory [12, 13], providing a context for making an *informed choice* about which behaviors to change will enhance autonomous motivation and self-efficacy, and result in higher rates of lasting change compared to assigning people specific behaviors to change. Since the average adult practices more than one unhealthy behavior [20], this creates the possibility of intervening comprehensively, efficiently, perhaps even synergistically on multiple risk behaviors simultaneously. To our knowledge, no one has determined predictors of behavior changes people would choose when not constrained. In order to make behavior change research more patient-centered, this is a necessary step.

Towards an Ontology-driven Framework to Enable Development of Personalized mHealth Solutions for Cancer Survivors' Engagement in Healthy Living

Sahiti Myneni, Muhammad Amith, Yimin Geng, Cui Tao

University of Texas School of Biomedical Informatics at Houston, TX, USA

Abstract

Adolescent and Young Adult (AYA) cancer survivors manage an array of health-related issues. Survivorship Care Plans (SCPs) have the potential to empower these young survivors by providing information regarding treatment summary, late-effects of cancer therapies, healthy lifestyle guidance, coping with work-life-health balance, and follow-up care. However, current mHealth infrastructure used to deliver SCPs has been limited in terms of flexibility, engagement, and reusability. The objective of this study is to develop an ontology-driven survivor engagement framework to facilitate rapid development of mobile apps that are targeted, extensible, and engaging. The major components include ontology models, patient engagement features, and behavioral intervention technologies. We apply the proposed framework to characterize individual building blocks ("survivor digilegos"), which form the basis for mHealth tools that address user needs across the cancer care continuum. Results indicate that the framework (a) allows identification of AYA survivorship components, (b) facilitates infusion of engagement elements, and (c) integrates behavior change constructs into the design architecture of survivorship applications. Implications for design of patient-engaging chronic disease management solutions are discussed.

Keywords:

Cancer survivor; Healthy lifestyle; Patient engagement; mHealth; Ontology.

Introduction

The term "cancer survivor" refers to an individual who has been touched by cancer, right from the time of diagnosis, beyond the treatment, through the balance of one's life [1]. The definition also includes family members, friends, and caregivers in addition to the patient, given the way cancer to a loved one can affect their lives. Recent estimates suggest that there are 14.5 million cancer survivors in the United States (US), and the projected numbers indicate a five million increase in the next decade [2]. Worldwide estimates of cancer survivors were 28.7 million in 2008 [3]. However, this reflects only the individuals within five years of diagnosis. In 2006, the Institute of Medicine's landmark report on cancer survivorship highlighted key gaps in the existing care delivery infrastructure and provided several important recommendations for quality survivorship care to this growing population [4]. Cancer survivorship broadly refers to cancer-related physical and psychological issues, lifestyle after treatment such as returning to work, follow-up care, and prevention of secondary malignancies. Survivorship Care Plans (SCPs) provision to every patient is seen as a major step forward in facilitating the care transition from specialists to primary care physicians. These plans can form a communication bridge between physicians and survivors to ensure care quality and continuity, and also act as engagement tools that empower patients to self-manage care.

However, developing a SCP is complex, and a single form cannot address the changing needs of the survivors. The SCPs need to be comprehensive, yet uniquely patient-specific depending on type of primary cancer, age of diagnosis, current age, age-specific late effects of cancer, availability of familial support. In the global context, other aspects including, but not limited to, health beliefs, religious beliefs, and cultural context need to be considered when developing an SCP [5]. Particularly, Adolescent and Young Adult (AYA) cancer survivors' needs demand special attention given the unique circumstances surrounding their survivorship and ever-changing scenarios of life [6]. An AYA survivor's context of survivorship is dynamic given their transition from adolescence to adulthood, physiological and psychological growth, self-identity, separation from parents/family, career pursuits, and involvement in intimate relationships [7]. Therefore, engaging an AYA cancer survivor in health management involves the design of a multi-component solution, where the modules comprising the solution can be used across the care continuum based on patient-specific personalization attributes. Harnessing contemporary technology platforms such as online social media, mHealth applications allow us to generate cancer survivor engagement tools that are cost-effective, ubiquitous, and scalable. In this paper, we provide a novel methodological framework to enable the design of comprehensive and personalized mHealth solutions to engage AYA cancer survivors in healthy living. The framework utilizes ontology to integrate the Patient Engagement Framework (PEF) [8] and Behavioral Intervention Technology (BIT) Model [9] to develop survivor digilegos, which we consider as building blocks of mHealth solutions for AYA survivorship. The unique features of these digilegos are their reusability and customization abilities according to the survivor care context. These digilegos can be put together to build mHealth solutions that are flexible and extensible, yet comprehensive.

Research shows the use of ontology for the design of mHealth applications with a patient-centered focus, specifically for the purpose of self-monitoring [10-12]. Ontologies are suitable for storing and retrieving semantic information, or expressive knowledge, in machine-readable format [13].This information in the ontology can be used to evoke rule-based machine intelligence and decision-making provided through intrinsic reasoning capabilities and querying [14, 15]. Subsequently, PEF acts as a bridging tool to identify opportunities that can help translate the knowledge abstracted within the survivorship ontological representation to engagement elements of a consumer-centered application. Finally, the BIT model allows us to conceive and instantiate the survivor digilegos as technological constituents of the intended

mHealth solution. In the next sections of the paper, we describe the framework components along with illustrative examples demonstrating its application to the domain of AYA cancer survivorship. Specifically, we focus on facilitating the development of mobile apps that engage AYA cancer survivors in follow-up care and healthy living through the digilego components.

Methods

Figure 1 provides a high level representation of our proposed survivor engagement framework. The three main components are (1) Ontology Modeling, (2) Engagement Elements and Opportunities, and (3) Digilegos development using the BIT model.

Ontology Modeling: We constructed an application ontology called "Profile Ontology for Cancer Survivors" (POCS) to model and store knowledge of the patient's after-treatment care plan. The model was sourced from Long-Term Follow-Up (LTFU) guidelines put together for AYA survivors by the Children's Oncology Group. The current draft of the POCS was built on top of the Friend of a Friend (FOAF) ontology model [16], which supported basic profile information of users and agents and also provided a template for associated documents, specifically the cancer survivor plan and its related information. The initial iteration of POCS was authored using Web Ontology Language (OWL), which is a W3C standard ontology language that supports standard knowledge representation and semantic reasoning [17], and was edited with Protégé, which is an open-source, commonly used ontology editor [18].

Engagement Elements: PEF has been developed by Healthcare Information and Management Systems Society (HIMSS) through cumulative layering of five phases- "inform me," "engage me," "empower me," "partner with me," and "support my e-community." A total of nine features have been specified at the highest engagement level, including 'information and way-finding', 'e-tools', 'forms', 'patient-specific education', 'patient access and use', 'patient-generated data', 'interoperable records', 'collaborative care and community support' [8]. This framework was used in our study to sketch the functionality of mHealth infrastructure that potentially facilitates the adoption of SCPs, self-management, goal setting and reinforcement, peer support, and patient-provider communication. A mapping process was conducted to identify the engagement features that could be used to operationalize the POCS ontology classes. The ontological representations derived in the previous step allowed us to understand the characteristics of the information that should be delivered to the user through PEF features. We also specified the level of intended survivor engagement to characterize granularity and complexity of the system features.

Digilegos Development: We used the BIT model to conceptualize digilegos (which are individual and reusable ontology-driven mHealth components) to delineate the operational aims, identify behavior change strategies (where applicable), define user interactions, and outline technical aspects for real-time implementation [9]. The BIT model was originally proposed to develop behavioral interventions, however all digilegos did not have a behavioral component associated with them. For the non-behavioral ones, we still used the BIT model to ensure workflow alignment and smoother interfacing among all the digilegos. Certain digilegos were conceived to be integrated with advanced query and reasoning capabilities of POCS (see Figure 1). In the next sections, we describe the application of the proposed framework to develop AYA survivor digilegos using illustrative examples. Such compartmentalized design architecture of the survivor digilegos allowed us to facilitate customization, harness machine-based querying, integrate engagement tactics, and adopt theory-driven techniques that ultimately enable the development of user-empowering flexible mHealth tools that can be used across the cancer care continuum. Further, the workflow for each of the components has been set toment levels,vors to better mange stress as partof ed the constr

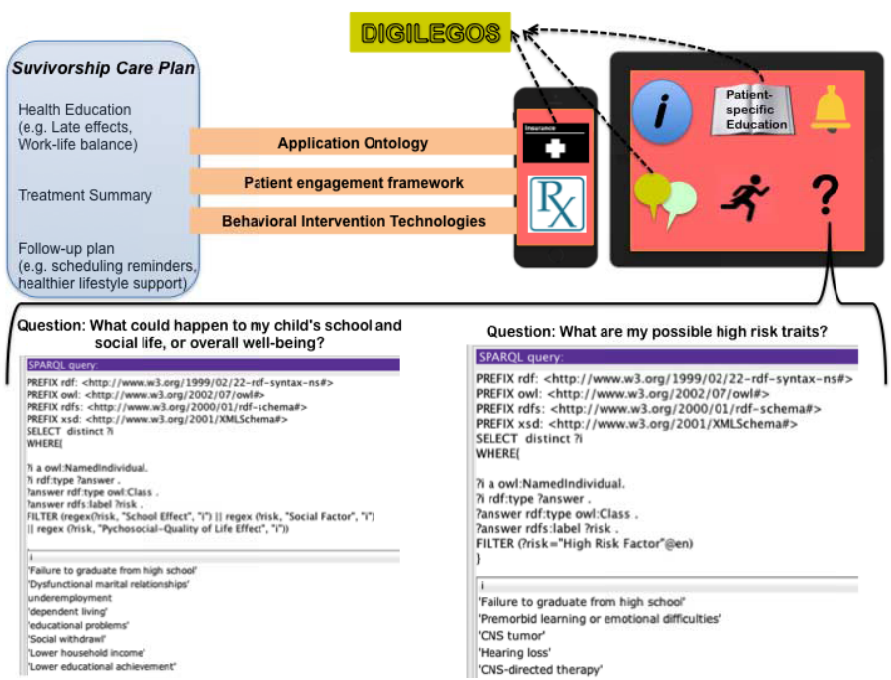

Figure 1- Proposed Survivor Engagement Framework for Development of Personalized mHealth Solution

Results and Discussion

Ontology Modeling: Figure 2 provides a general overview of POCS meta-level ontology. Information abstracted in POCS included end-user's personal information (e.g .marital status, age, gender), the patient's treatment information (complications, treatment type, follow-up schedules, late effects, etc.), and details of personal primary physician and related medical professionals. Initial metrics of our current draft include 58 classes and subclasses, 57 object properties, and 33 data properties. Rule-based intelligence and querying has been used to extract specific answers for survivors' questions posted in lay vocabulary. Examples of questions include "what could happen to my child's school and social life, or overall well-being)?" and "What are my possible high risk traits?" A SPARQL query was used to approximate the question to obtain possible outcomes based on the information represented in the ontology. The integration pipeline for such ontology-driven queries in the proposed mHealth design framework is as follows. Intended steps include: (1) A custom web server application to host the live version of POCS and publish a private interface that will allow our application to query the ontology (2) A separate client-based application ontology that is based on POCS may reside on the application to store personalized information of the user and the user's cancer survivor care information from the hosted POCS knowledge base.

Identification of Engagement Elements: A total of five survivor engagement features were identified using PEF. Given the implementation and domain constraints, the engagement features fell under different phases of PEF. Table 1 provides a list of features and phases that were chosen as part of this step. Most engagement elements identified using the framework are in Level II. This mapping process allowed us to gain insights into the attainable level of survivor engagement, features to be incorporated, and reusable information classes across the features. Few engagement features that have been listed in Table 1 may be pertinent to only certain AYA user groups depending on their gender, age, and cancer type. Examples of such features include the fertility tracker, pregnancy tracker, late effect symptom checker, and lifestyle tips. The PEF framework is intended to guide healthcare organizations in developing and strengthening their patient engagement strategies. Our proposed survivor engagement framework is motivated by the need to support technology development efforts of consumer-centered apps by non-hospital entities. Therefore, certain advanced features listed in the PEF may not be applicable to our study limiting the scope of the engagement elements to Phase II. Such advanced features require constant data sharing with health institutions.

***Digilego* Development:** A total of 11 survivor *digilegos* were conceived based on the engagement features selected using PEF. The individual components cover a variety of survivorship content and engage AYA survivors in care management. For example, "targeted health tips" provide patient-specific education to the survivor taking into consideration their current life scenario from the "personal profile" (e.g. age, gender, marital status). Our POCS ontology model forms the crux for the "late effect summarization" *digilego* to personalize content delivery that is cancer-specific, age-specific, and treatment-specific in nature. Table 2 provides an overview of the *digilegos* and the nature of content provided to the survivor. The overarching operational intention is to promote self-management of cancer care and survivorship among adolescents and young adults. Examples of the sub-goals for each component include increasing positive health behaviors such as physical activity, promoting social well-being through online community, facilitating accessibility to care summary and payment logistics, increasing knowledge

Table 1- Engagement Features and Ontology Relations

Engagement phase	Features	Related ontology classes
Engage (Level II) • Nearest primary care provider • Late effect symptom checker	Information and Way finding	Treatment center; Doctor; Late effects
Engage (Level II) • Fertility trackers • Pregnancy tracker • Social engagement tracker • Healthy eating tracker • Other risky behavioral trackers	e-Tools	Health behavior factor; Patient; Personal Profile; Risk factor; Social Factor
Create synergy and extend reach (Level V) • Care planning (e.g. follow-up scheduling) • Self-management • Daily reminders (e.g. Lifestyle tip)	Patient-specific education	Factor; Late effect; Treatment
Engage (Level II) • Patient profile • Insurance information • Bill pay • Email	Interactive forms	Patient; Personal Profile; Treatment summary
Create synergy and extend reach (Level V) • Online community support forums	Community support	Patient; Social factor; Treatment Center; Doctor

levels pertaining to late effects specific to certain life events (such as planning for parenthood), and promoting adherence to a follow-up care regimen. The operational intention for each *digilego* is unique depending on the content specialty. The usage intention is the same across all components where the aim is to engage survivors in self-management of their health. Henceforth, social media features, a responsive question corner using ontology-driven methods that can process lay vocabulary, and personalization features have been integrated to the design framework of *digilegos* to promote user engagement.

Several behavior change techniques have been integrated with 7 out of the 11 *digilegos* shown in Table 2. Based on their proposed functionality, the theoretical underpinnings range from education to provide information on health-behavior links, general encouragement through feedback and self-monitoring via e-health tools such as health behavioral trackers, social support through the social hub and community interactions, follow-up prompts to promote self-monitoring behavior, and integration of relapse prevention and stress management tactics for transition assistance and work-life balance [19]. Mapping these strategies to *digilego* elements is straight-forward, given the clear formulation of the intentions of each component and strategy using the BIT model. For instance, "Social Hub" has been mapped to the social support strategy. Similarly, *digilegos* such as "Late Effects", "Patient-specific education" have been designed to provide education on consequences, barriers, and benefits of in self-monitoring and management of cancer survivorship. Further, the instantiation criteria for each of the *digilegos* have been defined in terms of the interaction features and workflow. Notifications, logs, and information delivery are the most used interaction elements. For example, "Work-Life Balance" has interaction features, which include notifications to deliver daily reminders and information delivery mechanisms to provide multimedia educational content to AYA survivors. Similarly, logs have been assigned to "Personal profile", messaging elements and visualizations to "Social Hub" to provide users with (a) communication tools to interact with peer and care providers, and (b) consolidated feedback to users on their social engagement levels. Event-based and time-based workflow criteria have been used to derive personalization effects. For instance, consider a change in education level where the user indicates entering college from high school, event-based criteria are used to deliver appropriate lifestyle tips and transition assistance guidelines that are pertinent to their life in college. Similarly, another event-based workflow is defined for "Late effects" and "Behavioral trackers", where age-specific customizations will come to effect depending on the changes in life scenarios. In summary, a cluster of *digilegos* have been conceived, defined, and characterized using the BIT model to facilitate survivor engagement in cancer survivorship care. The use of ontology has facilitated the identification of abstract survivorship concepts and their interconnections to provide both general and personalized information. PEF and BIT models have provided a way to map and integrate user engagement attributes and theory-driven behavior change strategies.

A feature level comparison of the survivor *digilegos* and existing consumer apps available for AYA survivorship guidance is shown below in Table 3. We considered two apps, AYA Healthy Survivorship [20] and Cancer LateFX [21], developed by Cancer Alliance of Texas and Akron Children's Hospital respectively. Both the apps derive their content from the same LTFU guidelines we used in the study. AYA Healthy Survivorship app focuses on healthy lifestyle promotion while the Cancer LateFX app offers content on late effect management of childhood cancer treatments. Social support features, behavioral goal trackers, profile information and treatment summary management are made available in both the apps and our *digilegos*. While a subset of features delivering patient education, lifestyle tips, care reminders, and a question corner were also found in both the apps, context-specific personalization (e.g. transition assistance) and ontology-driven reasoning capabilities have not been integrated into the existing apps. In summary, the use of detailed ontologies along with the PEF framework and BIT model has allowed rapid construction of survivor *digilegos*, which facilitate behavior change, consumer engagement, and optimal technology use for self-management of survivorship care among AYA survivors.

Limitations and Future Work

The POCS model described in the paper has been created with manual identification of classes. However, a scalable ontology generation will be made possible with the implementation of automated (or semi-automated) natural language processing methods. The use of external sources (e.g. the National Cancer Institute Thesaurus Ontology) allows us to generate comprehensive ontological models. PEF used in the proposed model is aimed at health institutions to develop solutions that are patient engaging. However, the framework is not completely suitable to identify engagement features for technology solutions that solely involve health consumers (e.g. AYA cancer survivors). Future research should focus on consumer engagement taxonomy and a framework that allows technology developers (1) to choose the appropriate level of complexity to model system features, and (2) to identify smoother ontology-to-end user knowledge transfer and query loops. Finally, the *digilegos* described in this paper have not yet been operationalized. Future research should implement and evaluate the *digilegos* in terms of user acceptance, reusability, and technology effectiveness. As part of the next steps, we aim at developing a mobile application comprising the survivor *digilegos* that will interface with POCS using OWL-based API libraries.

Conclusion

Cancer survivorship is a lifelong endeavor for cancer patients, their families, and caregivers. Better survivorship care is vital to enhance the quality of life during and after cancer treatments. With advancements in early detection and treatment protocols, the number of cancer survivors is on the rise around the globe. The proposed survivor engagement framework is a foundational step that will help influence the development of mobile applications with reusable and customizable components as per the needs of the cancer survivors across the care continuum. While the proposed framework is aimed at cancer survivorship, certain *digilegos* can be used to develop mobile solutions for management of any chronic disease (e.g. diabetes, cardiovascular health) that requires patient engagement and self-care. Use of informatics-driven methods, behavior change theories, and patient-centered design approaches can help us develop scalable and cost-effective mHealth products that can be deployed globally.

Abstract

By involving patients in their own long-term care, patient self-management approaches aim to increase self-sufficiency and reduce healthcare costs. For example, electronic patient diaries enable patients to collect health data autonomously, increasing self-reliance and reducing strain on health professionals. By deploying patient diaries on mobile platforms, health data collection can occur at any time and place, increasing the mobility of chronic patients who typically need to enter health data frequently. Importantly, an opportunity also arises for mobile clinical decision support, where health feedback is directly issued to patients without relying on connectivity or remote servers. Regardless of the specific self-management strategy, patient and healthcare provider adoption are crucial. Tailoring the system towards the particular patient and toward institution-specific clinical pathways is essential to increasing acceptance. In this paper we discuss a mobile patient diary realizing both the opportunities and challenges of mobile deployment.

Keywords:

Self-Management; Mobile Health; Clinical Decision Support Systems; Health Alerts and Notifications.

Introduction

In ageing societies chronic illnesses are becoming increasingly prevalent, negatively affecting people's quality of life and increasing strain on public healthcare systems [1, 2]. To rein in healthcare costs and increase self-sufficiency, patients with chronic illness are increasingly encouraged to self-manage their illness in a home-based setting [3-5]. Related approaches for patient engagement and education involve providing educational and motivational resources [4] and increasing patient self-efficacy by applying behavioural theories [5]. Electronic patient diaries empower patients to autonomously collect health data about their vitals, medications, hospital visits, and symptoms, thus avoiding manual collection by health workers and associated clinic visits. In particular, digital patient diaries accessible through mobile devices (i.e., smart phones and tablets) have the potential to capture patient health data in any setting and at any time. As such, mobile patient diaries provide an up-to-the-minute health profile of the patient and can supply relevant health alerts based on the current profile. Commercial health measurement devices are already accompanied by their own mobile health apps, such as iBGStar and OneTouch Verio Sync blood glucose monitors and iHealth and Withings blood pressure monitors. Moreover, major companies such as Google (Google Fit) and Apple (HealthKit) are developing mobile toolkits for collecting, analyzing, and monitoring personal health data.

As mobile platforms become more sophisticated, new opportunities arise to develop mobile patient diaries that go beyond typical patient data collection and reporting functions. We argue that mobile patient diaries can be extended to incorporate advanced functionalities, offering (i) mobile clinical decision support, (ii) personalized patient interactions, and (iii) data synchronization with centralized electronic medical records. Proactive decision support based on the current patient profile generates relevant interventions to adverse health conditions. By implementing a local Clinical Decision Support System (CDSS), mobile patient diaries are empowered to directly generate timely health alerts, even in situations where wireless connectivity is lacking or the server is unavailable. In previous work [6, 7] we studied how the scale of mobile decision support can be restricted by mobile hardware limitations (i.e., processing, memory). Based on this work we argue that distributed setups are more suitable for mobile systems, in which lightweight, time-sensitive reasoning is deployed locally and heavyweight processes are delegated to the server [2]. For this paper, we studied a lightweight mobile CDSS, configurable with decision rules derived from general or institution-specific clinical guidelines. In doing so, and combined with security and privacy support, we enable healthcare providers to incorporate patient-reported data and mobile CDSS recommendations within their practice.

Connectivity is an important issue in any mobile scenario because lack of Wi-Fi or mobile network coverage may result in temporary or long-term disconnections. One solution is to allow important functionality to be performed offline so disconnections do not limit mobile patient diary usage. As mentioned before, we argue that a mobile CDSS should function independently of connectivity to allow timely health alerts at any time and place. In addition, data entry may be performed offline as well, synchronizing the data with the Electronic Medical Record (EMR) server whenever connectivity is restored. To further ensure the health profile is current and to enable timely health follow-ups, patients should be encouraged to record their health data regularly and respond to alerts raised by the built-in CDSS. We achieve this by supplying personalized and recurring patient interactions, including data entry reminders and health alert notifications. Personalization options include customizing data entry schedules and alert notifications to suit patients' daily lives.

In this paper we present a mobile and intelligent patient diary for managing patients with Atrial Fibrillation (AF). As a core contribution we present a mobile CDSS configured with computerized Clinical Practice Guidelines (CPG) for AF. To improve patient engagement, the patient diary includes a notification engine, customizable with notification schedules that are personalized to suit the patients' lives. We address the connectivity issue by locally deploying a lightweight CDSS, and supporting offline health data collection. Whenever connectivity is restored, data that were collected offline are automatically synchronized with the back-end server. We

implemented the patient diary as a cross-platform mobile application, with current deployments on Android and iOS.

The AF-Mobile Patient Diary (AF-MPD) was developed for the self-management of Atrial Fibrillation (AF) in the context of the Integrated Management Program Advancing Community Treatment of Atrial Fibrillation (IMPACT-AF) project[1]. AF is the most commonly sustained irregular heart rhythm, affecting approximately 350,000 Canadians. Patients carry up to five times the normal risk of developing stroke [8], and stroke associated with AF is almost twice as likely to be fatal [9]. AF-MPD is being used by over 2,000 patients within the Canadian province of Nova Scotia as part of the IMPACT-AF project. Although the patient diary focuses on collecting & acting on AF-related health data in particular, it mainly comprises generic components that are re-usable for the self-management of other chronic diseases.

AF-MPD Architecture Overview

Figure 1 shows an overview of the AF-MPD. Below we summarize the functionality of each component.

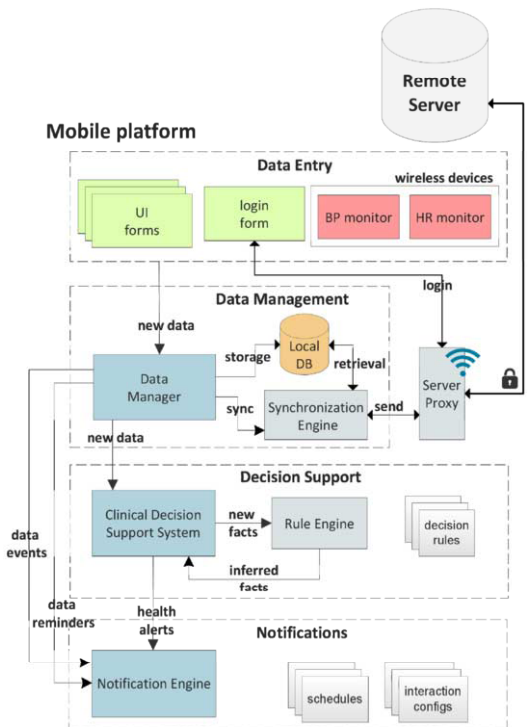

Figure 1 – Architecture Overview

To ensure security and privacy of personal health data, a patient needs to login (**login form**), which requires contacting the server *(login)* for validating the login credentials. Upon authentication, the patient can interact with his AF-MPD by providing health data and reviewing the recommendations. Health data is entered either manually via **UI forms** or automatically via **wireless devices** (e.g., using Bluetooth). This data is passed *(new data)* to the **Data Manager** for persistence in the **Local Database** *(storage)*, and synced with the server *(sync; send)* by the **Synchronization Engine**. If no connectivity is available, the engine will send (*send*) the persistent data *(retrieval)* when connectivity is restored. All server communication occurs via the **Server Proxy**, which maintains a secure server connection. Afterwards, the **Data Manager** sends the new health data *(new data)* to the **CDSS** for inferring new health findings. The **CDSS** incorporates a mobile **Rule Engine** to execute the CPG-based decision rules on the incoming patient data *(new facts)*, and returns the inferred facts *(inferred facts)* as alerts *(health alerts)*.

The **Notification Engine** issues notifications to the patient, including health alerts and reminders. The patient diary components invoke the **Notification Engine** for issuing health alerts *(health alerts)* or registering reminders *(data reminders)*. Such reminders or alerts can be repeated to notify the user frequently until a required action occurs (e.g., acknowledging the alert or performing data entry). In other words, we have implemented persistent notifications that have lifecycles influenced by particular events (e.g., data entry). For this purpose, the **Notification Engine** receives relevant events from other components *(data events)*. As discussed later on, these lifecycles are defined by *schedules* and *interaction configurations*. Below, we elaborate on each component.

Data Entry

Health data may be entered into AF-MPD either manually via UI forms or automatically via wireless measurement devices. A variety of such devices are already available, often accompanied by their own monitoring apps. Open and standards-based Bluetooth communication is available via the Health Device Profile [10], and Bluetooth Low Energy (LE) is typically utilized to conserve battery. However, in practice most devices only allow communication with their accompanying applicationss by applying validation protocols, and manufacturers are not keen on sharing access details (similar issues are mentioned in [3]). Short from hacking their systems, this makes it very difficult to integrate off-the-shelf wireless devices into custom mobile apps. For this reason, the mobile patient diary currently only supports manual data entry.

The AF-MPD supplies UI forms for collecting AF-related health data including heart rate, blood pressure (BP), and relevant symptoms or complications. To enter their current medications, patients can search a local copy of the Health Canada drug and health products database[2]. Additionally, patients can track their costs in dealing with their illness (e.g., clinic visits, loss of work). Graphical overviews of health measurements are also made available, allowing patients to track their progress over time. Figure 2 shows the blood pressure form and the graphical overview of the patient's blood pressure history over time. Figure 3 shows screens for recording AF symptoms.

Data Management

Health data is stored persistently in the local database on the mobile device and synchronized with a remote EMR database server when connectivity permits. Data synchronization may occur in two directions as well. At startup time the Synchronization Engine checks for new patient-specific information in the patient's server EMR (e.g., new medications added by the healthcare provider) and adds them to the local database. To increase patient adherence, the Data Management component registers a persistent reminder to enter health data as well as a synchronization reminder to encourage patients to find connectivity in case data synchronization is overdue.

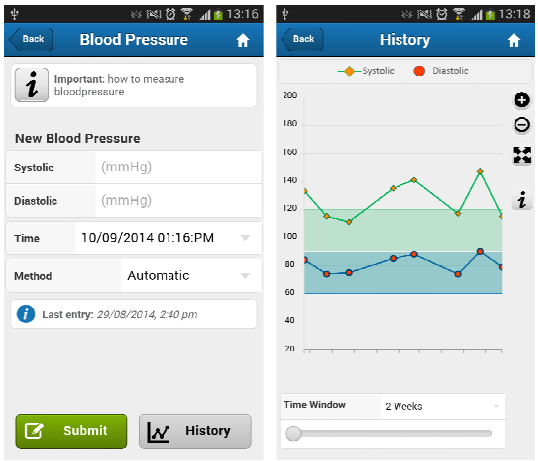

Figure 2 – Blood pressure form and overview

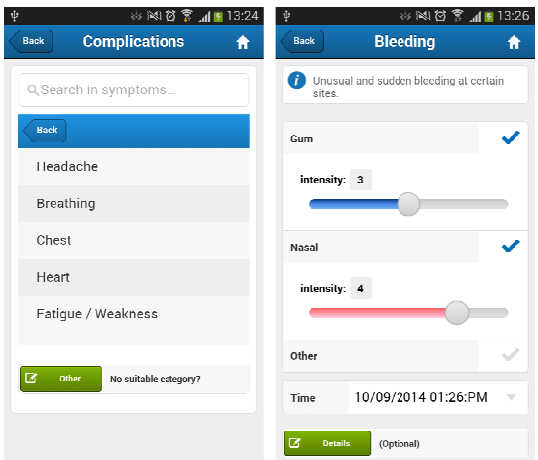

Figure 3 – Symptom browsing/searching and entry form

Server Proxy

Security and privacy are critical concerns when sending health data across the Internet. All server communication occurs via the server proxy, which maintains a secure HTTPS connection with the remote server. On the server side, the valid provenance of health data is ensured via a token system. The server proxy sends the patient's login credentials to the remote server, which returns a unique, temporary token to be included in further communication. Matching the included token to the patient indicated in the health data allows the server to rule out invalid data sources.

Decision Support

By incorporating mobile CDSS, the patient diary can directly issue health alerts based on local health data without requiring connectivity or relying on the remote server. On the other hand, mobile hardware limitations may restrict the scope of mobile decision support. To support large-scale and complex decision logic, the reasoning load was distributed [2], such that we deployed lightweight and urgent processes (e.g., problematic measurements) locally, and delegated more heavyweight processes to the IMPACT-AF server.

In previous work, we developed a framework for benchmarking mobile rule engines [6] and performed benchmarks in the clinical field of AF using off-the-shelf rule engines [7]. Importantly, we observed that in the case of limited reasoning scale and complexity, acceptable performance can already be reached. For the AF patient diary we deploy 11 local decision rules that involve checking for certain symptoms, whether heart rate and blood pressure are within acceptable bounds, and whether dangerous health trends exist (e.g., elevated heart rates for an extended period of time). Since the rules only reference the latest or aggregated health measurements, the reasoning dataset is relatively limited. Patient personalization is supported by parameterizing the rules with patient-specific values (e.g., heart rate limits given the patient's age) that are also included in the dataset. The decision support rules were extracted from CPG for the treatment of Atrial Fibrillation given by the Canadian Cardiovascular Society [11] and the European Society of Cardiology [8]. A key feature of our design is the clear separation between the decision support logic and the application logic; allowing both the rules and application to be updated independently. As such, mobile CDSS can be tailored to suit different, institution-specific clinical pathways and other comorbid chronic diseases.

To illustrate the mobile CDSS, consider a patient who enters high BP measurements over a period of three days with an average systolic BP greater than 135 mmHg and/or diastolic BP greater than 85mmHg (prehypertension). After a measurement is added to the database the rule engine applies its configured rules to infer new health findings. After adding the latest measurement, the relevant rule infers an *uncontrolled blood pressure* finding, indicating prehypertension. In response, the CDSS issues a health alert via the Notification Engine. It can be noted that since reasoning is only applied after adding new health data, the local CDSS has only a minimal impact on battery life.

Notifications

Although health data entry is facilitated by mobile patient diaries, patients still need to frequently perform data entry. In addition, follow-up interventions by physicians are only possible when the collected data is synchronized frequently with the remote server. As a result, a second notification category includes reminders that are issued for data entry and server synchronization. Below we discuss the requirements for these kinds of notifications.

Mobile patient monitoring solutions allow issuing notifications at any time and place. However, this also means patients can be notified in situations where they are not able to perform the required action, such as collecting health data. To account for this constraint in our solution, it is possible to repeat notifications until the desired action can be performed. Since the urgency of the notification will typically increase as time passes (e.g., reflecting an increased necessity for health data entry), we apply a time-delayed strategy that increases notification obtrusiveness over time. This has been achieved through an *event-based* and *evolving* notification lifecycle, where (1) the employed interaction resources (e.g., icons, audio and haptic feedback) increases in obtrusiveness over time, together with notification frequency; and (2) the occurrence of events, such as performing the desired action (e.g., data entry), influences the current state of the lifecycle.

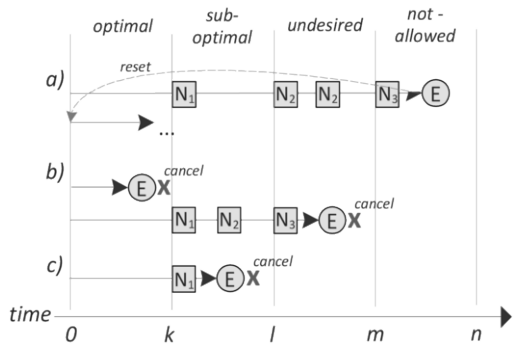

Figure 4 – Example notification lifecycles

In Figure 4 we illustrate several examples of our notification life cycles, including health alerts, data entry, and data synchronization reminders. Notification lifecycles are divided into sequential stages (e.g., optimal, sub-optimal, etc.). To reflect the increased urgency, these progressive stages typically (a) increase the notification's obtrusiveness, by using more intrusive interactions (e.g., sounds and vibrations) and different icons and content templates; and (b) increase the notification frequency per elapsed time. For each progressive stage, interaction configurations and notification frequencies can be predefined for each category (i.e., alerts and reminders). In contrast, registered notifications will each have *individual* lifecycles specifying when each progressive stage starts and finishes; supported events and their effects on the lifecycle; and notification-specific data (e.g., action about which the patient is being reminded) to be filled into content templates.

Each notification lifecycle starts when the notification is registered and is *reset* or *cancelled* when relevant events are received. Figure 4 shows four progressive stages, where the *optimal* stage indicates the initial timespan where no action needs to be taken. The s*ub-optimal, undesired,* and *not-allowed* stages indicate stages with increasing notification obtrusiveness and frequency. In example *a* the system registers a reminder for data entry at install time, where the patient starts receiving reminder instances (N_x symbols) after *k* time has passed. In this case the time *k* depends on the data entry schedule. For example, if the patient needs to enter blood pressures every day, a suitable value for *k* could be 24 hours. Later, the notification frequency and obtrusiveness increase as the *undesired* and *not-allowed* stages are entered until the patient enters the health data. In that case, an event (E circle) is received and the lifecycle is *reset*, starting again from 0. In example *b*, two reminders for data synchronization are registered each time after the patient entered health data while lacking connectivity. In this case, suitable times for *k* depend on the necessity for timely health data uploads (e.g., depending on the urgency of server-side decision support). After *k* time has elapsed, the patient will start receiving reminders of increasing obtrusiveness whereby the start times of subsequent stages (*l* and *m*) will likewise depend on the necessity for timely uploads. For the first reminder, connectivity is re-established before any notification is issued, resulting in an event that *cancels* the reminder's lifecycle. For the second reminder, the patient finally encountered a Wi-Fi hotspot after entering the *undesired* stage, again resulting in the cancellation of the reminder lifecycle. In example *c*, the local CDSS issued an alert after inferring a problematic health issue. In case of alerts, the *optimal* stage will most likely be skipped (setting *k* to 0) so the patient is directly notified of the health issue. In this example, the patient responds immediately after the first notification, generating an event that *cancels* the alert. For instance, patients may respond by simply indicating they will follow-up on the alert, or the alert may include an option to directly dial the clinic or emergency room. The notification lifecycle is terminated after the *not-allowed* stage. We note that notification lifecycles likely depend on the particular clinical setting and chronic illness being managed, and thus should be specified by domain experts.

It is important to note that persistent notifications may result in alert fatigue if not reconciled with the patients' personal schedule [12]. In particular, if patients continuously receive notifications but often are not able to directly perform the associated actions (e.g., health data entry), they will simply start ignoring them. Therefore, we have implemented the functionality to personalize notification lifecycles (within acceptable limits). Currently patients can configure the starting time of the *sub-optimal* stage for *data entry* reminders, thus delaying the time at which they start receiving reminder instances. In doing so, the patient may better align data entry with their own personal schedule. In case this configured time overlaps with subsequent stages (e.g., undesired), the system will display warnings of increased severity during configuration, informing the patient that the current schedule does not allow for an optimal follow-up, but that they should proceed if this is the only timing corresponding to their personal schedule. Setting this time beyond the start time of the *not-allowed* stage is not permitted as it would result in too long a delay for data entry reminders to still have purpose.

Figure 5 shows an example of an Android reminder instance that includes options for directly performing the task ("*Do"*) and personalizing the particular reminder's lifecycle ("*Settings"*). For both our Android and iOS implementations, platform-specific features are utilized to minimize battery usage: on Android, the Notification Engine is only made active by the operating system when notifications need to be issued; on iOS, future notifications to be fired are registered with a platform-specific service. Currently, persistent reminders are registered for data entry and synchronization, while alerts are one-off notifications. Finally, AF-MPD provides patients with a chronological overview of notifications.

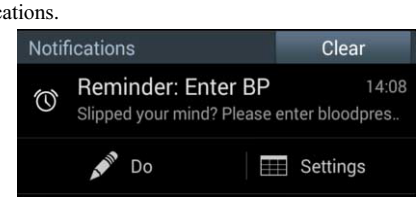

Figure 5 – Example Android notification.

Implementation

The mobile patient diary was implemented using the Adobe PhoneGap [13] cross-platform development framework. In this framework, mobile apps are developed using HTML, CSS, and JavaScript, which are deployed as embedded websites in automatically-compiled native apps. Platform-specific components such as databases, platform-specific notification code, and connectivity listeners are then added to these native apps. Currently, the mobile patient diary is deployed on Android and iOS and the necessary platform-specific components were developed for both platforms.

Related Work

Hommersom et al. [3] examine mobile clinical decision support for multiple chronic illnesses. In order to provide

clinical decision support, they discuss the possibility of using rule-based systems, Bayesian networks, and case-based reasoning. However, this work seems to be in its early stages, summarizing requirements, challenges, and opportunities of mobile smart assistants but not supplying concrete solution designs. Ambroise et al. [2] present a concrete mHealth solution for collecting health data, targeting a group of chronic illnesses. It features a hybrid architecture with lightweight reasoning occurring on the client side and more heavyweight reasoning taking place on the server. Locally collected health data is synchronized at frequent intervals with the server as well. Although the system has an automatic notification system, no details are given on how notifications are managed. At the same time, no consideration is given to increasing patient adherence and the discussed scenarios do not focus on aligning the system with existing, complex clinical pathways.

iALARM [12] is a language for specifying intelligent alerts and introduces the concept of an alert lifecycle. Alerts are triggered by monitoring temporal clinical data whereby alert reminders are fired in case the problem persists and no appropriate alert response has been given. The proposed language focuses on monitoring medical factors in clinics and issuing alerts to healthcare professionals. As a result, reminders only exist in the context of clinical alerts and cannot be issued separately for performing other self-management actions. In the same vein, issues such as notification lifecycle personalization and indicating the increased urgency of notifications (e.g., by increasing interaction obtrusiveness) are not considered.

Conclusion and Future Work

We presented a mobile intelligent cross-platform patient diary for the self-management of chronic illnesses, focusing on AF. Its main features include a local CDSS that allows for timely health alerts without connectivity and a notification system that supports evolving, event-based, and personalizable notification lifecycles. The supplied patient personalization options, combined with CDSS and notification lifecycles customizable towards different clinical settings, allow for improved adoption by healthcare providers and patients. We note that the patient diary comprises generic, configurable components that are re-usable for self-managing other chronic illnesses as well. The mobile patient diary will be used in a large-scale clinical trial (5,000 AF patients).

Future work includes studying additional opportunities for patient personalization, for instance by automatically suggesting suitable data entry times based on analysis of the patient's schedule (e.g., in iCal format). Since only manual data entry is supported at this point, further efforts also involve attempting to plug in wireless measurement devices and using the mobile device's camera to scan medication barcodes and automatically add them to the system. Importantly, we also aim to apply the patient diary to self-manage other chronic illnesses and investigate the extent to which other types of reasoning (e.g., Bayesian networks) would be more suitable for realizing clinical decision support in those cases.

Abstract

Current approaches to the management of severe mental illness have four major limitations: 1) symptom reporting is intermittent and subject to problems with reliability; 2) service users report feelings of disengagement from their care planning; 3) late detection of symptoms delay interventions and increase the risk of relapse; and 4) care systems are held back by the costs of unscheduled hospital admissions that could have been avoided with earlier detection and intervention. The ClinTouch system was developed to close the loop between service users and health professionals. ClinTouch is an end-to-end secure platform, providing a validated mobile assessment technology, a web interface to view symptom data and a clinical algorithm to detect risk of relapse. ClinTouch integrates high-resolution, continuous longitudinal symptom data into mental health care services and presents it in a form that is easy to use for targeting care where it is needed. The architecture and methodology can be easily extended to other clinical domains, where the paradigm of targeted clinical interventions, triggered by the early detection of decline, can improve health outcomes.

Introduction

Severe mental illness, including what is diagnosed as schizophrenia and psychosis, usually appears early in adult life and has a high risk of relapse. Relapses often result in unscheduled hospital admissions, with substantial suffering of the individuals affected and their families, and high costs for mental health services. Current approaches to the management of mental illness are limited by sporadic monitoring that takes place during consultations with mental health staff who ask service users to recall symptoms from as much as a month earlier. This has led to problems with averaging, reliability and recall, and has made accurate clinical assessment difficult [1]. Maintaining remissions and supporting recovery represents a major challenge for mental health services, which have lacked an approach that is personalised, responsive and service user-focused. Moreover, a recent report by the Care Quality Commission, the independent regulator of health and social care services in England, noted how service users often do not feel involved in their care planning [2], while National Guidelines stress the importance of service user self-management of symptoms [3]. Over recent years there has been an explosion of mobile, ubiquitous and connected health technologies, which can be used to detect diagnostic signals from individuals with much greater precision and resolution than ever before. These technologies promise to transform healthcare [4] and could support the coproduction of care between service users and care professionals [5].

In severe mental illness, the early detection of a change in symptoms can be used to trigger early intervention and so prevent relapse [6,7]. We have extended the standalone ClinTouch app [1] to close the loop between service users and care teams to enable the early detection of relapse and the targeting of interventions. We anticipate that this will improve patient outcomes by preventing relapse and hospitalisation. A reduction in hospitalisation will result in costs savings for healthcare providers.

Methods

To our knowledge, ClinTouch is the only system in the UK that offers a validated mobile assessment technology for severe mental illness with real time symptom reporting, online monitoring, relapse detection and the proven ability to integrate with existing mental health services. The use of smartphone apps within mainstream mental health care services in the UK is nascent and innovative and current clinical approaches to the management of mental illness typically rely on infrequent face-to-face consultations. The clinical aims of the ClinTouch system are to provide improved modes of personalised clinical monitoring and to enhance service user self-management. From a technical standpoint, the challenges include: a) developing a secure system that can collect and monitor service user symptoms in real-time; b) providing a reliable system to store service user clinical data; c) allowing flexible integration with diverse electronic clinical record systems across providers in the UK National Health Service (NHS); d) providing a way for clinical staff to easily view and monitor service user data; e) presenting summaries and visualisations of data that are relevant, understandable at a glance, and actionable; f) detecting deterioration in symptoms and risk of relapse; and g) supporting clinical research by making collected data available to researchers.

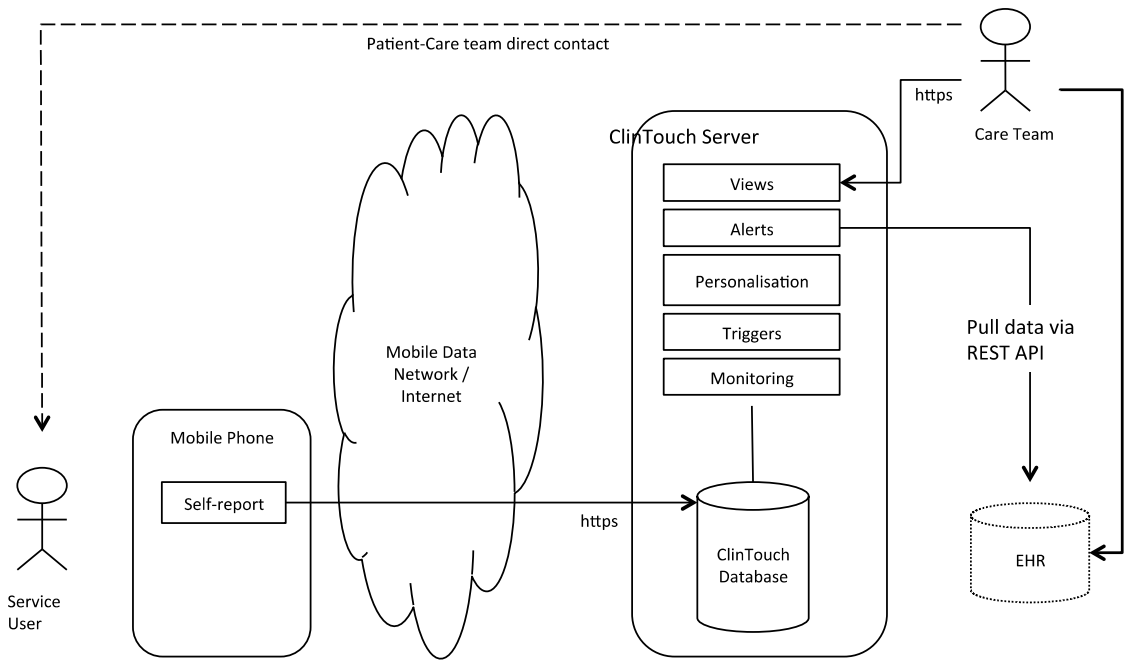

Figure 1 – Overview of ClinTouch system architecture. Service users use the app on their smartphone to capture continuous, longitudinal symptom data, which is transmitted in real-time through the mobile phone network to the central ClinTouch database for persistent storage, hosted on a backend server. This server also hosts a process running the clinical monitoring algorithm and provides a web-based interface for health professionals to configure service user accounts and to view data and alerts. Another process on the server manages data exchange between the ClinTouch system and the electronic health record system.

The architecture of the ClinTouch system is shown in Figure 1. The core elements of the system include: a smartphone application which allows service users to record their symptoms several times a day and wirelessly uploads the data to a central secure ClinTouch server; a web-based interface, which allows mental health staff within the provider organisation to view the uploaded symptom data, and a custom clinical alert algorithm, which is run over the collected data. All communication to and from the ClinTouch server (from the app, from the web-based client and via the REST API) is secured over https. All symptom data are stored against a unique participant identifier on the phone, uploaded as soon as possible and then stored securely in the ClinTouch database.

An agile, user-centred design methodology was adopted throughout the project. An iterative approach to development was supported by a series of focus groups conducted with care staff and service users, who provided input on requirements and qualitative feedback on software prototypes and designs.

Smartphone Application

A smartphone application prompts service users to record their symptoms several times a day at pseudo-random intervals. Data are then wirelessly and automatically uploaded to the ClinTouch server. The mobile assessment technology uses gold-standard rating scales and has been shown to be reliable and valid for assessing psychotic phenomena [1]. Drawing on Sama et al's [8] categorisation of user engagement, derived from the transtheoretical model of change and behaviour modification models, the app supports self-monitoring and progress tracking, which are achieved through collection and summary displays of symptom data.

Figure 2 – A screenshot of the question response page on the smartphone application.

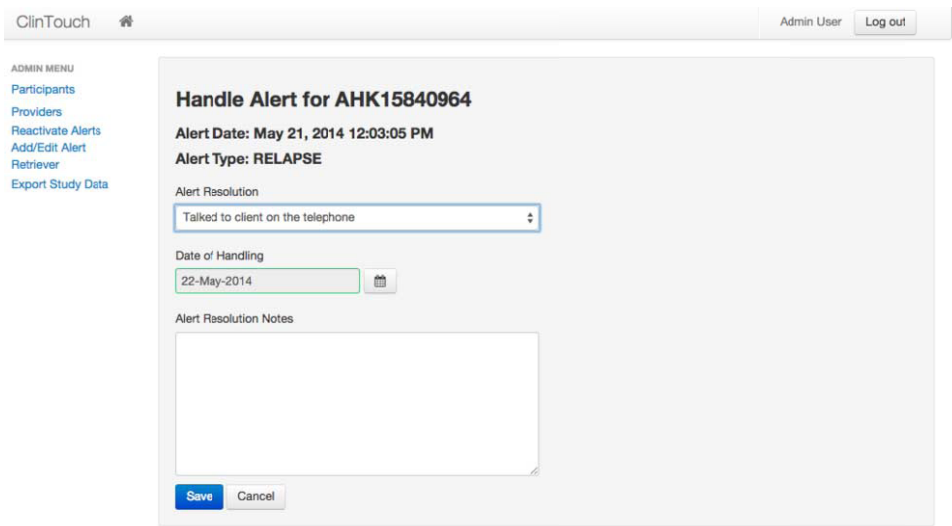

Figure 3 – A screenshot of the ClinTouch web interface: web page shows the screen for handling an alert raised by the clincial algorithm when it detects a high risk of relapse.

Web Interface

A web-based interface allows mental health staff to securely view the symptoms recorded by the service users in their care. The web interface supports multiple user roles, restricting access to service user data based on the logged-in user and allowing researchers to export symptom data for further analysis. The web interface provides configuration screens for adding and editing service user and staff accounts to the ClinTouch system. When adding service user accounts, questionnaires to be displayed on the smartphones for symptom monitoring can be personalised.

Clinical Algorithm

A custom-developed clinical algorithm is run across the symptom data to detect risk of relapse. If a high risk of relapse is detected, an alert is raised in the system. ClinTouch can be configured to either send an alert email automatically or third parties can integrate with the system through a REST API [9] provided by the ClinTouch server. In addition to email notification, the alert status of a service user (ALERT or OK) is viewable via the web interface. A raised alert must be manually cleared by the care provider via the web interface, where an alert resolution must be entered for auditing purposes (see Figure 3). The alert algorithm is highly personalised for individual service users at the time of configuration of the service user within the ClinTouch system. The weighting for symptoms for relapse used in the algorithm can be further edited after the participant has started using the smartphone application. This allows for ongoing personalisation following clinical assessment.

Results

The ClinTouch system has been developed based on findings from two pilot studies which used the smartphone app. The first pilot study confirmed that symptom reporting within the smartphone app is a valid way for assessing psychotic phenomena [1]. This pilot study involved 44 participants and used six pseudo-random alarms per day, for one week. Compliance (defined as completion of at least 33% of datapoints over seven days) was found to be 82% among participants. The second pilot study extended the time period for which participants used the smartphone app to six weeks and involved 7 participants. Of the 6 participants who completed the study, compliance was 80%. The majority of participants reported finding the app helpful.

The current ClinTouch system embeds the smartphone app within the loop of care to enable real-time clinical monitoring and detection of relapse. The system has been successfully deployed in two English NHS provider organisations. At the time of writing, 34 service users and 12 staff members are actively using the system as part of a randomised controlled trial to assess the system's feasibility for use in clinical practice. The total number of participants involved is set to rise to 40 during the course of the trial.

Input from staff and service user groups throughout the development of the software has ensured the software is meeting the needs of end users. Feedback from our user groups highlighted the importance of an engaging user interface for the smartphone application. Development resources were consequently invested in this area, leading to a professionalised smartphone application and ensuring quality of the user experience. Service user focus groups led to increased personalisation of the smartphone application, including a) the ability to enter contextual data to accompany symptom data and b) the ability to customise the look and feel of the application. The design of the web interface was guided by staff input, who defined the formats used in the display of symptom, alert and export data.

As NHS provider organisations in England do not have a standardised technical platform for maintaining electronic clinical records, the software was developed with the flexibility to integrate both with diverse electronic clinical record systems and to operate as a standalone solution. To support integration, a secure REST API [9] allows secure pulling of the alert data from the ClinTouch system by a third party. The system can also operate in standalone mode with the web-based interface operating as a fully functional platform with a comprehensive view of service user data. In practice, both solutions proved useful: one NHS provider organisation integrated ClinTouch with their electronic clinical record system prior to the start of the trial; at the second site, delays in the development of the local electronic

clinical record system meant that the ClinTouch system has been used in standalone mode.

While qualitative feedback from staff who have engaged with the system has thus far been largely positive, strains on mental health services generally in the UK have meant that it has been difficult for some staff to find the time to use the system. It is hoped that as more staff engage with the system, the value of ClinTouch for enhancing care will be more widely recognised and will drive further engagement. Service user feedback highlighted the need for further personalisation of the app and future development will focus on this area.

Discussion

The ClinTouch system was designed to address the gaps in current care provision. The problem of intermittent symptom reporting is overcome in ClinTouch by incorporating a validated assessment tool within the smartphone app where symptoms can be recorded in real-time. Service users can use the app to self-manage and monitor their symptoms and work collaboratively with their care providers which could help address previously-reported feelings of disengagement. As symptoms are monitored in real-time by a clinical algorithm which alerts care staff when risk of relapse is high, ClinTouch could facilitate earlier intervention and reduce hospital admissions.

For clinical staff, ClinTouch provides enhanced, personalised clinical monitoring. For service users, ClinTouch provides tools to assist with self-management. For mental health services, the system can reduce costs by facilitating early intervention, and reducing unscheduled hospital admissions. ClinTouch has been successfully deployed across two English NHS provider organisations and aims to improve the care of individuals who experience psychosis.

ClinTouch has proven ability to both integrate with existing electronic health records systems and to operate as a standalone platform. The platform provides a rich feature set, including: display and capture of questionnaire data via a personalised smartphone application; wireless uploading of questionnaire response data; a web-based interface for viewing symptom data in tabular and dynamic graphical format; a data export facility for researchers; and a mechanism for generating alerts based on a personalised clinical algorithm for detecting risk of relapse. Ongoing challenges include engaging a broader care provider population and providing further personalised modules within the app.

Conclusion

The ClinTouch system was developed to close the loop between service users and health professionals, and to address key limitations of current approaches to the management of severe mental illness. ClinTouch provides an end-to-end secure platform, incorporating a validated mobile assessment technology, which allows service users to record symptoms in real-time; a web interface to display service user data to service users and care staff; a clinical algorithm that runs on submitted symptom data to detect risk of relapse; and an alerting system to flag the need for clinical intervention. ClinTouch integrates high resolution, continuous longitudinal symptom data into mental health care services and presents it in an intuitive format that enables clinical staff to target care where it is needed. The system is currently being trialled in two NHS provider organisations in England. The architecture and methodology can be easily extended to other clinical domains, to enable early detection of decline and improve health outcomes.

The ability to identify the need for early intervention through real-time personalised monitoring has widespread applicability across a range of health conditions, where early intervention is key to preventing adverse outcomes. The ClinTouch platform offers a psychometrically well-founded customisable framework for real-time symptom capture, data visualization and analysis, which has been successfully deployed in mental health and is ready to translate to other contexts of co-produced self and professional care.

Mobile Health Applications, in the Absence of an Authentic Regulation, Does the Usability Score Correlate with a Better Medical Reliability?

Mobin Yasini[a], Guillaume Marchand[a,b]

[a] *DMD santé, Research and development department, 51100, Reims, France*
[b] *Department of psychiatry, Rouen University Hospital, 76031 Rouen Cedex, France*

Abstract

Health-related mobile applications (apps) have been shown to improve the quality of health and patient care. Their use in clinical and health-related environments is becoming more considerable. The number of health-related apps available for download has considerably increased, while the regulatory position of this new industry is not well known. Despite this lack of regulation, measuring the usability score of these apps is not difficult. We compared two samples of twenty health-related applications each. One of the samples contained the apps with top-rated usability scores, and the other contained the apps with lowest-rated usability scores. We found that a good usability score correlates with a better medical reliability of the app's content ($p<0.005$). In the period in which a valid regulation is still lacking, calculation and attribution of usability scores to mobile applications could be used to identify apps with better medical quality. However, the usability score method ought to be rigorous and should not be rounded off with a simple five stars rating (as is the case in the classic app stores).

mHealth, Mobile Applications, Regulation, Smart Phones, Equipment Safety.

Introduction

Mobile technology solutions have an important place in daily life today. In addition to simple communication and text messaging, a variety of applications running on smartphones and tablets could offer easily accessible solutions to almost any possible requirement that may arise in the field of information and communication. Health-related information and communication is not an exception in the exploding penetration of mobile technology phenomenon.

Mobile Health – or mHealth – is the practice of medical or public health supported by mobile devices, such as mobile phones, patient monitoring devices, personal digital assistants, and other wireless devices [1]. Service care providers, researchers, and national governments are excited at the opportunities mobile health has to offer in terms of improving access to health care, engagement and delivery, and health outcome [1]. Numerous functionalities including data collection [2], patient communication [3], health care delivery [4,5], and patient and professional education [6,7] have been used to support patients or healthcare professionals.

Currently, more than 97,000 mHealth applications are present in the classic app stores, and approximately 1,000 new applications are being published every month [8]. In the next few years, more than 3,000,000 free downloads and 300,000 paid downloads are expected to be made of mHealth applications just in the USA [9]. Being easily accessible and highly available make smart devices (smartphones and tablets) very attractive for consumer and professional areas of application [8]. The smartphone is considered to be the most popular technology among physicians since the stethoscope [9]. Therefore, there are high expectations for growth in the mHealth market. With this growing market and the overwhelming diversity of applications, there is a need to recognize which applications are safe and trustworthy. In the recent literature, potential dangers and reliability of some health-related applications were investigated [10–12]. Various aspects of mobile health applications have been called into question, including medical professional involvement in the development of the applications [13], the accuracy and reliability of the content of the applications used in diagnosis and patient management [14], the potential danger of camera function in mobile devices to judge weather skin lesions are suspicious [15,16], deficiencies in self-management applications in diabetes [17] and asthma [18].

The mobile health application industry is still in its infancy. Existing laws and public regulations for approving health-related applications are only relevant to a rather small number of applications [8]. Happtique, a private certification of health-related applications suspended its operation after a developer discovered that two certified apps contained data insecurity issues [19]. Various reasons, including the number of functionalities, diversity of information and rapid development of health-related applications in the market, make certification difficult to achieve [20].

A usability score indicates the satisfaction and effectiveness of an application. Major platforms for mobile applications (Google Play store & Apple store) provide consumers the ability to rate the applications. Users can rate the applications by giving them a mark out of five stars. In the absence of a comprehensive and rigorous certification of mobile applications for health care, the only easily accessible quantitative measurement is the usability score. The main aim of this study was to evaluate if good usability scores correlates with a better medical safety. We therefore set out to determine if health-related apps with disparate usability scores differ in medical safety aspect.

Methods

French language-based health-related mobile apps in classic app stores (Google play store and Apple iOS app store) were gathered on our website at www.dmdpost.com. A monitoring system based on keywords extracted health-related applications from the classic app stores. App editors who would like to have their applications evaluated by our community could also directly send us their apps. The website currently contains 896 mobile health applications. These applications were divided into two categories according to

their target user: health professionals and the general public. A panel of application users (health professionals and the general public including patients) voluntarily completed usability satisfaction questionnaires for each mobile application. Everyone (health professionals, patients, and healthy individuals) could evaluate the apps addressed to the general public. However, if the target users of an app are health professionals, it would be evaluated solely by its target users. There were three questionnaires according to the evaluator's profile:

- A questionnaire for patients or healthy individuals to evaluate the apps intended for the general public
- A questionnaire for health professionals to evaluate the apps intended for the general public and to identify whether the health professional is willing to prescribe the app to his/her patients
- A questionnaire for health professionals to evaluate the apps intended for health professionals to verify if the application matches the healthcare professionals needs

There are two types of questions in each satisfaction survey both in a closed-ended format:

- Influence questions: to quantify application usage and reliability of answers (for example, Did you use the application several times a day for more than one week?)
- Perception questions: to assess the quality of the application on its functionality and ergonomic aspects (for example, Do you find the application easy to use?)

When the number of evaluations reaches five (at least four individuals and one health professional), the embedded algorithm assigns a score out of 20, judging the overall quality of the application. If an application is updated, it will pass to the status "Rating in progress" and will be re-evaluated by at least four individuals and one health professional to mark its current version.

We then selected the 20 highest-rated and the 20 lowest-rated applications. These applications constitute the material for this study. Two medical doctors working on mHealth evaluated four basic issues to assess medical safety of these applications. The four issues are:

- Prescence of at least one related health professional in the conception or development of the application
- Using reliable and valid bibliographic references to create the application contents
- Clear identification of objectives, target audience, and/or mentioning the possibility (or no possibility) of substituting a medical advice within the application
- Validation of the application in a peer-reviewed scientific paper

These criteria were then validated by a group of academic experts in the relevent field. The best rated and lowest rated applications were listed randomly so that the evaluators did not know the applications' usability scores during their evaluation process. The evaluators examined independently each application with the basic criteria. Discordances were then discussed to obtain a consensus. The name of each application was searched in Medline and Web of Science databases to identify if the application was the subject of a peer-reviewed published research. We then compared the total scores in the two groups. Descriptive information was produced for each basic issue of medical safety. The results were analyzed using Chi-square test. Significance of the statistic test was set at $p<0.05$.

Next, we compared the given app store usability scores of the two groups. In this step, we were interested in finding out if the user evaluations out of five stars could be considered as a reliable criterion to predict the medical reliability of the applications. The user evaluations out of five stars, published in the classic app store platforms within the app description, were analysed and compared in the two groups. We used the Wilcoxon rank-sum test to compare the mean score in the two groups.

Results

The applications used in this study covered various subjects including allergies, contraception, pregnancy and menstrual cycle, calorie intake, bipolar disorder, multiple sclerosis, medical or therapeutic education, cardiology scores, general follow up, diabetes mellitus, traveler's health, and hepato-gastroentrology recommendations. The target users of these applications were health professionals and the general public including patients. The majority of apps in both groups were intended for the general public. However, the number of apps intended for health professionals was more prevalent in the highest-rated group than the lowest-rated group (40% of the apps in the top-rated group against 5% of the apps in the lowest-rated group).

The number of concordances with our medical safety criteria together with the relevant percentages are illustrated in table 1.

Table 1– Prevalence of fulfilled medical trustworthy criteria in top rated and lowest rated applications

	Highest rated applications (%)	**Lowest rated applications (%)**
Presence of related health professional	14 (70%)	8 (40%)
Reliable references	11 (55%)	0 (0%)
Identification of objectives, target audience, possibility of replacing a medical advice	16 (80%)	16 (80%)
Validation of the application in a peer reviewed scientific paper	0 (0%)	0 (0%)
Total	41 (68.3%)	24 (40%)

Prescence of related health professionals in the conception or development of the application was observed more in the top-rated applications than the lowest-rated applications. The criterion satisfied in the fewest number of applications in both highest-rated and lowest-rated groups was mentioning whether reliable or valid bibliographic references were used to create the application contents (11 in top-rated applications and 0 in lowest-rated applications). The third criteria fulfillment (idenitification of objectives) was observed equally in both top-rated and lowest-rated applications (16 out of 20 for each group). In the top-rated group, we found a total of 41 times (68.3%) satisfaction to our medical safety criteria versus 24 times (40%) in lowest-rated applications. None of the studied applications were the subject of a peer-reviewed paper to assess its effectiveness. We therefore decided to remove this criterion from our calculations.

According to our criteria, the medical reliability was significantly higher in the highest-rated applications compared to the lowest-rated applications ($p<0.005$).

In comparing an application's usability score to the classic app store rating, we found that the highest-rating group have a mean score of 3.87 (standard deviation = 0.67). In the highest-rated group, four applications were removed due to an insufficient number user ratings for the application. The range of marks was between 3.5 and 5. In the lowest-rated group, six applications were removed due to insufficient user ratings from the classic app store. The mean score for the 14 remaining was 3.78 (standard deviation= 1.03). The range of ratings in this group was between 2 and 5. We did not find a statistically significant difference between these two means ratings ($p<0.9$) in our samples. We therefore did not compare the store provided usability scores with our medical criteria.

Discussion

Mobile applications comprise a flourishing industry today. Health-related applications provide users with an unprecedented opportunity to achieve a better quality of health as well as a better quality of healthcare. However, when it concerns health and healthcare goals, one must consider the potential risks and dangers. The ubiquity of mobile applications – including health-related apps – brings additional risks to less-experienced users who might download applications with dubious medical information and advice [21]. Although some voluntary app certification schemes like "Happtique Health App Certification Program" exist [21], a worldwide comprehensive and rigorous certification or regulation in all possible aspects concerning the mobile health applications including privacy, operability, security, ethical issues, medical content reliability, etc., is still lacking. The traditional methods of evaluation are not suitable for the fast paced nature of technology [22]. However, calculating a usability score is more common and has already been used in the published investigations [17,23–26]. In this study we present an analysis of 40 health-related applications to assess the feasibility of judging the medical reliability of mobile health-related applications by their usability score. In particular, we developed a usability evaluation method that was more rigorous than the present rating system out of five stars available on the classic store platforms. We defined four basic criteria to assess the medical content of health-related applications. We found that these criteria are significantly more fulfilled in the applications with a better usability score than the applications with lower usability score.

Other studies that evaluated the usability of health-related applications admitted that good usability scores in applications are related with better results in functionality and high compliance of consumers [17,23–26]. This corroborates the results of our study, which report that good usability scores correlate with better medical safety.

We then compared the store platform provided usability score in our samples. Our findings showed that the store-provided usability score was not significantly different in the two groups. A simple consumer rating out of five star is therefore not a good benchmark for evaluation of the usability of health-related apps.

This study had several limitations, which we tried to mitigate. We blinded evaluators of applications' usability scores to reduce bias during their evaluation of medical criteria.

The rate of being approved by a peer-reviewed publication was poor in both highest-rated and lowest-rated groups of apps. This is in line with another published study in which among 283 pain-related apps, none of them had been scientifically validated or proven to be effective [9]. However, our sample applications were only in French language. This can reduce the chance of being the subject of a peer-reviewed publication, because most of these publications are in English language and assess rather the English language applications.

The use of reliable references in the app development was not sufficiently mentioned for any of the apps, even in the highest-rated applications. This defective feature could be somewhat compensated by having a licensed health care professional implicated in the development of the application. Furthermore, valid and reliable sources might have been used in some applications without being mentioned.

Prescence of related health professionals in the development of the application was found to be the most prevalent source of support to health-related apps. This finding corroborates with another study who reports the implication of health care professionals in the app development followed by being recommended by a patient association as the most important source of support to the apps [9]. An analysis of colorectal disease smartphone apps in another study showed that only 29% of the apps had had customer satisfaction ratings and 32% had named medical professional involvement in their development or content [13]. This finding is in line with our results in lowest-rated health-related apps with 40% of medical professional involvement.

The present user evaluation system provided by the store platforms seems not to be a good reference to conclude if a health-related app is medically safe. This study demonstrated that a more rigorous system to measure usability score of the health-related apps could correlate with a better medical reliability. It is not yet clear how the assessment for health-related apps should best proceed [22]. In this situation, although the correlation with usability score is not an absolute and precise solution, it can be used in the absence of a comprehensive regulation.

The proportion of apps intended for health professionals was found to be more prevalent in the highest-rated group. It seems that app editors or developers pay more attention to the content when the target consumers are health-literate professionals. However the majority of health-related applications are intended for the general public (as is also evident in our samples) who may not have the same health literacy and numeracy of health professionals. Educational programs for health-related app users could not only empower patients and healthy individuals to have a better insight of the apps that they are using, but also arouse app editors to develop better quality and reliable apps.

Perhaps the most important limitation of this study is that we only looked at French language applications. This could have limited the yield of the results. However, some of these apps were present in the stores in a multilingual format. Small sample size is another limitation. We selected only 40 of the possibilities, not only because it was convenient, but also because it was what could be feasibly done. In this study the apps were taken from all the diverse categories of health related apps that could be found. As the different health fields have different characteristics, further studies analysing apps by dividing them according to their purposes or functionalities would be of considerable interest.

Even in the top-rated group, a great percentage of applications (more than 20%) lacked at least one of the medical criteria. This implies the need for a comprehensive multi axial program to assess the health-related apps in all aspects. Medical trustworthy of health-related apps is of utmost importance, however high-quality, evidence-based content

alone is of limited value, if presented in a way that does not adequately match and address the usability, accessibility, readability (reading with understanding) and health literacy needs of targeted audiences [21].

Conclusion

Mobile health technology seems to be a logical, acceptable, and efficient way to improve the quality of health and health care services. It can make healthcare more accessible and affordable for all [9]. It has been demonstrated that smartphone-based applications improve the efficiency of healthcare delivery and make healthcare more effective [27]. To achieve this objective, it is clear that the content of applications used in a medical or health context are required to be trustworthy. Mobile health applications still comprise a new industry. Therefore, it takes some time to achieve a valid comprehensive assessment procedure to proceed the app review. Meanwhile, calculation of usability scores that are more common among mobile applications could be used to distinguish apps with better medical quality. However, the usability score method ought to be rigorous and should not be rounded off with a simple five stars rating. Further research with more important samples would help to confirm the results of this study and pave the way to find trustable methodological issues to assure the quality of mobile health.

Towards Improving Hypertensive Patients Care: Pervasive Monitoring and Diagnosis Support

Jorge Céspedes[a] and Cynthia Villalba[a]

[a] *Facultad Politécnica, Universidad Nacional de Asunción, Paraguay*

Abstract

Hypertension is the most common chronic condition dealt with by primary care physicians and other health practitioners. It usually has no symptoms, causing a delay in diagnosis. Moreover, around 20% of the global population suffers from "white-coat syndrome", which can lead to misdiagnosing hypertension. When diagnosed, patients find it difficult to constantly monitor their blood pressure to ensure it is within acceptable levels. In this work, we propose a pervasive solution model for ambulatory monitoring of hypertensive patients and for supporting a clinician with the task of diagnosing hypertension. It contributes to the selection of attributes and techniques for assisting hypertension diagnosis, and also to an implementation which dynamically adjusts itself to each patient's average blood pressure.

Keywords:

Pervasive Healthcare; Assisted Diagnosis; Hypertension; Patient Monitoring.

Introduction

Arterial hypertension (HTN), has been globally recognized as the leading chronic disease that causes premature cardiovascular mortality and morbidity [1]. If HTN is properly controlled, cardiac mortality will decrease 49%, while cardiovascular mortality will decrease 62% [1]. Conversely, uncontrolled HTN, according to information from the Panamerican Health Organization (PAHO), could cause terrible health issues, such as myocardial infarction, kidney failure, blindness and/or heart failure [2]. Considering the above mentioned facts, an early diagnosis of the disease and providing mechanisms to maintain blood pressure within acceptable levels, is very important. However, there are issues that need to be addressed. First of all, at least 20% of the world's population suffers from "white coat syndrome" [4]. In the context of HTN, this means that a person's blood pressure readings might be higher in the doctor's office, but once he/she leaves the room, it goes back to normal. Another issue, which is opposite of the previous one, is "masked hypertension". It causes normal blood pressure readings in the doctor's office, but readings at home are in the hypertensive range [5].

Hypertensive patients, find it difficult to constantly monitor their blood pressure. In spite of the existence of well tolerated effective drugs, these are not enough to maintain blood pressure within acceptable levels [6]. It is claimed that around 20 million patients, will suffer a hypertensive crisis at some point of their lives [7].

This work presents a pervasive solution model to support hypertension diagnosis and provide monitoring of hypertensive patients. Supporting diagnosis by automated processing of data retrieved from patients could lead to more accurate diagnoses, while monitoring hypertensive patients could introduce several benefits. First, the patient is notified as his/her blood pressure starts to become abnormal. Second, every reading is stored in a central repository, allowing the clinician to view behavior of the blood pressure of any given patient and whether medication needs to be adjusted or not. Finally, the set of data in the repository, could be used in other research works.

This work is organized as follows. The next section presents recent work related to assisted diagnosis and patient monitoring systems. Then, a description of the proposed solution model is presented. Next, we present the methods used to perform tests and results obtained with them. Finally, a discussion of the results and a conclusion of this work is presented.

Recent Work

Assisted Diagnosis Systems

Most systems performing assisted diagnosis of hypertension use machine learning techniques, extracting features from available patient data or from available laboratory test results [8-11]. Whereas, others use techniques different from machine learning [12, 13], which we refer to as non-machine learning. Most of the works, in the non-machine learning group, ask for input from the user, by means of questionnaires or forms the patients need to fill in.

Currently, clinicians could make use of an ambulatory blood pressure monitoring (ABPM) device to diagnose hypertension when white-coat syndrome is suspected. It is worn by patients for 24 hours and once completed, it is connected to a computer that prepares a report for the patient [14]. A disadvantage of this approach is that it doesn't provide real-time notifications as blood pressure starts to become abnormally high, and that 24 hours might not be a long enough period of time to gather relevant data.

As a final point, we can mention that there are many challenges most work doing assisted diagnosis need to address, such as features to choose, sources of data to extract features from, and deciding whether to use machine learning or non-machine learning techniques, since better results might be obtained by choosing one or the other. This work tackles the challenges related to technique and attribute selection.

Patient Monitoring Systems

In this section, we focus on work performing patient monitoring by using wireless sensors and a smartphone to process data generated by them, that is, work oriented to pervasive monitoring. It is worth mentioning, that not only works monitoring hypertensive patients are considered.

There are studies that used specific sensors and machine learning to identify patient's health condition [15, 16]. Others

allow use of any type of sensors, and apply machine learning techniques to check patient's health status [17-19, 34]. On the other hand, some apply non-machine learning techniques and do not constrain sensors to be used for monitoring [18, 20, 32, 33]. Works dedicated exclusively to monitoring hypertensive patients, apply non-machine learning techniques and some of them combine wearable sensors with sensors installed around the patient's environment [21-24].

Similarly to assisted diagnosis systems, these systems also face some challenges, such as developing a system that can adjust itself to every monitored patient, and one that can provide pervasive monitoring, that is, monitoring without disrupting patients' everyday activities. Other challenges are related to technological issues, medical issues, administrative issues, usability, and validation issues [25, 26]. This work tackles the challenge of providing monitoring by means of an implementation which dynamically adjusts itself to every patient that needs to be monitored.

Solution Model

In Figure 1, a graphical description of the solution model is presented. The model has the following behavior. Sensors transmit data over the air to the patient's smartphone. Once the device gets incoming data, it starts real-time processing to determine whether the patient's current health status is normal or requires attention. If it requires attention, an immediate notification is sent to the patient and clinician in charge. In order to support diagnosis, every piece of data is stored in a main server, where offline processing will take place once a diagnosis is required.

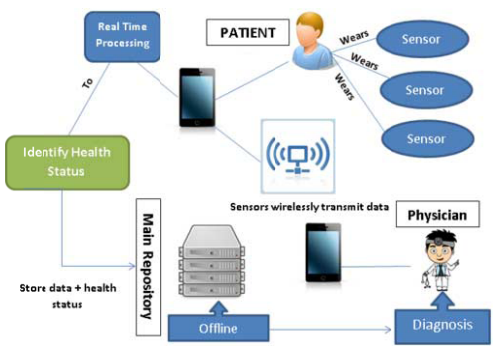

Figure 1 - Graphical description of the solution model

By monitoring a hypertensive patient, we expect to identify situations where severe blood pressure elevations occur. This is done by reading data from an ambulatory blood pressure device, which is attached to patient's left arm. This device measures blood pressure automatically, that is, without explicit request from the user. A smartphone will be in charge of processing the incoming data. Once an abnormal situation is detected, the patient, the clinician treating him or both will receive a notification. The model allows its components to be extended to easily include new sensors; for example, we could add an ECG sensor and include new notifications when emergencies occur.

For assisting hypertension diagnosis, we use machine learning techniques. Although we mentioned many works doing assisted diagnosis in the Recent Work section, there is not a golden rule that establishes which features will lead to reliable diagnosis support. Therefore, this solution proposes use of an activity tracking device, which a patient wears on his wrist, to include sedentary behavior as a new feature, since it has been proven that it is associated with a higher risk of hypertension [27]. Other features are weight, height, BMI, average systolic blood pressure (SBP), and average diastolic blood pressure (DBP).

It is worth mentioning that this is not an attempt to replace the clinician in the task of diagnosing hypertension, nor is it about ruling out standard diagnostic procedures. However, an obvious advantage of this solution model is that it considers longer periods of time, thus leading to more accurate and detailed information [30] which could improve diagnosis. Additionally, it also allows real-time notifications to patients and physicians as readings start to become abnormal. This would allow them to take actions earlier in emergency situations, whereas ABPM would only report abnormal values to the physician once he/she downloads the readings from the device.

Average blood pressure is also used for monitoring, since in order to identify a patient's health condition, the system uses values adjusted to this patient. This is a valid interesting approach since essential hypertension produces structural and functional modifications as a result of the growth or remodelling of blood vessels [28]. We will refer to these values as dynamic values. Previous work has used both dynamic and fixed values to monitor a hypertensive patient [22].

It is important to mention that for calculating average SBP and DBP, we used a weighted average equation (1) that proved to be better than arithmetic mean [24] when certain readings might be deleted due to errors. It considers the number of minutes elapsed between one reading and the next.

$$wAvg = \frac{\Sigma_i (L_i * P_i)}{\Sigma_i P_i} \qquad (1)$$

$$P_i = \mid T_{i+1} - T_i \mid$$

Methods

Test Method for Assited Diagnosis

A prototype of the proposed model was built to perform tests. Even though blood pressure readings can be obtained directly from worn sensors, it is not mandatory to do so. It can also be obtained manually, by requesting a patient to measure his blood pressure and then providing an interface where he can upload the current reading. But this manual approach is less convenient, as the patient can inadvertently make mistakes and has to interrupt his activities to measure his blood pressure. But, this latter approach is convenient when wireless devices are not available, and has been adopted by this work for getting required data. Sixty patients were selected from two Paraguayan hospitals to be part of the tests. Only those 18 – 90 years old, who were able to measure their blood pressure, were enrolled. Patients were requested to write their blood pressure readings down every eight hours, until they completed 10 readings each. Sedentary behavior information, like blood pressure readings, can also be obtained manually by asking patient for information about physical activities performed every day. Once patients accepted to be part of the test, they were interviewed to find out about sedentarism and obtain demographic data. A doctor classified each one of the 60 patients as hypertensive or non-hypertensive (i.e. healthy).

In order to apply a machine learning technique for assisted diagnosis, the full data set was grouped in two sets. The first one contained 35 records and it was used as the "training set", while the latter had 25 records and was used as "test set". Records in the "training set" were partitioned as follows: 20%

of the patients were sendentary and hypertensive, while 8% were hypertensive but non-sedentary. Additionally, 43% of them were non-sedentary and healthy, while 29% were sedentary and healthy. The test set was divided as follows, 40% of patients suffered from hypertension and 60% were healthy. We used an online learning algorithm consisting of a variation of gradient descent, since most work dedicated to assisting diagnoses choose online learning algorithms to generate suggestions [31].

In order to validate the assisted diagnosis systems, a confusion matrix was built. A confusion matrix is a table of at least size m by m, where an entry, CM(i, j) indicates the number of cases i labelled by the system as class j [29]. For the system to have good accuracy, values along the diagonal would be far from zero, while the rest would be close to zero.

The following measures were taken into account [29]:

1. Sensitivity: refers to how well the system can identify a hypertensive patient (True Positive / Positive).
2. Specificity: refers to how well the system can identify a healthy patient (True Negative / Negative).
3. Precision: used to access percentage of hypertensive patients that are actually hypertensive (True Positive / (True Positive + False Positive)).
4. Accuracy: It is a function of sensitivity and specificity (Sensitivity * Positive / (positive + negative) + Specificity * Negative / (positive + negative)).

Where:

- Positive is number of hypertensive patients.
- Negative is number of healthy patients.
- True Positive is number of patients suggested as hypertensive that actually are hypertensive.
- True Negative is number of patients suggested as healthy that actually are healthy.
- False Positive is number of healthy patients suggested as hypertensive patients.
- False Negative is number of patients suggested as healthy but actually suffer from hypertension

Test Method for Monitoring System

The monitoring system is comprised of two main components, a data gathering component and a health condition inference component. For testing purposes, simulated blood pressure readings were used, that is, the data gathering component did not connect to sensors, instead it obtained data from a simulator. The simulator starts with a patient's average SBP and DBP values, and then several events are generated, where each event would alter a patient's blood pressure. An event could be one of the following: **salty food, rough emotions (e.g., anger), physical activity, relaxation, and no change**. Each event, but the last one, causes blood pressure to increase or decrease by three levels: low, medium, high. The health condition inference component calculated average SBP and DBP as new events appeared, using the weighted average formula described in the Solution Model section. However, since values were simulated and none of them was invalid, weighted average and arithmetic median would have lead to the same values.

To perform tests, three fictitious hypertensive patients were created and events were generated all day long every 30 minutes. That is, 48 readings per day with a total of 240 readings for each patient, since these fictitious patients were monitored for five days. Even though blood pressure readings were simulated, we expect to test the system with real patients and sensors in upcoming phases.

The purpose of the test was to observe the differences between using values adjusted to each patient (i.e. dynamic values) and fixed values.

Results

Test Results for Assisted Diagnosis System

In Table 1 we can observe the results obtained after performing the test. The system indicates that 10 patients suffer from hypertension and 12 patients are healthy. It has a false positive rate of three, which means that three patients are considered hypertensive even though they are healthy. It does not generate any false negatives. It has 100% sensitivity and 80% specificity, which has been affected by the existence of false positives. This also affected the obtained precision, which was 77%. Finally, the system has 88% accuracy, which is affected by the specificity the system has.

Table 1 - Values obtained for each measure

Measure	Value
True Positive	10
True Negative	12
False Positive	3
False Negative	0
Sensitivity (%)	100
Specificity (%)	80
Precision (%)	77
Accuracy (%)	88

Test Results for Monitoring System

In Figure 2, we can observe SBP and DBP values for patient P1 during a single day, displaying generated alerts. Dashed orange and solid red lines represent warning and critical alerts for dynamic values, respectively. Whereas, dotted light blue and mixed blue lines represent warning and critical alerts for fixed values, respectively.

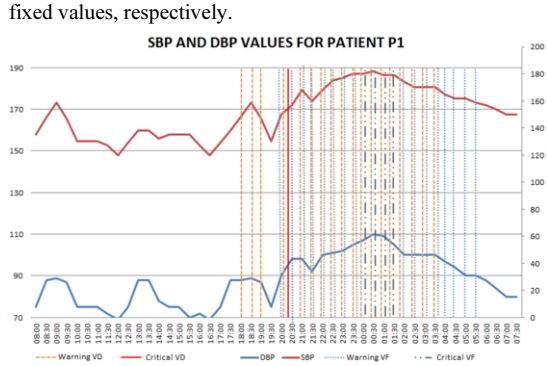

Figure 2 - SBP and DBP values for patient P1 for a day. Warning and Critical alerts are shown for both dynamic values and fixed values.

It is important to note that only one critical alert was generated when dynamic values were used. Though SBP/DBP values higher than the one at the specified time were generated, only warning alerts occurred later. This is due to the average blood pressure of P1 adjusting itself to a new value. However, this might be seen as an incorrect behavior because in practice, average blood pressure cannot change in such a short period of time. Thus, Figure 2 exposes two important matters to be defined when using dynamic values instead of fixed ones, that is, the time window to consider blood pressure readings for

calculating average blood pressure and the frequency at which blood pressure is to be measured. These must be defined so that average blood pressure is realistic.

The results from the tests are displayed in Table 2. We can observe a lower number of warning and critical alarms when dynamic values are used.

Table 2– Results for Monitoring System

Patient	Fixed Values		Dynamic Values	
	Warning Alarms	*Critical Alarms*	*Warning Alarms*	*Critical Alarms*
P1	80	20	76	3
P2	103	92	57	4
P3	120	71	86	5

Discussion

In Table 3, we show the results obtained by work dedicated to assisting hypertension diagnosis along with ours. Information in the table encourages us to believe that we are on the right track since sensitivity and specifity values are greater than those obtained by some recent works. However, a comparison cannot be made since datasets are different. Our results might be improved, perhaps by using larger datasets or by trying different attribute combinations.

Table 3 - Values obtained by others and this proposal

Measure	Su&Wu	Ture et al.	Hsu et al.	Proposal
Sensitivity	46.89%	95.24%	--	100%
Specificity	73.96%	71.79%	--	80%
Accuracy	72%	--	92.8%	88%

The monitoring system obtained results similar to those in [21], where the authors showed that fewer alerts are generated when values adjusted to patients are used. We expect that, in practice, this translates to generating critical alerts only when a patient's current health status needs attention from the clinician in charge.

Conclusion

This work presented a pervasive solution model to support hypertension diagnosis and provide monitoring of hypertensive patients. Although, there are many works on assisting diagnosis, there are challenges that need to be addressed. One of these is the selection of features to be used to accomplish the task. This work introduced a feature that previously mentioned works had not included, that is, whether a patient has sedentary behavior or not. We also contributed to the selection of a diagnosis technique, by choosing an online learning algorithm different from artificial neural networks and support vector machines, which are the most commonly adopted techniques by recent works.

Furthemore, identifying a patient's health condition, by using values adjusted to himself, allowed the system to generate fewer alarms than the case when fixed values were used. In the context of hypertension, this is a valid approach, since a severe blood pressure elevation might represent a crisis for some patients, but it might not be dangerous for someone who often has high blood pressure.

As future work, we expect to try the prototype with real patients. That is, to obtain data from the ambulatory blood pressure sensor and process them in real time instead of simulating readings, since this will allow us to create a confusion matrix; and perform an analysis similar to that in Test Results for Diagnosis System. We also expect to get feedback from doctors and patients to validate the system.

E-Patient Reputation in Health Forums

Amine Abdaoui[a], Jérôme Azé[a], Sandra Bringay[a] and Pascal Poncelet[a]

[a] *LIRMM UM2 CNRS, UMR 5506, 161 Rue Ada, 34095 Montpellier, France*

Abstract

Online health forums are increasingly used by patients to get information and help related to their health. However, information reliability in these forums is unfortunately not always guaranteed. Obviously, consequences of self-diagnosis may be severe on the patient's health if measures are taken without consulting a doctor. Many works on trust issues related to social media have been proposed, but most of them mainly focus only on the structure part of the social network (number of posts, number of likes, etc.). In the case of online health forums, a lot of trust and distrust is expressed inside the posted messages and cannot be inferred by only considering the structure. In this study, we rather suggest inferring the user's trustworthiness from the replies he receives in the forum. The proposed method is divided into three main steps: First, the recipient(s) of each post must be identified. Next, the trust or distrust expressed in these posts is evaluated. Finally, the user's reputation is computed by aggregating all the posts he received. Conducted experiments using a manually annotated corpus are encouraging.

Keywords:

Trust, Reputation, Social media, Online health forums.

Introduction

Internet is allowing patients to play a more active role in their own health care. Today, more than 46% of patients in 12 different countries use internet for self-diagnosis [1]. The use of Web-derived health information is rapidly increasing and has been termed as the *e-patient revolution* [2]. They have a strong desire to learn, to understand their own symptoms and to have access to medical knowledge. Although accessible and easy to use, the reliability of information on Internet represents a major risk on e-patients health. The consequences of an erroneous self-diagnosis are difficult to estimate if measures are taken without consulting a doctor. Indeed, only 21% of e-patients ask their physician confirmation of information obtained from Internet [1]. According to a recent study conducted by the Health On the Net foundation, 90% of e-patients use search engines to initiate their requests. Most of the returned links propose health forums which are used by more than 50% of e-patients. Thus, these forums are becoming the first source of medical information on the Internet. They are areas of exchange where patients, on condition of anonymity, freely relate their personal experiences and give their views and advices.

It is difficult to prevent e-patients to consult irrelevant or unreliable information on health forums; however it is possible to design tools to highlight the trustworthiness of information as well as the users in it. Many online health forums give a rank to each user, which is usually based only on the number of messages posted since his registration. Actually such ranking does not really give a good estimation of users' trustworthiness. A discussion with moderators of a French forum confirmed this intuition, since they know trusted users who post few messages and untrusted users who posted a lot of messages. In a previous work, we proposed a method to automatically distinguish posts made by health experts from those made by laymen [3]. In this new work, we are interested on the reputation of online health forum users independently from their medical roles. Many definitions of trust and reputation can be found in the literature according to each context [4]–[7]. Here we define the trust that a user *A* gives to a user *B* as: "*the belief of A in the accuracy of the information posted by B*", and the reputation of a user *A* as "*the aggregation of the values of trust given to user A*". Most studies of trust in social networks usually focus on the structure of the website (ratings, number of posts, number of likes, number of quotes, distance between posts, etc.) [8]. However, explicit liking and quoting functionalities are rarely used in the case of online health forums. For example, in the French health forum *CancerDuSein.org* only 2% of posts have explicit quoting. Besides, most users in this forum prefer posting a new reply where they express their agreement or recognition rather than simply pressing the like button.

In this study we suggest to infer the user's reputation from the replies he receives in the forum. Therefore, our method is divided into three main steps. First, links between each post and the person(s) to whom it is addressed, also called the recipient(s), are identified. Some works have already addressed this task [9], [10]. Three types of relationships have been extracted: structural relationships, name relationships and text quotation relationships. In this work, we consider nine kinds of different relationships. After that, posts are evaluated and classified into one of the following classes: trust, distrust and neutral, according to the use of agreement, disagreement and thanking expressions. Finally, the user's reputation is computed by aggregating the trust and distrust expressed in the posts he received. It may computed in the whole forum or in specific topics by aggregating only replies posted in that specific topic. Users' reputations can be used either by moderators in order to investigate users having very bad reputations, or by forum readers in order to have an idea about the authors trustworthiness.

The rest of the paper is organized as follows. Section 2 presents the corpus and describes the used methods. Section 3 presents the obtained results and Section 4 discusses them. Finally, Section 5 concludes and gives our main perspectives.

Materials and Methods

First, the corpus of study is described. Then, the three main steps of our method are presented: identifying the recipient(s) of each post, inferring the trust expressed by each post and computing the reputation of each user.

Corpus of study

CancerDuSein.org is a French health forum specialized in breast cancer. 1,050 threads have been collected which holds 16,961 messages posted by 675 users. It represents all the data that have been posted between October 2011 and November 2013. Some threads have more than 500 posts, which make the use of semi-automatic systems a challenging task. This forum gathers women with breast cancer or their families, who want to exchange their experiences, advices and emotional support. However, the consequences of acting on incorrect advices can be severe. The forum gives a rank to each user based on the number of posts since his registration as described in Table 1. However, an active member on the forum is not necessarily a trusted member and similarly a new member is not necessarily an untrusted one.

Table 1 – Number of posts for each rank

Rank	Number of posts
New member	[0, 20[
Regular member	[20, 40[
Accustomed member	[40, 80[
Active member	>80

Step 1: Finding the recipient(s)

The first step of our method consists in finding the recipient(s) of each post in the forum. In order to construct a network of replies, a rule based heuristic has been developed. Nine rules have been designed and applied chronologically as described below. If a message does not match the first rule, the heuristic will check the second one and so on. The first post in each thread is not considered since it does not answer anybody.

Explicit quoting: *CancerDuSein.org* allows users to explicitly quote another user's post. However, only 2% of posts on the Website contain explicit quoting. These quotes have been detected using the HTML tag <*quote*> and by comparing the content of these tags and the pseudonym of the quoted user with the messages posted before in the same thread. This process allowed us to detect 312 quotes automatically. The rest of quotes (37) have been related manually because the quoted text has been modified or truncated by the user.

Second posts: Messages posted at the second place in each thread have been considered as replying to the first one.

Names and pseudonyms: If a message contains the pseudonym or the name of a user who previously posted a message in the same thread, then this user is considered as the recipient of the message. The pseudonyms have been extracted automatically while the names have been extracted from the signatures and validated manually. The following preprocessings have been applied in order to detect names and pseudonyms inside the text:

- Remove all non-alphabetic characters except spaces (***John Woe 34*** becomes *John Woe*).
- Replace all accented characters by the corresponding non-accented ones (*Jérôme* becomes *Jerome*).
- Lowercasing (*Sandra* becomes *sandra*).

Grouped posts: If a message contains a group marker ("hello everyone", "Hi girls", "Thank you all", etc.) then all the users who previously posted in the same thread are considered as recipients for this post.

Second person pronouns: In French, singular second person pronouns and plural second person pronouns are different. If a singular second person pronoun is used then the recipient is the author of the previous post.

Activator posts: When the activator of the thread (the user who opened the the thread by posting the first message) posts a new message in the same thread, we consider that all the users who posted after his last message are recipients of his new message.

Questions: If the message contains a question then the message is addressed to all the users who previously posted in the same thread.

Answers: If there is a question posted before in the thread, the recipient is the user who posted this question.

Default: If none of the rules mentioned before is satisfied, we consider that the recipient of the message is the activator.

Table 2 presents the number of posts that match each rule.

Table 2 – Number of posts that match each rule

Rule	Number of posts
Explicit quoting	349
Second posts	942
Names and pseudonyms	7,121
Grouped posts	740
Second person pronouns	2,406
Activator posts	1,239
Questions	298
Answers	1,790
Default	772
Total	**15,657**

Step 2: Inferring the trust

The second step consists in classifying each post according to the expressed trust. Posts containing agreement and thanking expressions have been considered as expressing trust to the answered person. Posts containing disagreement expressions have been considered as expressing distrust. The rest of posts have been considered as neutral.

Building the lists of expressions: The expressions of agreement, disagreement and thanking have been built manually based on terms extracted from the LAROUSSE thesaurus [11] and with the help of some specific Websites. All these expressions have been lemmatized in order to detect all the forms of words. Finally, the trust list contains 34 expressions of agreement and thanking while the distrust list contains 15 expressions of disagreement.

Negation: if one of the trust expressions is under the scope of a negation term, it is considered as a distrust expression and vice versa. The scope of a negation term may be two words after, two words before or two words after and two words before according to the nature of the negation term.

Computing the frequencies and classifying the posts: First, all posts have been lowercased, lemmatized using the TreeTagger tool [12] and corrected using the spell checker

Aspell (www.aspell.net). Next, posts are classified as expressing trust, distrut or neutral as follows:

- If a post contains more trust expressions than distrust ones, it is considered as expressing trust.
- If a post contains more distrust expressions than trust ones, it is considered as expressing distrust.
- Otherwise, it is considered as neutral.

Step 3: Computing the reputation

Once the posts addressed to each user are identified and the trust expressed in each post evaluated, we can compute the reputation of each user based on the trust and/or distrust expressed by the replies he received. We suggest computing the difference between the rate of replies expressing trust and the rate of replies expressing distrust. For a user "*u*" the reputation is computed as follows:

$$Reputation(u) = \begin{cases} \frac{NRT(u) - NRD(u)}{NR(u)}, if\ NR(u) \neq 0 \\ 0 \quad\quad\quad\quad\quad\quad , Otherwise \end{cases}$$

Where:

NRT(*u*) is the number of replies expressing trust to user "*u*"
NRD(*u*) is the number of replies expressing distrust to user "*u*"
NR(*u*) is the total number of replies addressed to user "*u*"

Reputation(*u*) belongs to the range [-1, 1]

Results

In order to evaluate the rule based heuristic that finds the recipient(s) of each post and the automatic inference of trust, 2,433 manual annotations have been done. The results obtained using these annotations and those obtained after computing the reputation are described below.

Step 1: Finding the recipient

Two datasets have been used to test our rule based heuristic. The rules have been designed according to the development set (the authors used this dataset to have an idea on the rules that need to be designed). After that, a test set has been used to test our heuristic on unseen threads.

Table 3 – Number of threads, posts and links found by the heuristic in each dataset

Datasets	Number of threads	Number of posts	Number of links
Development set	10	105	152
Test set	10	109	150

Prior-assessment: 15 non-expert annotators (they do not know the designed rules) annotated our two datasets. Each one annotated between 1 and 5 threads so that each thread had 3 annotators. The goal was to find the recipient(s) of each post without knowing the results of our heuristic. Classical measures of agreement are not well adapted, here we simply present the number of links (message, recipient) found by our three annotators at the same time, the number of links found by two out of the three annotators and the number of links found by only one annotator.

Table 4 – Links found by one, two and by the three annotators in each dataset

Datasets	Found by	Number of links	Percentage
Development set	3 annotators	102	53.4%
	2 annotators	54	28.3%
	1 annotator	35	18.3%
	Total	191	100%
Test set	3 annotators	103	60.3%
	2 annotators	44	25.7%
	1 annotator	24	14%
	Total	171	100%

Post-assessment: 3 expert annotators (the authors) annotated the links found by the heuristic in the two datasets. The goal was to validate or not the links found automatically with the possibility of adding a link which was not found by the heuristic. The agreement between the annotators was very good, (the obtained Fleiss' Kappa [13] is **0.89** for the development set and **0.74** for the test set).

Evaluation: Using these annotations, the quality of the developed heuristic has been evaluated. The links obtained automatically have been compared with those obtained from the annotations by considering only those that have been validated by more than two annotators (a majority vote). Table 5 presents the obtained precision, recall and F1-score.

Table 5 – Precision, recall and F1-score of the heuristic obtained on both dataset using prior and post assessments

		P	R	F
Prior assess-ment	Development set	0.70	0.68	0.69
	Test set	0.81	0.83	0.82
Post assess-ment	Development set	0.80	0.84	0.82
	Test set	0.83	1	0.91

Step 2: Inferring the trust

Two new datasets have been used to evaluate the automatic trust inference. Unlike the first step where both datasets had prior and post assessment, here prior-assessment has been done only for the first dataset and post-assessment has been done only for the second one.

Prior-assessment: 3 annotators annotated the trust expressed in 97 messages without knowing the results of the automatic system. The agreement between them was less than the recipient assessment but still acceptable (the obtained Fleiss' Kappa is **0.61**).

Post-assessment: The same 3 annotators annotated the trust expressed in 102 other messages. The results of the automatic system have been displayed, and annotators can chose the same value of trust or another one. The agreement between the annotators was also acceptable (the obtained Fleiss' Kappa is **0.69**).

Evaluation: The results obtained by comparing the classification made by the system with the annotations are presented Table 6. The annotations have been combined by using a majority vote.

Table 6 – Precision, recall and F1-score of the trust inference system using prior and post assessments

Datasets	Class	Number of posts	P	R	F
Prior assessment	Trust	28	0.67	0.93	0.78
	Distrust	4	0.50	0.25	0.33
	Neutral	65	0.96	0.83	0.89
	Global	**97**	**0.86**	**0.84**	**0.84**
Post assessment	Trust	31	0.77	0.87	0.82
	Distrust	5	0.23	0.60	0.33
	Neutral	64	0.92	0.75	0.83
	Global	**100**	**0.84**	**0.78**	**0.80**

Step 3: Computing the reputation

First, Table 7 presents the number of authors, the mean of the reputation and the standard deviation of the reputation for each rank.

Table 7 - The mean and the standard deviation of the reputation for each rank

Rank	Number of authors	Avg(R)	Std(R)
New member	561	0.29	0.29
Regular member	42	0.35	0.10
Accustomed member	26	0.35	0.09
Active member	41	0.38	0.07

Next, Figure 1 presents a scatterplot of the reputation and the number of posts while Figure 2 presents a scatterplot of the reputation and the number of replies.

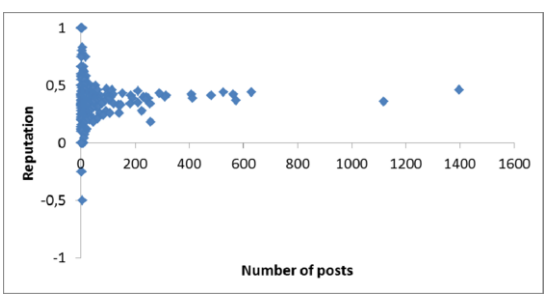

Figure 1 - The reputation and number of posts scatterplot

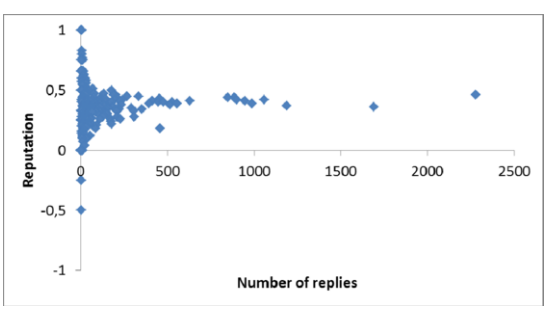

Figure 2- The reputation and the number of replies scatterplot

Discussion

In this section, we discuss the results obtained in each step.

Step 1: Finding the recipient

As expected, results obtained by using a post-assessment have been better from those obtained using prior-assessment. The difference is larger between the recalls than between the precisions. The gain in precision is 0.10 for the development set and 0.02 for the test set whereas the gain in recall is 0.16 for the development set and 0.17 for the test set. This observation can be explained by two reasons. First, the nature of the prior assessment itself gives the non-expert annotators much more freedom to choose the links, which increases the chances of validating links that the heuristic will not find. Furthermore, the non-expert annotators do not know the heuristic rules at all, they may validate links that the heuristic is not designed to find. Their annotations may be useful to add or update some rules. But surprisingly, the results obtained from the test set have been better than those obtained from the development set. Luckily, the test set has less particular cases that we did not implement in our heuristic.

Step 2: Inferring the trust

Unlike the first step, results obtained by using a prior assessment have been slightly better than those obtained using a post assessment. This observation tends to reduce the effect of the knowing the system's results while annotating in the case of trust inference. This small difference may be due to the chosen posts and not to the way that annotations have been done. The results obtained on the trust class have been good, but the recall is higher than the precision using both prior and post assessment. It means that the system finds the majority of posts expressing trust but also gives some posts that are not expressing it as so. Therefore, even if the list of trust expressions has been built manually, it seems to be sufficient to find the majority of trust posts. The results obtained on the neutral class have also been good, but the precision is higher than the recall. It means that the majority of neutral posts have been correctly classified but some posts have not been found by the system (classified in other classes). Finally, the results obtained on the distrust class have been the worst but it is difficult to make conclusions since very few distrust posts have been annotated. In fact, users in this forum do not usually express a lot of disagreement since the first goal is to exchange emotional support.

Step 3: Computing the reputation

Since the forum has very few disagreement posts, the reputation of almost all users is positive. Only, 3 users had negative reputation (two points are superposed in Figure 1 and 2). They posted less than 7 posts and received less than 5 replies. Indeed, the more posts a user receives the more chances he has to receive trust posts and more importantly neutral posts. This is why the standard deviation of the reputation decreases with the increase of the number of posts. Because neutral posts have a mitigating effect to both good and bad reputations.

As presented Table 7, the majority of users have the first rank on the forum (New member). The users' reputations mean increases slightly from lower rank levels to higher ones while the standard deviation decreases. However, authors from the first rank level have reputations ranging from -0.5 to 1 which is very diverse. This observation confirms our hypothesis that the Website rank is not a good estimation of the users' trustworthiness.

Conclusion

In this paper, we presented a method to infer the user's reputation from the posts he receives in online health forums. Indeed, a lot of trust is expressed inside the posted text which can not be detected by structure based trust models. Our method may be used either by the users to have an idea on the trustworthiness of each user or by the moderators, for example to reward the users having the best reputations and to detect the ones having the worst reputation. The method is divided into three steps. First, the recipients of each post are identified using a rule based heuristic. Next, the trust expressed in each post is evaluated by searching the use of agreement, disagreement and thanking expressions. Finally, the reputation of each user is obtained by aggregating the trust or distrust expressed in all the posts addressed to him. The method has been tested on one French health forum specialized in breast cancer where users exchange a lot of emotional support but few disagreement. Therefore most of them have got positive reputations. Manual annotations have been done in order to evaluate the methods. The results obtained for the first and the second step are encouraging.

This paper presents a first implementation and test of a method that infers the trust from the posts addressed to each user. Many perspectives can be done in order to go further in this idea. First, the users' reputations are now computed in the whole forum, we may also compute the reputation in each topic since one user may be trusted differently in several topics (reputation is topic dependent), which can be done by considering only posts received for specific topics. Second, even if the annotated corpus is relevant, still now its size is quite small according to the size of the whole forum. Improving a more complete annotation could probably provide more accurate results. Therefore, we are planing to use crowdsourcing services in order to annotate the whole forum. The quality of annotations obtained using crowdsourcing services are usually questioned but many solutions may be used to overcome this issue. For example, we can put the posts that had a perfect agreement in this study between the posts of the new corpus to make sure that the future annotators will correctly do their work. A large annotated corpus will not only gives us a better estimation of the method's performances, but can also be used in order to learn models that will be able to better classify each post according to the expressed trust. Text mining and supervised classification techniques might give better results in this case.

Moreover, following the evolution of the user's reputation since his registration may also be very interesting. Indeed, we noticed that new users usually receive less trust replies than old ones. But, their reputation can increase over time. Especially in the case of chronic diseases, users remain on the forum for years. Using their experiences and the knowledge acquired, they will become experts and will receive more thanking and agreement replies. Finally, the posts expressing trust posted by users having good reputation may have more weight than posts expressing trust posted by users having a bad reputation. One way to include these propagation aspects is to use PageRank based trust models [14]. This algorithm ranks webpages according to their importance. The basic idea is to give more importance to web pages that are pointed by many other important pages. It has been wihdly applied in social media for example to find key users in terms of connectivity and communication activity [15].

Web-based Self-management Support Interventions for Cancer Survivors: A Systematic Review and Meta-analyses

Ae Ran Kim[a], Hyeoun-Ae Park[a,b]

[a]College of Nursing & Systems Biomedical Informatics Research Center, Seoul National University, Seoul, Korea
[b]Research Institute of Nursing Science, Seoul National University, Seoul, Korea

Abstract

Those who are living with cancer as a chronic disease need to self-manage the late and long-term effects of cancer and its treatment. We conducted systematic searches of English-language peer-reviewed publications in PubMed, Cumulative Index for Nursing and Allied Health Literature, Cochrane Central Register of Controlled Trials, and EMBASE between January 2000 and June 2014. We searched for web-based interventions designed to help cancer survivors manage their symptoms and the side effects of cancer treatments, which yielded 37 studies that were systematically reviewed. For the meta-analyses, five articles were selected for fatigue, seven for depression, five for anxiety, and five for overall quality of life. The most popular mode of intervention delivery was "peer-to-peer access" in the communicative functions category, followed by "the use of an enriched information environment" in the automated functions category. The effectss across all outcome measures were small to moderate compared to standard care. Healthcare providers could use information technologies to support self-management among cancer survivors based on their needs across the cancer care continuum.

Keywords:
Self-management; Cancer survivor; Web; Intervention.

Introduction

Patients living with a chronic disease such as cancer experience significant limitations with respect to activities of daily living, reduced quality of life, and increased medical costs and burden [1, 2]. People with chronic diseases need to be active participants in their own care and manage their health over time [3]. It is also very important for nurses to be involved in the care of patients with a chronic disease to support and educate them on self-management of the disease.

The number of cancer survivors continues to increase due to improvements in early detection and treatments [4]. Although most chronic cancers are still difficult to cure, they can be managed and controlled as chronic diseases with long-term surveillance and, in some cases, treatment [5]. Since more active participation is required in day-to-day self-management for patients with a chronic disease [6], it is important for cancer survivors to be able to manage the late consequences of treatment or comorbidities on their own [7]. Self-management refers to "the individual's ability to manage the symptoms, treatment, physical and psychosocial consequences, and lifestyle changes inherent to the life with a chronic condition" [8], as guided by healthcare practitioners [9].

Rapid advances in information technology have led to its increasing use among patients with chronic diseases and among healthy people [10]. Information technology can provide self-management tools and material, and can support dynamic decision-making as per patients' needs, preferences, and values [11]. Cancer patients use the Internet to access self-care information regarding symptom management, and are empowered through the decision-making and peer support [12]. The development of more effective self-management interventions for cancer survivors using information technology requires exploration of previous intervention studies for cancer patients and identification of the factors required for effective cancer care [10].

This systematic review is aimed at identifying the general characteristics of web-based self-management support interventions for cancer survivors and to perform the corresponding meta-analyses to assess the effects of these interventions.

The main research questions were as follows:

1. What are the characteristics of the current web-based self-management support interventions for cancer survivors?
2. What modes of intervention delivery are used for cancer survivors on the Web?
3. Were the web-based interventions for cancer survivors more effective than the standard interventions?

Methods

We performed a systematic review and meta-analyses following the guidelines of the Preferred Reporting Items for Systematic Reviews and Meta-analysis [13]. The following inclusion criteria were applied to select studies for the systematic review:

1. Study subjects: patients diagnosed with cancer or their caregivers.
2. Interventions: Web-based self-management support interventions.
3. Outcome variables: behavioral or health outcomes.
4. Research design: randomized controlled trials or quasi-experimental designs.
5. Publication types: Original research articles published in English in peer-reviewed journals between January 2000 and June 2014.

Studies meeting the following criteria were subjected to further meta-analyses:

1. Studies comparing the effects of Web-based self-management support interventions with those of standard care.

2. Outcome variables reported for more than five studies.
3. Outcomes evaluated with the same measurement tools in more than three studies.

We performed an electronic search in the following four databases: PubMed, Cumulative Index for Nursing and Allied Health Literature, Cochrane Central Register of Controlled Trials, and EMBASE. The following keywords were used for the literature search: "cancer," Web-based ("Internet" OR "Web" OR "online"), self-management interventions ("self-management" OR "self-care" OR "self-guided" OR "self-help" OR "intervention" OR "program"), and study design ("randomized controlled trial" OR "non-randomized controlled trial" OR "quasi-experimental study" OR "before-after study"). The literature search was conducted in July 2014.

For the systematic review, the characteristics of each study were collected: design, subjects, phase, intervention duration, sample size, theory or models used, modes of intervention delivery, and outcome measures. Modes of intervention delivery were classified using the following coding scheme developed by Webb et al. [14]: automated functions, communicative functions, and the use of supplementary modes. Frequencies of the general characteristics and the modes of intervention delivery were tallied among the studies.

The risk of bias in individual studies included in the systematic review was assessed using the Cochrane risk of bias assessment tool [15]. The statistical details about the sample size and outcome variables were collected for the treatment and control groups from the studies included in the meta-analyses using Comprehensive Meta-Analysis Version 2.0. Since some of the individual studies had small samples (for example, n=18 for 2 groups), Hedges' g was used as an effect size [16]. Heterogeneity between studies was evaluated using Q and I^2 statistics. Fixed-effect and random-effect models were used to aggregate the effect sizes of the homogeneous and heterogeneous studies, respectively. Effect sizes of <0.2, 0.2–0.8, and >0.8 are considered to be small, moderate, and large, respectively [17]. The risk of bias across the studies included in meta-analyses was assessed by evaluating the symmetry of funnel plots.

Results

In total 37 articles were selected for the systematic review, and the meta-analysis included 5 articles for fatigue, 7 for depression, 5 for anxiety, and 5 for overall quality of life (Figure 1). The risk of bias in the individual studies included in the systematic review was assessed for the 34 randomized controlled studies. The random sequence generation was adequately described in 30 studies (88.2%), and an allocation concealment procedure was clearly reported for 12 studies (35.3%). Blinding of participants and researchers was described in only three studies (8.8%), but assessment of blinding outcome was not reported at all. However, most of the studies (82.4%) measured outcomes using self-reported questionnaires, and blinding outcome assessment was not applicable to these studies. All pre-specified outcomes were available for all but one of the studies. Thirty-two studies (94.1%) adequately addressed "other sources of bias" (Figure 2).

Thirty different interventions were used in the 37 studies. Regarding the modes of interventions delivery, automated functions were used in 7 interventions, communicative functions in 7 interventions, and both automated and communicative functions in 16 interventions. Supplementary modes were used in 16 interventions (Table 2). The most widely used function in the automated functions category was "the use of an enriched information environment" (n=17), and the most widely used function in the communicative functions category was "peer-to-peer access" (n=18). Examples of the use of an enriched information environment are linking to publically available health recommendations, websites, and multimedia such as videos or audios. Examples of peer-to-peer access are online discussion forums, bulletin boards, and chat rooms. Examples of supplementary modes are use of email, short message service, and telephone.

Synthesis of Results

The effect sizes for fatigue (n=5), depression (n=7), anxiety (n=5), and overall quality of life (n=5) are presented in Figure 3. Since all of the selected study outcomes were homogeneous between studies (fatigue: Q=5.670, p=0.225, I^2=29.458; depression: Q=7.674, p=0.263, I^2=21.809; anxiety: Q=1.416, p=0.841, I^2<0.001; overall quality of life: Q=2.125, p=0.713, I^2<0.001), effect sizes were computed using a fixed-effect model. Web-based self-management support interventions had statistically significant effects on improvements in fatigue (Hedges' g=–0.259, 95% CI: –0.405, –0.114, p<0.001), depression (Hedges' g=–0.169, 95% CI: –0.282, –0.055, p=0.003), anxiety (Hedges' g=–0.293, 95% CI: –0.465, –0.122, p=0.001), and overall quality of life (Hedges' g=–0.221, 95% CI: –0.358, –0.084, p=0.002). Some degree of asymmetry in the funnel plots was observed for the meta-analyses for fatigue and depression, representing the risk of bias across studies.

Table 2 – Web-based modes of delivery[1] (n=30)

	Access to an advisor	10 (33.3)
Supplementary modes	Email	13 (43.3)
	Text message (SMS)[2]	3 (10.0)
	Telephone	2 (6.7)

Discussion

We conducted a systematic review and meta-analyses of studies on the Web-based self-management support interventions for the cancer survivors. Our review revealed that only two theories were used by these studies to develop the intervention: social cognitive theory and the trans-theoretical model (TTM). Previous review studies on Internet-based interventions designed to alter behavior [14] also found that social cognitive theory and the TTM were the two most popular theories used. A behavioral theory can provide a mechanistic basis for specific behavioral changes [14], leading to a theory-based intervention [18]. It would be interesting to determine whether theory-based interventions produce better

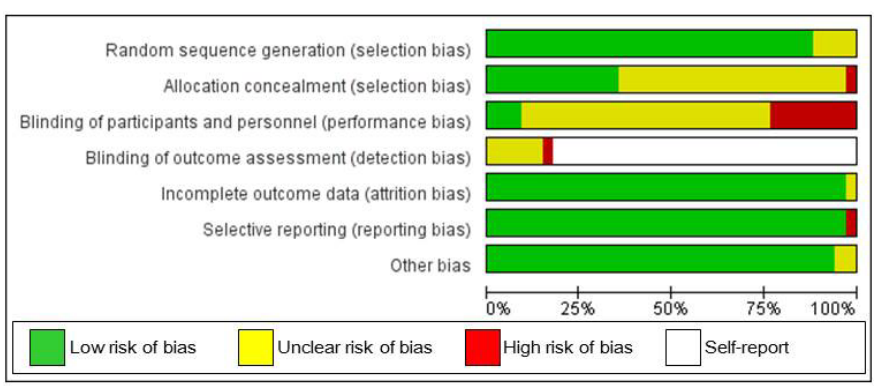

Figure 2 – Risk of bias in individual studies

[1] Multiple counts were possible for one study.

[2] Short message service

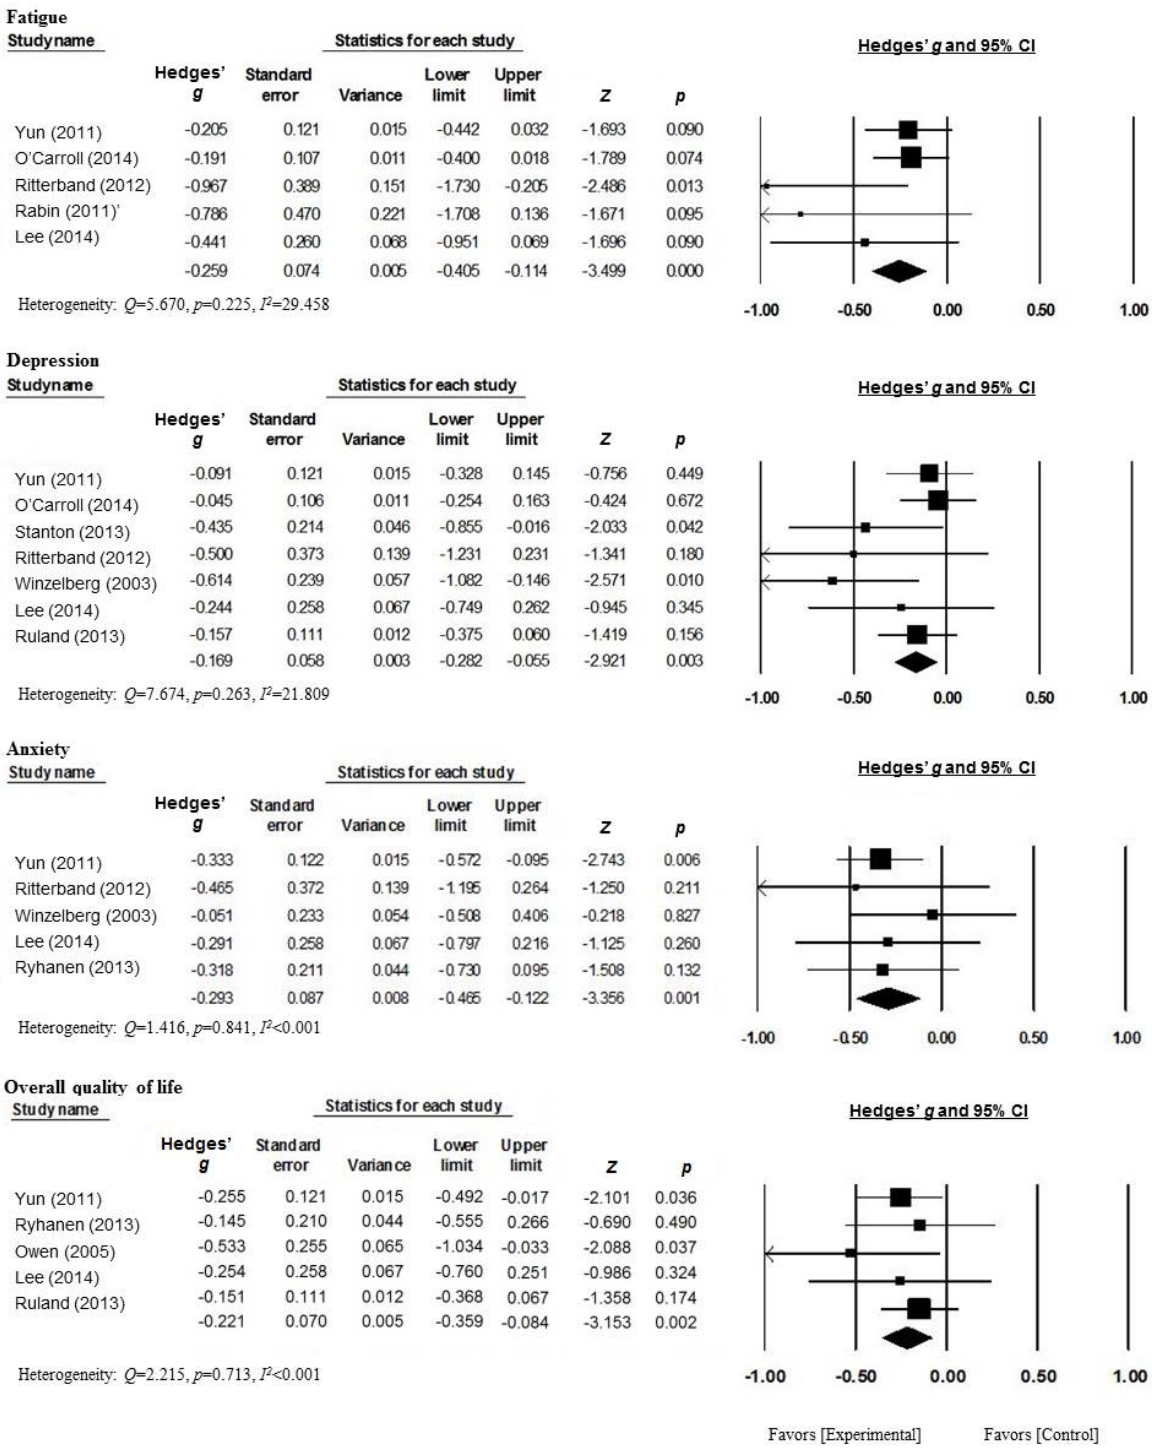

Figure 3 – Effect sizes of fatigue, depression, anxiety, and overall quality of life

behavioral changes compared to interventions that are not theory-based.

The use of an enriched information environment was the most popular function in the automated functions category of intervention delivery modes. Compared to conventional interventions the web-based interventions provide diverse health information in various forms by providing links to rich information sources. Another unique feature of automated functions of the web-based interventions is the tailored feedback, which was used in the eight interventions in the

studies reviewed herein. The automated tailored feedback provides customized information based on specific patient data [19], thereby avoiding the problem of information overload for patients [20]. This will also lead to an active patient participation in self-monitoring.

Peer-to-peer access was the most popular function in the communicative functions category followed by access to an advisor. According to a review study of off-line self-management interventions seeking advice from healthcare providers was the main communicative function [5, 21]. By participating in the online support groups, such as chat rooms and message boards, cancer survivors can compare their disease process with those of their peers, seek opinions from other patients, and learn daily life management skills from other patients [12]. However, the quality of the health information posted by the online support groups cannot be relied on[22]. Thus, it is important for healthcare providers to ensure the reliability and accuracy of information being exchanged and shared in online support groups.

In the meta-analyses, small-to-moderate effects of Web-based self-management support interventions were found on fatigue, depression, anxiety, and overall quality of life as compared to the standard of care. However, these meta-analyses have some limitations. First, the outcome variables were mostly self-reported by patients, which may carry reporting bias [20]. Second, blinding of participants and researchers was reported for only two of the studies (20.0%) included in the meta-analyses, which may have resulted in overestimation of the effect sizes [23]. Finally, we could not test for the existence of publication bias in the meta-analyses since quantifying the risk of error by interpreting the funnel plots was not feasible due to the small number of articles included in the meta-analyses. To the best of our knowledge this is the first study to compute the effects of web-based self-management support interventions on the patient outcomes such as fatigue, depression, anxiety, and overall quality of life for cancer survivors.

Conclusion

Web-based self-management support interventions for cancer survivors were found to be effective in improving fatigue, depression, anxiety, and overall quality of life, with the benefits of the automated and communicative functions available on the Web. Healthcare providers can use these findings to encourage cancer survivors to participate in Web-based self-management support programs. We also recommend that healthcare providers develop intervention strategies that utilize information technologies based on theoretical frameworks to support self-management for cancer survivors along the cancer-care continuum.

The Shared Decision Making Frontier: a Feasibility and Usability Study for Managing Non-Critical Chronic Illness by Combining Behavioural & Decision Theory with Online Technology

Amina Russell[a], William Van Woensel[a], Samina Raza Abidi[b]

[a] *Department of Computer Science, Dalhousie University, Halifax, NS, Canada*
[b] *Department of Medicine, Dalhousie University, Halifax, NS, Canada*

Abstract

The objective of this study is to determine if shared decisions for managing non-critical chronic illness, made through an online biomedical technology intervention, us feasible and usable. The technology intervention incorporates behavioural and decision theories to increase patient engagement, and ultimately long term adherence to health behaviour change. We devised the iheart web intervention as a "proof of concept" in five phases. The implementation incorporates the Vaadin web application framework, Drools, EclipseLink and a MySQL database. Two-thirds of the study participants favoured the technology intervention, based on Likert-scale questions from a post-study questionnaire. Qualitative analysis of think aloud feedback, video screen captures and open-ended questions from the post-study questionnaire uncovered six main areas or themes for improvement. We conclude that online shared decisions for managing a non-critical chronic illness are feasible and usable through the iheart web intervention.

Shared Decision Making; Behavioural Medicine; Choice Architecture; Biomedical Technology Intervention; Chronic Illness.

Introduction

Shared decision making (SDM) is considered the cornerstone of patient-centred care [1], signifying an important paradigm shift away from paternalistic medicine. In SDM, the patient and physician collaborate to select the best diagnostic and treatment options. It is a meeting of experts, in which the physician is the expert in medicine and the patient is the expert in his or her own life, values and circumstances [2].

Clinical trials have demonstrated that SDM can improve adherence to treatment and clinical outcomes [3, 4]. Despite its proven effectiveness, literature shows that only 10% of face-to-face clinical consultations involve SDM [5]. Biomedical technology interventions, also known as decision aids, have sought to fill this SDM gap [6]. Web-based apps aimed at improving lifestyles (i.e., weight change, nutrition, and physical activity) show evidence of positive impacts [7]. One study [8] concludes that web-based interventions increase patient activation and have the potential to enhance the self-management capabilities of the growing population of chronically ill people. A systematic review of internet-based interventions for hypertension revealed they significantly reduced systolic blood pressure by 3.8 mm Hg and diastolic blood pressure by 2.1 mm Hg [9]. In the Netherlands where heavy drinking among young adults has become a public concern, a tailored web-based intervention aims to reduce drinking practices amongst college students [10].

Use of behavioural theories improves the success rate of these health interventions [11]. For example, theory-driven behavioural strategies can reduce the risk of cardiovascular disease through lifestyle change rather than increasing medication [12]. Many different behavioural theories exist such as the Integrated Change (I-Change) behavioural model which has three simple states: awareness, motivation and action [13]. Its straightforwardness makes it a good fit for biomedical technology interventions, which should be kept simple as they involve patient interaction.

Choice architecture (CA) is another technique for improving decisions, as well as their implied long-term behaviour change (e.g., reduce smoking) [14]. CA is a decision theory originating from the field of economics [15] and has been successfully used to improve adherence to medication use [14]. It serves to fill the well-known intent-behaviour gap [16], characterized by a disconnection between intention and actual behaviour.

Reinforcement through multiple methods may increase patient motivation, and adherence to decided-upon health changes [17]. Both behavioural and choice theories are strategies aimed at improving patient engagement, which is an essential ingredient to SDM. The objective of this study is to demonstrate that behavioural theory and decision theory can complement one another within a technology intervention for SDM.

Methods

The iheart web application is a "proof of concept" to determine whether SDM for the management of a non-critical chronic illness, using a biomedical technology intervention, is feasible and usable. In the software development lifecycle, feasibility determines whether it is sensible to develop a system by objectively reviewing its strengths, weaknesses and opportunities, for instance via proof-of-concept functional prototypes [18]. Usability according to the ISO 9241 standard is the extent to which a product can be used by specified users to achieve specified goals with effectiveness, efficiency, and satisfaction in a specified context of use [19].

The iheart solution evolved over five phases: 1) conceptual, 2) design, 3) application development, 4) testing and 5) assessment of feasibility and usability.

Conceptual Phase

The initial blueprint for the biomedical technology intervention, employing the I-Change behavioural theory and CA, was first defined in a conceptual process flow diagram. The diagram visually outlined the patient navigation when using the system, indicating the different choices and SDM steps between patient and provider.

Design Phase

This conceptual diagram informed the application design. Firstly, the employed behavioral theories, SDM steps, and domain-specific content (i.e., related to hypertension) were represented as an ontology knowledge model. The logic rules for the application, including the SDM logic, were documented externally in decision tables, along with domain-specific messaging.

For hypertension, behaviour change choices include increasing exercise, reducing smoking or reducing sodium. Depending on their current lifestyle, the patient is presented with one or more of these options, and chooses one based on SDM with the healthcare provider. Afterwards, the patient fills out a behavioural questionnaire, which scores his/her initial I-Change behavioural state. I-Change is a behavioural theory with three behavioural states (awareness, motivation and action) and determines the patient's readiness for making the selected behaviour change. Importantly, this state informs elements of the CA, a decision theory that attempts to fill the intent-behaviour gap. In particular, based on the patient's behaviour state, appropriate CA messaging was presented, adapted to his/her readiness for making the selected behaviour change. An expert in Industrial-Organizational Psychology devised and validated the behavioural questionnaire. Questionnaires, content and informational messages were further reviewed by a nurse to ensure they were patient appropriate and also met patient education readability guidelines [20]. Finally, the patient was able to set a concrete goal given his/her health, again during an online SDM chat session with the healthcare provider.

The ontology model was built to be flexible, accommodating any disease condition, the selection of different behavior change theories and different CA concepts; as well as scalable, to support multiple health care providers and patients. This patient-centric model further contained the core constructs, relationships, content, messages and description logic that formed the foundation for the technical solution.

We devised mock screens based on the ontology model, rules and conceptual flow. An entity-relationship diagram defined the underlying database model for the application.

Application Development

The biomedical technology solution consisted of a web-based interface storing information on a centralized server within a secure relational database (Figure 1). The Vaadin open source web application framework [21] was used to produce an internet application accessible on PCs and mobile devices. Vaadin has a plug-in for chat sessions that enabled online SDM.

The iheart data was physically stored in a MySQL database [22] on a secure server. Eclipselink [23] was used to automatically persist application objects in the database, and implement the Java Persistence API (JSR 317) [24]. The Drools business management system [25] implements the Java Rules Engine API (JSR 94) [26], and was used for implementing decision logic based on decision tables. This decision logic included suggesting behaviour changes, based on the patient's current lifestyle; and determining CA messages depending on the patient's I-Change behavioural state. Finally, the Big Life Sodium Calculator [27], a third party web service, was made accessible from iheart, and calculated the participant's daily sodium consumption based on a series of questions.

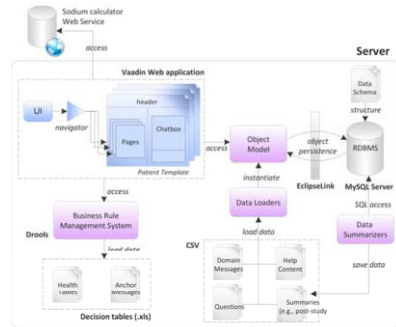

Figure 1 – iheart application architecture

Testing Phase

SDM via an online chat system (Figure 2) represents a novel approach for healthcare. Thus, several rounds of testing were applied to objectively prepare the system for evaluation. First, two medical doctors and two hypertensive patients critically reviewed the first-cut of the iheart prototype. Adjustments followed in response to this initial, informal feedback.

Figure 2 – iheart decision making and chat box

The formal application testing involved both white box and black box testing. An inward look at the application (white box) focused on unit and integration testing of internal components. An outward look at the application (black box) tested its external and user facing features. For example, the black box portion validated the seamless use of the Big Life Sodium Calculator web service within iheart. During both types of testing, modifications were made in iterations followed by regression testing of the application.

Study Assessment

The assessment of iheart was completed through a pilot study approved by the research ethics board of Dalhousie University, Canada. Only four to five subjects are needed to identify 80% of the usability problems with a system [28]. The study recruited nine hypertensive participants, approximately twice the recommended number, from the local area for this purpose.

Three goal-based scenarios were devised in collaboration with a medical doctor to assess the feasibility and usability of iheart. The scenarios were intentionally devised to present more than one lifestyle choice for reducing hypertension. This would compel the participants to make shared decisions. Each participant completed two of the three scenarios in order to sufficiently assess and rate the iheart application. Each scenario was used six times by the pool of nine participants.

This ensured uniformity and consistency in the assessment of the application.

Results

Quantitative Analysis

A post-study questionnaire solicited the participant's usability scores using a five-point Likert scale, combined with open ended questions for capturing experience and thus allowing qualitative analyses (see next section). The questionnaire contained sections on the usability, content, CA, SDM and overall functionality of iheart. The Likert Scale used: 1=Strongly Agree, 2=Moderately Agree, 3=Neither Agree nor Disagree, 4=Moderately Disagree and 5=Strongly Disagree. A score of 1 or 2 favoured iheart whereas scores of four or five indicated discontentment.

The questionnaire contained 41 Likert scale questions. Statistical software calculated the mean, median and mode scores within each section of the post-study survey (Table 1). Further analysis transpired at the participant level (Table 2).

Table 1 – Section Level Data

Section	Mean	Median	Mode	Chronbach's Alpha
Usability	2.07	1.5	1	0.97
Content	2.35	2.0	1	0.94
Choice	1.98	1.0	1	0.85
SDM	2.09	1.0	1	0.95
Overall	2.13	1.0	1	0.97

Within survey sections in Table 1 showed participant satisfaction across the board. Chronbach's alpha validated response consistency within survey sections.

Table 2 – Participant Level Data

Participant	Mean	Median	Mode
p1	1.44	1.0	1
p2	1.34	1.0	1
p3	1.80	1.9	1
p4	1.05	1.0	1
p5	1.61	1.0	1
p6	3.49	4.0	4
p7	4.24	4.0	5
p8	2.95	3.0	2
p9	1.24	1.0	1

Table 2 demonstrated that six participants (two-thirds) favoured the iheart application while participant 8 appeared neutral, participant six leaned towards dissatisfaction and participant seven appears dissatisfied. This quantitative data, when collated with the qualitative information, identified specific areas for improvement to iheart.

Qualitative Analysis

The study captured qualitative data primarily using the "think aloud protocol" [29]. This protocol captures participant feedback spoken out loud while using iheart to achieve the goal-based scenarios. The software, Active Presenter [30], captured the audio and video feedback including screen captures. Participants also responded to three open ended questions in the post-study questionnaire.

The qualitative data was imported into a qualitative analysis tool, ATLAS.Ti [31]. Inductive thematic coding [32] occurred in two stages: 1) open coding and 2) axial coding [33]. First, a comprehensive code list was increasingly built as each piece of qualitative data was openly coded. Open coding involves reading through the data several times, and labeling chunks of data. Afterwards, the frequency or "groundedness" of each code (Figure 3) was reviewed to identify the most common feedback, either positive or negative (prefixed with a plus and minus sign, respectively).

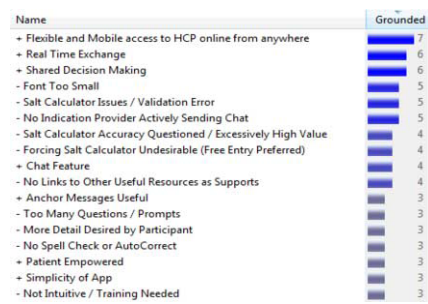

Figure 3 – Participant Feedback by Frequency

Axial coding was then applied to draw categories from the open code list. Axial coding identifies commonalities or relationships amongst the open codes. The "family manager" in the ATLAS.Ti software managed these categories or themes. The derived themes and their frequencies were: communication (10), usability (8), content (8), user interface (9), features (7), chat (6), salt calculator (3) and a miscellaneous (3) category. The themes included both positive and negative feedback, meaning each theme represents areas for improvement. Sorting by theme gives a detailed account of the specific improvements needed. Analysis of the negative feedback showed that all desired improvements were feasible, including functional (e.g., no indication a chat is being sent back), informational (e.g., links to other resources desired) or cosmetic (e.g., font size too small) in nature.

Discussion

A mixed methods study provided rich feedback on possible refinements for the iheart web application. In particular, the qualitative data presented a wealth of information on the benefits and challenges of the intervention that was not apparent in the quantitative data. For instance, the usability section of the post-study questionnaire had a mean score of 2.07, implying the participants moderately agreed the application was usable. Nonetheless, six items were identified in the qualitative analyses to improve the user interface and four items to improve the chat feature. Both the user interface and chat feature contribute to usability.

Additionally, the qualitative feedback identified other practical situations where iheart could be applied to manage chronic illness. In particular, participants felt that iheart would

be very useful in general long term care where a physician is not always present onsite. They also saw value in situations where patient mobility is limited (e.g., cannot leave home).

Vision

A notable feature of iheart is its scalability. The application was designed with expansion in mind. The ontology knowledge model accommodates decision-making with more than one health provider per patient to accommodate multi-disciplinary teams of medical professionals providing care. Due to its reusable components, the web application can be customized for other chronic illnesses as well, thus expanding its use to other medical domains.

The study data demonstrates that participants most appreciated the flexibility, mobility, shared decisions and real time chat exchanges with a remote healthcare provider. This suggests a paradigm shift within the practice of traditional medicine. It means medical providers, endorsing a tool such as iheart, would have to accommodate scheduled "chat time" in their daily or weekly schedule to interact online in a real-time fashion with patients. Or, similar to an online call centre, the configuration could include recruitment of a pool of qualified medical professionals to provide real-time interaction with patients. It is the next frontier in online medicine. Patients are increasingly seeking timely and informative medical answers online. Currently, they seek it in the form of static information (e.g., webMD knowledge bases). Based on our study, it seems that online, human interactive exchange is another appealing knowledge medium for patients.

Limitations

A limiting element of iheart was the loss of face-to-face communication currently used in traditional medicine. Some participants expressed that without facial expressions, body language and visual cues, it was difficult to read the healthcare provider and also describe their medical situation adequately. Seeing how patients appreciated the flexibility and mobility of the real-time text-based chats, this challenge could be addressed through the use of a video chat option. Patients could alternatively have a combined video and text chat (much like a Snapchat session) during shared decision points to reduce the communication void from a text-only session.

Future Work

The iheart application should be revised based on the study feedback. Moreover, a logical next step would be performing an efficacy study, to assess adherence to the application's daily use for managing chronic illness such as hypertension. This study should also solicit input and feedback from a larger selection of healthcare providers.

To further assist in decision making, behaviour change choices available during SDM could be accompanied by evidence-based metrics. A health informatics approach could capture each participant's intervention choice and their adherence to the particular behaviour. After a fixed number of participants (e.g., 100) have used iheart, the cumulative data from people with similar demographics could be used to indicate success rates for each behaviour choice.

Conclusion

The majority of study participants positively perceived the iheart application. Think aloud and qualitative feedback identified specific areas for improvement. The desired improvements are all possible with the exception of the salt calculator, which needs to be changed by its creators. Overall, making shared decisions through a biomedical technology intervention proved both feasible and usable.

As Canada's population is set to enter a period of relatively rapid aging [34], we need to pursue innovative means of delivering care. The Canadian trend for elderly patients with chronic illness or low mobility is to seek care in their homes [35]. As indicated by our test subjects, a system like iheart could be a good fit for residential and long term care of non-critical chronic illness. We recommend the revised version of iheart be pilot tested in a variety of settings where patients have low mobility or challenges reaching their physicians.

Acknowledgments

This study was supported by a NICHE Research grant under the oversight of Dr. Syed Sibte Raza Abidi. The Big Life Salt Calculator was devised by the Ottawa Hospital Research Institute and Dr. Douglas Manuel. Dr. Nelofar Kureshi, Dr. Susan Alexander, Cheryl Merkel and Ann Dent provided feedback or domain expertise to this study.

Experiences of Healthcare Professionals to the Introduction in Sweden of a Public eHealth Service: Patients' Online Access to their Electronic Health Records

Ture Ålander[a], Isabella Scandurra[b]

[a] *Department of Public Health and Caring Sciences, Uppsala University, Sweden*
[b] *School of Business, eHealth, Örebro University, Sweden*

Abstract

Patients' increasing demands for medical information, the digitization of health records and the fast spread of Internet access form a basis of introducing new eHealth services. An international trend is to provide access for patients to health information of various kind. In Sweden, access by patients to their proper electronic health record (EHR) has been provided in a pilot county since November 2012. This eHealth service is controversial and criticism has arised from the clinical professions, mainly physicians. Two web surveys were conducted to discover whether the opinions of healthcare professionals differ; between staff that have had experience with patients accessing their own EHR and those who have no such expericence. Experienced nurses found the EHR more important for the patients and a better reform, compared to unexperienced nurses in the rest of the country. Similarly, physicians with their own experience had a more positive attitude compared to non-experienced physicians. The conclusion of this study is that healthcare professionals must be involved in the implementation of public eHealth services such as EHRs and that real experiences of the professionals should be better disseminated to their inexperienced peers.

Introduction

The increasing demands of patients to read medical information pertaining to themselves, the digitization of health records and the fast spread of Internet access form the foundation of the implementation of a service giving patients direct online access to their electronic health records (EHR). All Swedish patients have a right to obtain a part of their health records [1] and the national eHealth strategy states that all health records should be accessible via Internet (i.e., online electronic health records) by 2017 [2].

Also in European directives, such a solution is sought to gain increased patient safety and security [3]. As the introduction of access to health records by patients and their families is an international trend, findings from research on pilot sites with real experience are of wide interest.

However, patients' access to their own health record is a controversial issue with many aspects. It is since a long time stated that the computerization transforms the accountability of professionals in relation to different actor groups: patients as well as managers, politicians and auditors [4]. The autonomy of the medical profession in relation to organisational governing and control systems has been discussed [5]. A common fear among the professionals is that the autonomy of the medical profession is expected to change and decrease. Less attention has so far been drawn towards professional transparency versus autonomy in relation to the patients, for which this kind of studies provides a basis. With this study, we want to focus on the impact on professionals due to patients new EHR transparency.

In Sweden, EHR systems were adopted quite early. Internet access as well as mobile phones have been widespreaded in the population from the early 1990's. In 1997, Uppsala County Council in Sweden started a project with the aim to give patients access to their medical data. The project called Sustains had financial support from the European Commission [6]. A system was developed to allow patients to have direct access to their clinical notes as well as to several other eServices through a "Healthcare account" similar to a bank account, over the Internet [6]. The system was introduced and used on a solo family practice in Uppsala and tested in clinical practice for many years [7].

The fast digital development and experiences from the Sustains project [6,7] pushed forward a change of the Swedish legislation in 2008 [1], which permitted the healthcare organizations to give patients direct access to their EHRs including the laboratory values and doctors' notes.

All hospitals and primary healthcare centers, except community nurses and some private doctors, in Uppsala County Council, used the same system developed by Cosmic, from a Swedish healthcare IT company: Cambio Healthcare Systems.This facilitated the initial integration work between the region-wide EHR and the public eHealth services.

Within the scope of an EU-project [8] Uppsala County Council in august 2012 introduced a new eHealth service called "My medical record" with the content from the Cosmic EHR. With this eHealth service, the patients from the age of 18 years old have access to all written text, including doctors' notes, on the Internet. The system was tested with employed health personnel in Uppsala County Council before it was launched [9].

In November 11th 2012 the e-service was offered to all 350,000 registered inhabitants in Uppsala County Council and soon later, in December 3rd, to all Swedish inhabitants with EHRs in the Uppsala County. As the first region-wide trial, the patients were given access to their health records through a secure log in to the national eHealth patient portal "My Healthcare Contacts" (www.minavardkontakter.se). People log in to the portal using the same general electronic ID as they use for banking and government e-services. Other e-

services successively introduced in the pilot county through the national patient portal were to:

- book, re-book/re-schedule or cancel an appointment,
- request certificates,
- extend sick leave,
- create safe messages with nurse or doctor,
- update personal data,
- change house physician/family doctor,
- renew medical prescriptions and assistive tools,
- and to order a written copy of the proper medical health record [10].

Apart from reading the medical text, the patient also has access to the audit log, block access to their records, give access to a friend or relative, order, get a SMS reminder of appointments, get a written list of prescriptions and laboratory values, can fill in a health declaration form saved in their records, and see the status and entire flow of their referrals to specialists or hospital. Both authors of this paper have access to their own health record and current version of views of data starts with either a time line or a calendar view, of the patient's choice.

From the release of the eHealth service in the pilot county, the number of users was growing with about 100 new users every day and in September 2013 6.4% of the eligible patients (n=477,928) were users [10]. By the end of 2014 the service had 48,664 unique users that could access their own and/or their family members' records [10]. In March 2015 there are 80,000 users who have had an average of four accesses to their health record and 800 patients accessed their health records every day [11,12].

Although the eHealth service is popular among patients, it is controversial among many professionals, especially physicians [13]. It is evident that increased knowledge of how the e-service influence users, both patients and clinicians, is essential for successful deployment of public eHealth [14] and that such services in general are challenging to put into practice.

This was the first region-wide trial in Sweden. The introduction of patients' access to their EHR creates an unique possibility to examine both longitudinal changes as well as momentary aspects related to professional transparency, patient relations, and patient empowerment.

The study presented in this article is part of a larger research project, DOME, Deployment of Online Medical Records and eHealth services in Sweden [15] with the aim to highlight experiences and effects related to the introduction of public eHealth services. The project was created in July 2012 in order to connect the first European deployment project, Sustains [8], to a purposive research group consisting of 16 nationally spread researchers from various scientific fields. This multi-site and multi-disciplinary composition provides a unique opportunity to highlight the issues from various research aspects through different methods and studies. Currently the senior researchers cover the areas of information management, human-computer interaction, IT and work environment, management and business studies, information security, healthcare informatics, medicine, organization theory, eGovernment, information technology, engineering education and statistics [15].

Different evaluation studies are taking place within three work packages, where this work is part of comparisons of surveys directed towards health care professionals in work package B, professions and management. The research questions for this study were:

- Which were the attitudes of the nurses and the physicians after they had been working some time within the pilot county compared to professionals that were not yet experienced with the eHealth service?
- Do experiences from the pilot county differ from regions where patient access to Electronic Health Records are not yet implemented?

Materials and Methods

Patients from Uppsala County Council who were treated in hospital and primary care and patients from other counties who had received care in Uppsala County Council all have direct access to their EHRs since December 2012. The service is optional to use for patients and there is no requirement for staff or patients to talk about the usage of the service.

The two web surveys of this study were distributed to the physicians in Uppsala county 6 months after the deployment of the new e-service and to the nurses 9 months after the deployment. Data were collected from two similar 5-graded Likert scale web surveys (S1 and S2) to Swedish healthcare staff and is focused on attitudes and opinions of physicians (S1) and nurses (S2). To each set of statements, there was also a possibility to give answers in free text.

S1 was sent out in June 2013 to 1,602 physicians in the pilot county with a response rate of 25% (399 respondents, 52% women, age 25-71 years, median worktime 14 years, 78% worked inhospital and 22% in primary care, 85% native in Swedish language).

S2 was sent out in March 2014 to 8,460 registered nurses and midwives in Sweden with a response rate of 35,4% (2,867 respondents, of whom working as nurses were 84%, midwives 6%, chief position 5%, in projects 2% and other 3%). The questionnaires consisted of background questions and five sets of items with free text fields to each set. To deliver the questionnaires the Uppsala County Council's and the Swedish Association of Health Professionals' internal web survey tools were used. The accompanying letter stated that responding was voluntary and that the time spent to respond according to the strongly agree (5) - strongly disagree (1) - scale was approximately 10 minutes.

Ethical approval for S1 was granted by the Uppsala County Council's research units as well by the Swedish central ethical committee. S2 was conducted according to the principles of the Declaration of Helsinki.

Standard data reports were created for each survey with charts showing the most prominent differences in each statement. As the questionnaires were jointly developed and contained some identical statements, this first analysis expects to discover differences between nurses and physicians that have experience of patients accessing their EHRs online and those working in regions where the eHealth service had not yet been implemented. The two different questionnaires distributed to the nurses and physicians contain more statements to analyze, however the responses handled in this study are consistent between the two surveys. Currently other statements from the data-sets are jointly being analyzed by statistics, clinical and healthcare informatics researchers and students and will be published in the near future.

The statements analysed in this study regard to which extent patients' access to EHRs online is considered useful for the patients, if their relatives were given access to their EHRs and whether the professionals consider the new eHealth service being a good reform. In the questionnaires the statements read:

- To which extent do you consider it a benefit for the patients that their relatives have a possibility to take part in their EHR?

- To which extent do you consider the eHealth service "online health records" a good reform?

Simple statistics were used for analysis. The Mann-Whitney ranksum and χ^2 tests were used for evaluating the statistical significance for ordinal and nominal data, respectively. The data was analyzed by the Stata statistical package 13.1 [16].

Results

The responses of the physicians to the multiple choice questions are presented in Table 1 based on a 5-graded scale from strongly disagree (1) to strongly agree (5). The responses of the nurses are presented in Table 2 and Table 3. In general, professionals' opinions of patients reading their health record online were negative (grade<2.5) among physicians and positive (grade>2.5) among nurses. Physicians were negative to giving relatives of the patients access to the EHR and they were also negative to the reform as such. Both pilot nurses and those outside the pilot county were generally more positive than the physicians.

Nurses in Uppsala County Council with experience with EHRs were significantly more positive to reform ($p<0.001$) than nurses outside the pilot county. 40% stated that they agreed or strongly agreed to 'patients receiving online access to their EHRs being a good reform' compared to nurses in the rest of the country (25%) as well as physicians, where 82% disagreed or strongly disagreed.

Table 1 – Physicians working in the pilot county (Uppsala County Council) Responses to the statement "To which extent is it a benefit for the patients that their relatives have a possibility to take part in their EHR?" and whether the eHealth service "is a good reform".

Five-graded Likert scale 1-5 where 5 = strongly agree.

	Access for relatives	A good reform
N	381	385
Mean	2.22	1.66
SD	1.08	0.97

In one of the background questions of the web questionnaire, 61 physicians of 399 (15%) stated that they for themselves or their relatives had personal experience of using this eHealth service as patients.

A sub-analysis revealed that their own usage was equal between hospital and primary care physicians, females and males, but that the users were younger ($p=0.0004$).

Physicians using the eHealth service themselves, compared to non-users, regarded the eHealth service:

- more important for patients ($p=0.0001$),
- to improve quality in care ($p<0.0001$),
- to contribute more to equality in healthcare ($p=0.0003$),
- they experienced less change in their working conditions ($p=0.014$),
- found the eHealth service being a good reform to a greater extent ($p=0.003$),
- thought their medical noting had improved since the eHealth service was introduced ($p=0.021$) and
- found the launch of the reform better ($p=0.019$).

Table 2 – Nurses working in and outside the pilot county (Uppsala County Council). Responses to the statement "To which extent do you consider it a benefit for the patients that their relatives have a possibility to take part in their EHR?"

Five-graded Likert scale 1-5 where 5 = strongly agree.

	Pilot county	Outside Pilot	P (Mann-Whitney)
N	234	2495	
Mean	3.08	2.92	0.0454
SD	1.16	1.12	

Table 3 – Nurses working in and outside the pilot county response to the statement "To which extent do you consider the eHealth service "online health records" a good reform?"

Five-graded Likert scale 1-5 where 5 strongly agree.

	Pilot county	Outside Pilot	P (Mann-Whitney)
N	235	2494	
Mean	3.17	2.71	<0.0001
SD	1.27	1.17	

Again, nurses from the pilot county were far more positive (35% agree and strongly agree) to the importance of this eHealth service for the patients, compared to nurses outside the pilot (25%) as well as physicians (64% disagree or strongly disagree).

Discussion

This study aimed to investigate the opinions of health professionals related to the introduction of a new eHealth service: giving patients direct access to their EHRs, in Sweden. The main outcome of this study was that many professionals were reluctant with the proposed eHealth service, and that professionals with personal experience with the innovation were more positive as to the benefit for patients than healthcare professionals without experience.

Nurses with experience with the service were significantly more positive to reform ($p<0.0101$) than nurses outside the pilot region. The physicians within the pilot region were generally more negative compared to nurses in the same region. However, the time spent between the questionnaires (9 months) does cause an uncertainty as to comparability between the opinions of the professionals. The longer use time for nurses compared to physicians may have given the nurses a more positive attitude.

The authors' knowledge about the context in which this deployment process took place is worth mentioning. During the deployment project [8], representatives of the physicians' local union in the pilot county expressed a distrust of the eHealth service, whereas the Swedish Association of Health Professionals (the union for the nurses and midwives) embraced the development and deployment of such eHealth services. These different statements could have affected the respondents of this study.

However, in another study, free text responses from the survey of the physicians were analyzed and revealed that the physicians in general were negative and many also upset over the deployment of an eHealth service giving all patients digital access to their medical records. The physicians were especially concerned about increased workload and patients' risk of misunderstanding the notes and laboratory findings. These findings are further presented by Erlingsdottir et al [13].

These findings correspond to the hypothesis that physicians have a wider knowledge and a stronger patient relationship

than nurses. Thus they feel a greater threat to their autonomy and thus get a more negative attitude to online EHRs for patients.

As the patients become more knowledgeable, the privileged position of the professionals changes. As early as in 1985, Freidson argued that computerization may contribute to the decreasing of the knowledge gap as more and more information becomes easily accessible [4]. According to Freidson, the key question is whether laymen are able to mobilize sufficient motivation to become knowledgeable to the extent that they will be able to challenge professional actors. Possibly, the resistance that is noted in this study could be related to the intrinsic conflict when patient empowerment encounters professional autonomy [17], which needs to be further investigated.

It appears that the overall trend in the results of this study is that a negative attitude predominated among the professionals. However, the difference between experienced and inexperienced nurses, as well as physicians, was significant. As the introduction of electronic access to patients' health records and other similar eHealth services is on the eHealth agenda of many countries, we find it important not only to display the attitudes of the majority of professionals to the idea of patient access to EHRs, but also to show the findings from real experience. Although the results from the pilot county are not strong enough to translate into real qualitative changes in attitude, we found the changes to be statistically significant and therefore worth discussion.

Again, the difference between experienced and inexperienced nurses as well as physicians, was significant. Possibly the nurses in the pilot county have not experienced an increased workload and no harm to the patients, which was stated as a fear by physicians in the free text responses [13]. Moreover, the eHealth service may have a positive effect on the patient consultation. The opinions of physicians who used the eHealth service for themselves or their relatives were remarkable. They differed significantly from physicians not using the service. They found that the eHealth service more important for patients and that it improved quality in care to a greater extent. Probably their own usage has a strong positive influence on their attitudes.

In previous studies on giving patients web access to their own health data, patients regard the online access as a step towards increased quality of care and patient empowerment [18,21]. Other studies indicate that patients think privacy concerns are outweighed by benefits [22] and physicians do not experience significance increase in work load [23]. Checkland et al. argue, somewhat in opposition to Freidson, that direct access to information over the Internet may contribute to enhanced trust in the patient-doctor relationship as the patient becomes knowledgeable and enlightened [19].

Information and communication technology innovations are being increasingly used to supply citizens with various health services which will lead to new demands on health and social care organizations. There is a strong need for further studies to investigate how this new trend will influence patients and health personnel. Knowledge that experienced staff hold a less negative attitude is a factor that could support future deployment processes and may lead to an increase in acceptance [24,25]. Therefore, it is important to disseminate these results to the inexperienced peers that today are standing on the verge of the deployment process of such eHealth services in their organizations.

It is in line with the interest of action researchers to address the challenge of overcoming the clash between patient empowerment and professional autonomy. One means could be to emphasize the introduction method of an innovation in a socio-technical way [18]. Different methods of measurement around the introduction of a system can be integrated with each other, e.g., TAM, Theory of Planned behavour and Innovation Diffusion Theory [24,25]. Yi et al. [24] offer a set of measurement criteria required for a specific intervention, which could be the deployment of a public eHealth service. Based on the suggestions from Yi et al. [24], an adaptation has previously been applied to support the introduction of an eHealth system in a Swedish county council, with successful results [18]. Such an adaptation would be interesting to repeat, when innovations like this eHealth service are to be implemented in other regions.

Conclusion

The main outcome of this study is that many professionals are reluctant when faced with patients having access to their EHR and that professionals with personal experience of the innovation are more positive as to the benefit for patients than healthcare professionals without experience. The study shows that health personnel have concerns about patients' direct access to their EHR in terms of the benefit for patients if their relatives also have access. Physicians and nurses having their own experience with online EHRs demonstrate a positive attitude towards the benefit for patients to a greater extent. The success of the introduction of reforms from the patients' point of view is accompanied by the possibility for professionals to get used to the eHealth services. We therefore recommend that healthcare professionals should be more involved in the implementation of Public eHealth services such as online EHRs and that real experiences of the professionals should be better disseminated to their inexperienced peers.

These findings, based on real experiences, are of interest in the upcoming introduction of similar eHealth services in Europe [25], as well as in other countries with a public eHealth strategy agenda.

Acknowledgements

The action research project "DOME - Deployment of Online Medical Records and eHealth Services" is financed by VINNOVA (2012-02233) – Swedish Governmental Agency for Innovation Systems. The SUSTAINS implementation project is supported by the European Commission (No 297206). We would also like to give our gratitude to the Uppsala County Council for supporting the distribution of the web questionnaires to the physicians and the Swedish Association of Health Professionals for distributing the questionnaire to their members. Special thanks to all the respondents who participated.

Abstract

Patient-facing technologies are increasingly utilized for direct patient data entry for potential incorporation into the electronic health record. We analyzed patient-entered data during implementation of a patient-facing data entry technology using an online patient portal and clinic-based tablet computers at a University-based tertiary medical center clinic, including entries for past medical history, past surgical history, and social history. Entries were assessed for granularity, clinical accuracy, and the addition of novel information into the record. We found that over half of patient-generated diagnoses were duplicates of lesser or equal granularity compared to previous provider-entered diagnoses. Approximately one fifth of patient-generated diagnoses were found to meet the criteria for new, meaningful additions to the medical record. Our findings demonstrate that while patient-generated data provides important additional information, it may also present challenges including generating inaccurate or less granular information.

Keywords:
Patient generated healthcare data; Patient facing technology; Electronic Health Record;

Introduction

As patient-centeredness is an increasingly important tenet in healthcare, technologies engaging patients for individual assessment of clinical status, satisfaction, and education are being implemented in larger number. Moreover, the importance of patient engagement for attracting and maintaining patients is increasingly recognized by health systems [1]. As part of this, the electronic health record (EHR) has undergone significant change, including the integration of patient-facing portals with the EHR. Increasingly, portals and other patient-facing tools allow patients to access their own medical data and in some cases grant the ability to modify or comment on the data in these platforms [2].

A number of studies have shown that patients find the use of a patient portal for direct data entry to be a positive experience. Wu et al. reported 98% of patients in their large cohort found the use of a clinic-based kiosk for patient-generated family health history information to be useful [3]. A similar study found over 90% satisfaction with a similar online patient-facing family health history tool in a population of Veterans Administration patients [4]. Patient-facing tools relying on patient-generated data for realtime feedback have also been used with success in the areas of lifestyle modification [5] and chronic disease management [6].

To date, there are few studies assessing the quality of patient-generated healthcare data. While there have been some reports of positive effects with the addition of clinically relevant data [7,8], these studies have been limited to certain diagnoses, such as cardiac disease, or to certain portions of the medical record, such as family history [4,8]. In this study, we sought to better understand patient entered data broadly for different aspects of health history through an evaluation of the quality of patient-generated data using a patient-facing health history tool for past medical history (PMH), past surgical history (PSH), and social history (SH).

Materials and Methods

The patient-facing tool evaluated in this study was available September 2014 to patients with appointments at a surgery clinic for the University of Minnesota Physicians. The content of the tool was an organization-wide health history questionnaire approved by the medical directors of the practice plan. The tool was available to patients enrolled in the EHR online patient portal prior to the clinic appointment. For those patients not enrolled in the online patient portal or with portal access but who failed to utilize the tool prior to presentation in clinic, tablet computers were made available on site for completion prior to meeting with the provider. Previous studies have shown that patients respond well to tablet computer-based health applications, despite bias that these technologies might be unusable in certain patient populations, such as the elderly [9].

The questionnaires were only available in English and covered PMH, PSH, and SH. Patients were presented with a list of 40 common medical diagnoses, 22 surgical procedures, and four social history domains. PMH and PSH sections included "Yes" or "No" options, as well as a "Comments" section for free-text of additional conditions and procedures. The SH portion of the tool included questions related to tobacco use, alcohol consumption, illicit substance use, and sexual history. For the first three, patients were asked about use, type, amount, duration, and date of cessation (if applicable). The sexual history domain included current status, partner gender, and any birth control measures.

Following completion of the tool, results were immediately available to the clinician on the enterprise Epic EHR system. The provider then was presented with the opportunity to "accept" or "reject" patient entered information. If accepted,

the entries were then associated with discrete diagnosis terms and diagnosis codes in the PMH and PSH sections, as well as the discrete data fields of the SH section.

Table 1 – Physician-rater Diagnosis Coding

Physician-rater grade	Example
Duplicate Diagnosis Diagnosis already in PMH/PSH. Granularity of diagnosis is equal or near equal to that in the PMH/PSH.	Patient enters "Hypertension". "Hypertension" in PMH.
Duplicate Low Granularity Diagnosis Diagnosis already in PMH/PSH. Granularity of diagnosis is less that that in the PMH/PSH.	Patient enters "Kidney Problems". "Diabetic nephropathy" in PMH - Patient enters "Fracture or Broken Bone". "L3 compression fracture" in PMH.
New Low Granularity Diagnosis Diagnosis not in PMH/PSH and insufficient granularity to provide clinical utility.	Patient enters "Respiratory Problem". No previous respiratory diagnosis listed. Patient enters "Fracture or broken bone" but fails to mention anatomic location.
New False Diagnosis Diagnosis not in PMH/PSH and with sufficient granularity to provide clinical utility but on EHR review appears unlikely to be true.	Patient lists "Blood Clotting Disorder". Clinician notes "no evidence of thrombophilia" in Hematology clinic progress note.
New Diagnosis with Utility Diagnosis not in PMH/PSH and with sufficient granularity to provide clinical utility and corroborating EHR information.	Patient enters diagnosis of "Anxiety". No mental health problem is listed in PMH. Review of patient's medication list shows benzodiazepine. Patient enters a history of cholecystectomy. None is listed in PSH. CT scan report reads "gallbladder surgically absent".

We reviewed the data of 50 patients who completed the tool within the first six weeks of implementation, out of a possible 146 eligible participants (response rate 34.2%). Inclusion criteria included any new or return patient to the clinic who previously had been seen within the institution. A "New" visit type was designated for a visit where the patient had not been seen in surgery clinic before and were new to the provider, but had been previously seen by another provider (outside of our surgery clinic) within the Fairview Healthsystem. Since our analysis included comparing patient-generated data against data already contained within the enterprise EHR, patients new both to the clinic and to the healthcare system were excluded from this study. All patient-generated diagnoses were reviewed, regardless of acceptance by the provider.

As summarized in Table 1, each diagnosis entered was then reviewed by an independent physician-rater. The initial step required the physician to determine whether the patient-generated diagnosis was previously listed in the PMH and PSH of the patient chart. The next step involved gauging the level of granularity provided by the patient-generated diagnosis. For those diagnoses previously listed in the EHR, the rater then determined if the patient-generated diagnosis was either equal in granularity or lesser in granularity compared to the initial diagnosis. The physician-rater also gauged the granularity of any diagnosis deemed "New" on review in the initial step. Patient-generated diagnoses lacking sufficient granularity to enrich the clinical picture of the patient were classified as "New Low Granularity Diagnosis". Those patient-generated diagnoses judged to be of sufficient granularity to provide enrichment of the clinical history underwent a third level of scrutiny. In this final step, the physician-rater reviewed the patient chart to look for evidence to suggest if the patient-generated diagnosis was likely to be accurate. Clinical narratives from physicians, both from within and outside of the health system, were utilized as well as imaging studies, relevant laboratory values, medication lists, and procedure/endoscopy notes, as appropriate. Inter-rater reliability was assessed in five (ten percent) patient charts by a second physician-rater. Percent agreement and Kappa were calculated for coding of PMH/PSH diagnoses/procedures. Institutional review board approval was obtained and informed consent waived for this minimal risk study.

Results

Information about the patients and their types of visits are summarized in Table 2. In total, the 50 patients had a total of 435 patient-generated medical diagnoses, 231 surgical procedures, and 188 social history elements associated with these visits.

Table 2 – Patient Demographics and Visit Type

Demographic	n (%)
Age, range (mean)	18-74 (49.0)
Gender (female)	26 (52.0)
Visit Type	
New	6 (12.0)
Return	44 (88.0)
History Information	
Patient-generated diagnoses	435
Patient-generated procedures	231
Patient-generated social history	188

Over 50 percent of patient-generated medical diagnoses were duplicates of diagnoses already contained within the PMH portion of the EHR (Table 3). Of these duplicates, slightly greater than half of patient-generated diagnoses were of equal granularity to previous provider-entered diagnoses. The remaining half of the duplicated diagnoses had less granularity compared to previous provider-entered diagnoses. Nearly ten percent of the patient-generated diagnoses were determined to be new, but lacked sufficient granularity to provide meaningful clinical enrichment (New Low Granularity Diagnosis). Of the patient-entered diagnoses determined to be

both new and providing sufficient granularity to be considered clinically meaningful, nearly half were corroborated on chart review with the other half lacking sufficient evidence within the EHR to verify diagnosis (New Diagnosis with Utility and New False Diagnosis, respectively). Over 20 percent of new diagnoses deemed true based on chart review were related to mental health conditions (13.8% anxiety, 7.5% depression). History of colon/rectal polyps (11.3%) and history of blood transfusion (8.8%) were also common patient-generated diagnoses that were found to be true. Inter-rater reliability with a second physician-rater resulted in percent correlation of 0.89 and Kappa statistic of 0.817.

Forty-six of the 50 patients in this study completed the surgical history section of the survey. Two patients listed no previous surgeries. A total of 231 surgical procedures were entered by the remaining 44 patients (Table 4). Nearly 75% of surgical procedures were duplicates of procedures already recorded within the PSH portion of the EHR. Twenty-three percent were determined by an independent physician-rater to provide equal granularity to procedures previously listed. Nearly 52% were found to be of insufficient granularity compared to the surgical history already available in the EHR. The remaining surgical procedures entered were new to the PSH portion of the EHR. Of these, nearly half (ten percent of total) were determined to provide insufficient granularity to be of clinical utility. However, 11.3% of the total surgical procedures entered by patients were found to be new, sufficiently granular, and had evidence within the EHR. Three percent of surgical procedures entered by patients were new and sufficiently granular, but had no evidence within the EHR. One patient entered the same surgical procedure twice (Duplicate Entry – 0.9% of total). Inter-rater reliability with a second physician-rater resulted in percent correlation of 0.9 and Kappa statistic of 0.837.

Table 3 – Past Medical History

Category	n (%)
Duplicate Diagnosis	117 (26.9)
Duplicate Low Granularity Diagnosis	112 (25.7)
New Low Granularity Diagnosis	43 (9.9)
New False Diagnosis	82 (18.9)
New Diagnosis with Utility	80 (18.4)

All 50 patients completed at least one of the four domains within the SH portion of the survey. Overall, 188 data elements relating to tobacco, alcohol, and illicit substance use, as well as sexual history data, were entered. This patient-generated data for SH was compared to that already present within the EHR as depicted in Table 5. There were very few instances where patient-generated data did not concur with pre-existing data in the EHR. Only one new data element was found in both the tobacco and alcohol use portions of the SH domain. In the illicit substance portion, three instances of new information were noted. Interestingly, 11 instances of new information were observed for sexual history.

Table 4 – Past Surgical History

Category	n (%)
Duplicate Diagnosis	53 (23.0)
Duplicate Low Granularity Diagnosis	120 (51.9)
New Low Granularity Diagnosis	23 (10.0)
New False Diagnosis	7 (3.0)
New Diagnosis with Utility	26 (11.3)
Duplicate Entry	2 (0.9)

Results of physician ratings were compared between Past Medical and Surgical History diagnoses (Tables 3 & 4) using post-hoc chi-square analysis. Notable differences between medical and surgical diagnoses were observed in New False Diagnoses (18.9 vs. 3.0%) and New Diagnoses with Utility (18.4 vs. 11.3%) with significant results (χ^2 = 63.36, $p<0.0001$). Results were also compared by gender, age (≥50), and visit type in post-hoc analysis. When combining both medical and surgical diagnoses, we observed a difference in physician ratings between male and female patient-generated diagnoses, with the largest difference observed in the rate of New Low Granularity Diagnoses (13.7 vs. 6.6%, χ^2 = 11.17, $p=0.0247$). Similarly, the difference in physician ratings of diagnoses generated at New versus Return visit types approached significance (χ^2 = 9.35, $p=0.0529$), especially with Duplicate Diagnoses and New False Diagnoses (13.6 vs. 26.8% and 23.7 vs 12.4%). Age did not correlate with any difference in physician rating of patient-generated medical or surgical diagnoses (χ^2 = 2.42, $p=0.659$).

Table 5 – New Social History Data Elements

Category	n (%)
Tobacco	1 (5.9)
Alcohol	1 (5.9)
Illicit Substance	3 (17.6)
Sexual History	11 (64.7)
Total	17

Discussion

This study summarizes the quality and potential value of data generated with web and tablet-based data entry of health history information by patients. Previous studies have found clinical utility in patient-generated data related to chronic disease management, such as entering home blood pressure measurements using an online patient portal [6] and family history [8]. This study provides an analysis of more comprehensive patient-generated data.

Over half of patient-generated medical diagnoses and nearly 75 percent of surgical diagnoses were duplicates of those already recorded within the PMH and PSH portions of the EHR. This is consistent with other studies including Manaktala et al. and Okura et al which found good concordance between patient self-reported data and the medical record [7,10]. A broader study by Tisnado et al. examining a paper-based patient survey compared to the medical record found concordance between both data sources varied considerably. Concordance between diagnoses like "History of acute myocardial infarction" and "Diabetes" were high. Less concordance was evident with more subtle diagnoses such as "Depressed Mood", "High Cholesterol" or history of having had a previous echocardiogram [11]. Our results were similar to these previous studies. Similarly, much of the duplication of previously-recorded diagnoses in this study occurred with cardiovascular health (data not included in results).

Surgical diagnoses mirrored medical diagnoses, in that the vast majority of patient-generated data was a duplication of what already existed in the EHR. Interestingly, the rate of New False Diagnosis was considerably lower for PSH vs PMH (3.0 vs 18.9%). Likely, this is due to clearer knowledge on the part of patients regarding previous procedures. Patient self-knowledge of past surgeries is not a novel finding. In the previously mentioned work by Tisnado, the authors found excellent correlation between the patient survey and medical record for the diagnosis "History of coronary artery bypass or angioplasty" and fair agreement for previous cardiac catheterization [11].

The rate of correlation between patient and medical record is encouraging. More interesting, nearly 20 percent of patient-generated medical diagnoses and 11 percent of surgical ones were found to provide a new, sufficiently granular piece of data that was deemed to be likely accurate based on chart review by a content expert. These diagnoses represent discrete data elements not previously being captured in the PMH or PSH sections of the EHR. However, there was some evidence found within the clinical narratives, laboratory values, or imaging data contained within the institutional EHR. The most frequent patient-generated diagnoses that met criteria related to mental-health, specifically anxiety and depression. Hulse et al. found a similar phenomenon during the introduction of a patient-facing health history tool at their institution [12]. Previous literature comments on the prevalence of mental health diagnoses in patients with gastrointestinal disease [13]. The implications of uncaptured data regarding mental health conditions in this population of patients in a single clinic requires further inspection and analysis.

The failure to capture diagnoses as discrete data elements within the EHR has wide-ranging implications. As the EHR is increasingly utilized for secondary use, the need for complete data is more important. Tate et al. describes data quality as a 'sine qua non' for EHR use in randomized control trials [14]. Accurate and complete data is necessary to ensure high quality phenotyping, cohort discovery and recruitment into randomized controlled trials.

An additional 20 percent of patient-generated medical diagnoses and only three percent of surgical ones were deemed both new and sufficiently granular, but no evidence of disease or prior procedure could be found based on chart review. We were limited by the information provided by our institutional EHR. In this era of fragmented care, patients can have missing clinical data that is contained within other institutions or health systems. In some cases, our institutional EHR included clinical narratives, laboratory values, and the results of imaging studies performed outside. It is reasonable to assume that some portion of these patient-generated diagnoses are true and that supporting healthcare data exists within another institution's EHR .

Nearly ten percent of both medical and surgical diagnoses entered were new additions to the chart, but were of such low granularity that they were not clinically meaningful. Further, nearly half of the duplicated medical diagnoses and two-thirds of the duplicated surgical procedures were rated as less-granular versions of diagnoses or procedures already within the PMH and PSH sections of the EHR.

This study also gives an initial insight into the design of the patient-facing tool. Many of the diagnoses listed in the survey provided sufficient granularity without the need for free text entry by the patient (i.e. "Hypertension", "Diabetes mellitus", "Cholecystectomy"). In order to provide a comprehensive list of medical history conditions and surgical procedures that would not be found cumbersome for most patients, the survey was reliant on free text entry in order to provide sufficient granularity for certain diagnoses and procedures. For instance, when "Fracture or Broken Bone" or "Cancer" was selected, the tool relied on patient free text to specify the anatomic site or type. When "GI surgery" was selected, the tool relied on free text entry to specify the site and procedure. An overwhelming majority of patient-generated diagnoses did not include any free text entries associated with them. This was a major limitation of our study. It can be reasonably inferred that patients will not provide further granularity to diagnoses beyond that which is suggested to them on the Health History tool. Further work needs to be done to elucidate reasons why most patients are not engaging with the tool with free text entry. It may be that during the clinic intake process, patient-generated diagnoses from the tool need immediate addressing and clarification by clinic staff. This would require a major shift in intake workflow, most of which is currently being done by medical assistants. This also is an opportunity to reflect on the design of the tool, specifically in regards to the granularity of the diagnoses provided. Perhaps a drop-down menu approach would provide greater ease of use and ensure greater granularity compared to free text entry by patients. Another limitation was the low response rate of patients eligible to use the tool (34.2%). Clearly, buy-in from clinic personnel needs to be sought prior to introduction of these patient-facing technologies in order to address inevitable changes in workflow. This is being done in further iterations of this work.

One important limitation of the current study and an important area to further characterize is the amount of time required for providers to review patient-entered data. While there is an assumption that having patients enter their own data brings efficiencies, the time saved with patient-entry must be counter-balanced by the time to review and potentially correct and verify patient data. This question could likely be answered with an additional observational study or possibly a log file analysis of provider use of the EHR and consumption of patient entered data.

A significant portion of the patient-generated Social History data matched that which was already present within the EHR. There were very few instances within tobacco, alcohol, and illicit substance use history where patient-generated data was found to provide new information. Likely, this is related to the fact that well-established structured data fields have been in existence for these topics and have been utilized preferentially for some time over unstructured free text [15]. In the domain of sexual history, eleven instances of new information occurred. In nine of these instances, no previous sexual history had been recorded and the patient-generated data represented the first present within the EHR. Thirty nine charts (78 percent) contained previous provider-entered sexual history data. This mirrors previous work by Goyal et al. who observed 82 percent of patient charts containing a sexual history in their cohort of emergency department patients. We also found similar results in that when sexual history had been previously entered by the provider, it had a high rate of concordance with the patient-generated sexual history data [16].

Conclusion

Patient-generated health data is becoming more prevalent in healthcare. We are starting to see the EHR as a dynamic instrument in which patients not only access health data, but are engaged in data input as well. In this pilot study, we observed and graded patient-generated health data obtained during the rollout of a comprehensive health history tool via two patient-facing modalities. While the majority of patient-entered diagnoses were already captured in the EHR, nearly 20 percent of patient-generated medical diagnoses and eleven percent of surgical ones were found to be new, granular, and supported by other data within the chart. These results should be met with guarded optimism. Successful implementation of patient-facing technologies requires significant front-end work. IT experts, informaticists, and clinicians need to be engaged to design a suitable tool that combines ease-of-use with granular data capture. Provider and non-provider clinic personnel buy-in is also necessary early in the process, as these technologies will highly affect existing clinic workflows. Future work will include engaging both patients and clinicians to further optimize the user interface and workflows. Ultimately, it appears that patient-entered health history data has the potential of improving clinical data in the EHR and improving these approaches could potentially enable easy, accurate, granular data entry valuable to clinicians and researchers.

Abstract

Recognizing clinical style is essential for generating intelligent guidance in virtual reality simulators for dental skill acquisition. The aim of this study was to determine the potential of Dynamic Time Warping (DTW) in matching novices' tooth cutting sequences with those of experts. Forty dental students and four expert dentists were enrolled to perform access opening to the root canals with a simulator. Four experts performed in manners that differed widely in the tooth preparation sequence. Forty students were randomly allocated into four groups and were trained following each expert. DTW was performed between each student's sequence and all the expert sequences to determine the best match. Overall, the accuracy of the matching was high (95%). The current results suggest that the DTW is a useful technique to find the best matching expert for a student so that feedback based on that expert's performance can be given to the novice in clinical skill training.

Keywords:

Automated procedure assessment; Dynamic time warping; Virtual reality; Haptics; Dentistry.

Introduction

The teaching of surgical skills, which has traditionally followed an apprentice style approach, is now facing a number of challenges that are driving medical schools to seek alternatives. One challenge is that increasing enrollment combined with time constraints on the time of expert surgeons means that students typically do not receive as much supervised training as would be desirable. Rather, students end up spending a significant portion of their training time carrying out unsupervised practice. Furthermore, medical schools have little choice but to set requirements for surgical curricula in terms of amount of training time spent rather than in terms of level of proficiency achieved [1]. Even when assessment is carried out, it is by nature subjective, lacking sufficient standardization.

In response to these challenges, researchers have been developing new types of simulators and medical schools have been exploring the use of simulation in surgical training curricula. These efforts have particularly benefited from advances in virtual reality (VR) technology. VR simulators now exist for training in a variety of surgical domains, [2–6] and VR simulators have been introduced into dental curricula as training devices for clinical skill acquisition in several tasks [7, 8]. VR simulators enable collecting detailed data on relevant metrics throughout a procedure and thus provide a basis for detailed and objective procedure assessment. Indeed, a great volume of recent research has focused on developing metrics and techniques for objective assessment of surgical skill level [9–12]. Such analyses can be used for summative assessment and more excitingly for formative assessment by incorporating mechanisms for tutorial feedback generation into the simulators. But as research has progressed in this direction, researchers have come up against the complicating factor of the great variability with which any particular operation may be carried out [13, 14]. Such natural variability, not only in minute details of movement but also in style, poses a challenge for assessment. In domains where procedures may be carried out in multiple acceptable ways, an effective teacher must be able to recognize the style that a student is naturally using and provide corrective guidance relative to that style. This should also be the case for any simulator that generates tutorial feedback. To achieve this, the first challenge that must be solved is to recognize the style being used by a student even if it is being carried out incorrectly.

In this paper we present an approach to identifying the expert procedure from a set of stored procedures carried out in different styles that best match a student procedure. We make use of a VR dental simulator that we have developed for teaching dental procedures [6]. The system includes haptic feedback that can simulate tooth surface exploration and cutting for tooth preparation. It can automatically record performance and kinematic data on how experts and novices perform each step of a task, e.g., tool path, angulations and force used, which are not available in conventional skill training environments. For the present work we make use of only information about tool path and time.

Identifying stylistically similar procedures based metrics such as tool path and timing is challenging. Even if the expert and student are following the same basic path, the student movements are typically less smooth, resulting in differences in path location and path length. Velocity of movement of students is also typically slower than that of experts. Dynamic time warping (DTW) [15, 16] is a technique introduced for the analysis of handwriting that is designed to cope with some of these challenges. DTW determines the similarity of two trajectories of motion in cases where the trajectories may differ in terms of length and timing. In analysis of surgical procedures, DTW has been applied to the problem of spatio-temporal registration of trajectories for recognition of surgical gestures [17]. The present study aims to determine the potential of DTW in matching novices' tooth cutting

sequences with those of experts for the task of performing access opening to the root canals.

Methods

Dental virtual reality simulator and on-line data collection

We developed VR simulator that operates on a standard PC with an Intel Core 2 Duo 2.8GHz CPU, 4 GB RAM, and an nVidia GeForce 9600GT video card with 512MB of RAM connected to a 15-inch monitor and two PHANToM Omni haptic devices in a dual configuration, representing a handpiece and a dental mouth mirror. (Figure 1). The PHANTOM Omni haptic devices (SensAble Inc., USA) allow six degrees of freedom positional sensing and generate three degrees of freedom force feedback with a maximum of 3.3 N. The simulation software was developed with C++, OpenGL, and OpenHaptics SDK (HDAPI). The tooth model was acquired using three-dimensional micro-CT (RmCT, Rigaku Co., Tokyo, Japan). Tomographic images were obtained using comprehensive dental imaging software (i-VIEW, Morita Co., Tokyo, Japan). Three-dimensional reconstruction was performed using 600 of these two-dimensional images processed by volume rendering. During simulation, a user could feel different force feedback when cutting through enamel, dentin, and pulp.

Figure 1 - A dentist performed access opening to the root canals with a haptic virtual reality simulator

Forty-four volunteers (40 fourth-year dental students (Novice), ages 20-23 years, and 4 dentists (Expert), ages 35-45 years) were enrolled in this study. All participants gave their written informed consent approved by the Institutional Ethical Review Board. Novices had experience using dental handpieces in cavity preparation from the operative preclinical course but no prior experience performing root canal treatment. Experts had professional training and experience in root canal treatment. All participants were right-handed. None of the participants had received any skill training using the haptic VR simulator.

All participants were briefly instructed on the use of the haptic VR simulator and the requirements of tooth preparation. The participants received a verbal explanation about the use of the system from the investigators and spent 15 minutes familiarizing themselves with the system interface, but not with the task. During this familiarization period, each participant was allowed to ask questions and receive further verbal explanation and suggestions from the investigators. After familiarization, the participants performed two trials of the task during which results were not recorded. The third trial was used for data collection. Participants were given the task of performing access opening to the root canals on the upper right first molar with the haptic VR simulator. The task was designed to mimic real access opening and to require hand-eye coordination for quality performance (Figure 1).

During data collection, data was gathered on elapsed time and kinematic variables with respect to the position of the handpiece in x, y and z direction, angulations of the handpiece with respect to x, y and z direction, transformation of the handpiece from the original position, drilling enabled/not enabled, position of the mirror in x, y and z direction, angulations of the mirror with respect to x, y and z direction, transformation of the mirror from the original position, and the force used in x, y and z direction.

Recognition of Clinical Process using DTW

Experts and novices performed operations on the dental simulator generating an output file which contained the kinematic attributes mentioned above in every millisecond. In this study, we selected the handpiece positions and movements as features for finding similarity between expert and novice and only the data when the user had enabled the drill for cutting was considered. Figure 2 shows the path of one expert and one novice in 3D space. Handpiece positions were normalized using $(X-\mu)/\sigma$, where X is the data sequence, μ is the mean and σ is standard deviation of those points.

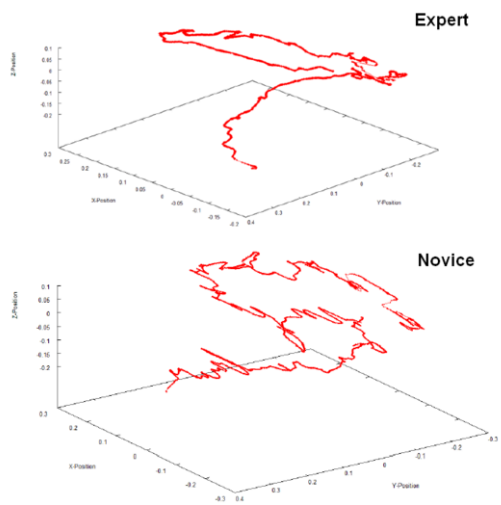

Figure 2 - Handpiece position in 3D generated from user's movement

Even when a novice is carrying out a procedure in the same basic way as an expert, the sequences of expert and novice movements will typically differ in length, positions, and speed. The expert's movements are usually more deliberate, economical and smooth throughout the operation. DTW is well suited to measuring similarity between sequences that may differ in speed and in which speed differences are not constant throughout the sequences. With DTW, the sequences are warped non-linearly in the time dimension to determine a measure of their similarity independent of non-linear variations in the time dimension but dependent on an application specific distance measure.

DTW [16] works as follows. Suppose we have two time series of length n and m respectively,

$$\text{Let } X = x_1, x_2, \ldots, x_n \text{ and } Y = y_1, y_2, \ldots, y_m$$

A matrix of size n by m is constructed such that the (i^{th},j^{th}) element of the matrix contains the distance $D(x_i,y_j)$ (in our case the Euclidean distance) between points i and j of the two series. After that, another matrix is constructed and the cost for each cell is determined using the condition:

- Initial Condition: $D(1,1) = 0$
- Recurrence: $D(i,j) = Dist(i,j) + min[D(i-1,j), D(i,j-1), D(i-1,j-1)]$

A warp path $W = w_1,w_2,...,w_k$ is constructed as the least cost path through the matrix from $(1,1)$ to (n,m) where k is the length of the warp path and the k^{th} element of the warp path is $w_k = (i,j)$. The warp path is typically subject to several constraints:

- Boundary conditions: The starting and ending points of the warp should be at two diagonally opposite ends of the matrix.
- Continuity: If $w_k = (a,b)$ then $w_{k-1} = (a',b')$ where $a - a' < 1$ and $b - b' < 1$. This restricts the allowable steps in the warp path to be adjacent cells (including diagonally adjacent cells).
- Monotonicity: If $w_k = (a,b)$ then $w_{k-1} = (a',b')$ where $a - a' > 0$ and $b - b' > 0$. This forces the points in W to be monotonically spaced in time.

Finally, cost is calculated as:

$$Cost = \frac{\text{Total cost of warp path}}{k}$$

The length of the warp path (k) in the denominator is used because for different sequences warp paths may have different lengths.

Data Analysis

Four experts performed access opening to the root canals using different sequences of operations.

Expert1 cut into the palatal pulp horn followed by extending the opening laterally to the mesiobuccal canal orifice, then followed a clockwise path to the distobuccal canal orifice, and the palatal canal orifice.

Expert2 cut into the palatal pulp horn followed by extending the opening laterally to the distobuccal canal orifice, then followed a counter clockwise path to the mesiobuccal canal orifice, and the palatal canal orifice.

Expert3 performed an initial cavity half way to the pulp chamber using a clockwise path then cut into the palatal pulp horn followed by extending the opening laterally to the mesiobuccal canal orifice, then followed a clockwise path to the distobuccal canal orifice, and the palatal canal orifice.

Expert4 performed an initial cavity half way to the pulp chamber using a counter clockwise path then cut into the palatal pulp horn followed by extending the opening laterally to the distobuccal canal orifice, then followed a counter clockwise path to the mesiobuccal canal orifice, and the palatal canal orifice.

Forty students were randomly divided into 4 groups of 10 students each. Students in groups 1, 2, 3 and 4 were trained to perform access opening to the root canals following experts 1, 2, 3, and 4 respectively.

Data from novices and experts was gathered as previously described and DTW was applied to determine whether each novice could be matched to the expert who had trained him based on the movement patterns, thus recognizing the approach to the procedure being attempted by the novice. For each novice procedure, DTW was applied to calculate the similarity between that novice and each of the four expert procedures. The lowest cost was taken as the best match. Figure 3 shows the warp between one expert and one novice sequence. Notice that these two sequences were warped from the beginning to the end.

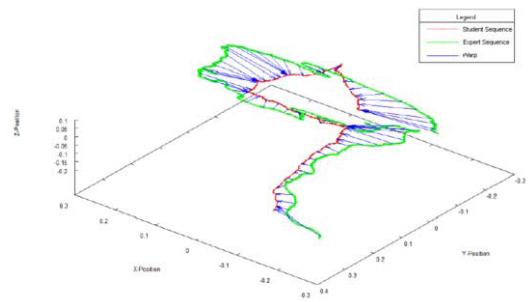

Figure 3 - Dynamic Time Warping between an expert and a novice sequence

The accuracy of the approach was computed as:

$$Accuracy = \frac{\text{Total number of correct matches}}{\text{Total number of students}} \times 100$$

Results

The data collection yielded 4 groups that differed widely for the tooth preparation sequence. Overall, the accuracy of the matching between novices and experts was very high (95%) compared to the probability of matching the sequences correctly by chance (25% in this four class problem). DTW correctly matched students in each group with the expert who trained them except for two cases. Case 1 was *Student8* (in group 1) who matched with *Expert2*, and case 2 was *Student24* (in group 3) who matched with *Expert1*.

In case 1, *Student8* should have matched *Expert1* but the lowest cost match was against *Expert2* at 170.45, with the match against *Expert1* being the next lowest at 339.54. The reason for this error can be seen from Figure 4. Figure 4(a) shows the sequences for *Student8* and *Expert1* and 4(b) shows the sequences for *Student8* and *Expert2*. The sequences in Figure 4(b) have initial segments that match closely, so DTW resulted in very low cost for the initial portion as compared to the sequences in Figure 4(a). Even though the cost was high for the later segment, the overall cost of the match between the sequences in 4(b) was lower than that in 4(a).

In case 2, *Student24* should have matched *Expert3* but the cost of the match against *Expert1* was lowest at 187.34 while the cost of the match against *Expert3* was only second lowest at 264.30. The reason for this mismatch can be seen from Figure 5. Figure 5(a) shows the sequences for *Student24* and *Expert3* while Figure 5(b) shows the sequences for *Student24* and *Expert1*. From Figures 5(a) and 5(b) it can be seen that the expert sequences were somewhat similar. The two expert sequences differ somewhat at the start but are similar at the

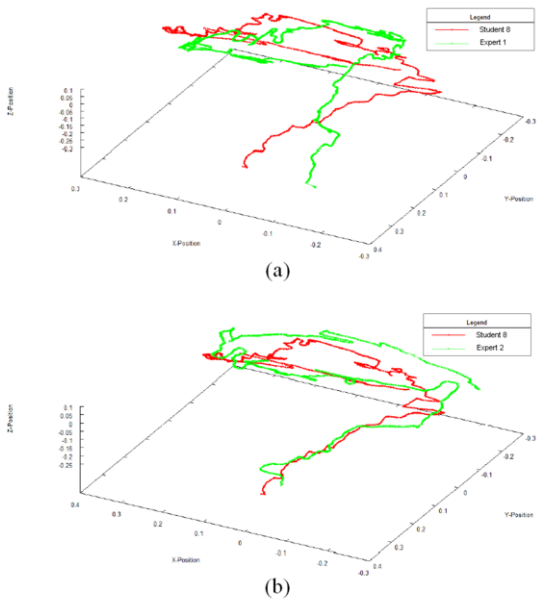

Figure 4 - Sequences of Student8 and Expert1 that should match (a) and sequences of Student8 and Expert2 that should not match but with lowest cost (b)

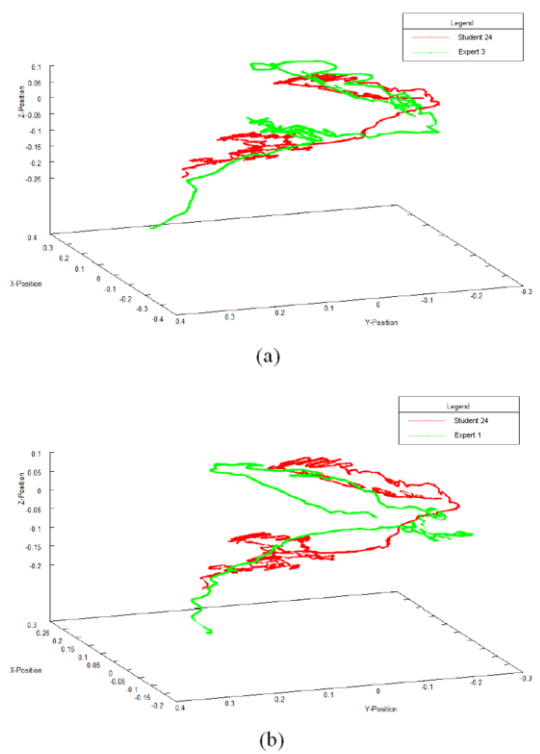

Figure 5 - Sequences of Student24 and Expert3 that should match (a) and sequences of Student24 and Expert1 that should not match but with lower cost (b)

later portions. Because of this, the costs of matching *Student24* with *Expert3* or *Expert* 1 were similar.

Discussion

Generally, knowledge of results (e.g., the pulpal depth was 1mm too deep) and knowledge of performance (e.g., was the handpiece held perpendicular to the long axis of the tooth when it should not have been) facilitate learning because they enable the performer to make appropriate adjustments to the movement on the next trial and increase the likelihood of the desired outcome will be achieved. In cases where procedures can be carried out using various alternative sequences, it is important to be able to recognize the correct sequence that a student is attempting in order to be able to provide effective corrective feedback. In this paper we have shown that metrics can be gathered from a virtual reality simulator that combined with dynamic time warping enable a student to be matched to the style of the expert who tutored him with a high degree of accuracy.

DTW seems to be a promising tool in the recognition of clinical performance in that it provides for objective evaluation of the trajectory of the instrument used to perform a dental procedure and is robust to differences in tool path length and velocity which differ greatly between novices and experts. The technique may enhance our understanding of the processes involved in clinical performance based on an unbiased assessment. Of course, the DTW technique alone cannot answer the question of how well a novice performs a task. Outcome measures need to be combined for comparison of outcomes under conditions where the movement trajectories are taxed, thus enabling analysis of their separate contributions to the outcome distortions in poor performance.

Conclusion

The current results suggest that DTW is useful technique to find the best matching expert for a student so that feedback based on that expert's performance can be given to the novice in clinical skill training. Several directions remain open for further work. First is the issue of improving the performance of the matching algorithm. In this paper we used only data of the tool location at each point in time. Performance could likely be improved by using information about trajectory of motion as well as information about other metrics such as force and angulation. The next step is to analyze the differences between the expert and novice procedures and identify those differences most relevant to quality of outcome for use in formative assessment. The final issue concerns how best to present this assessment information to the student to improve performance.

Abstract

INTRODUCTION. Adults and elderly users of hearing aids suffer psychosocial reactions as a result of hearing loss. Auditory rehabilitation is typically carried out with support from a speech therapist, usually in a clinical center. For these cases, there is a lack of computer-based self-training tools for minimizing the psychosocial impact of hearing deficiency. OBJECTIVE. To develop and evaluate a web-based auditory self-training system for adult and elderly users of hearing aids. METHODS. Two modules were developed for the web system: an information module based on guidelines for using hearing aids; and an auditory training module presenting a sequence of training exercises for auditory abilities along the lines of the auditory skill steps within auditory processing. We built aweb system using PHP programming language and a MySQL database .from requirements surveyed through focus groups that were conducted by healthcare information technology experts. The web system was evaluated by speech therapists and hearing aid users. An initial sample of 150 patients at DSA/HRAC/USP was defined to apply the system with the inclusion criteria that: the individuals should be over the age of 25 years, presently have hearing impairment, be a hearing aid user, have a computer and have internet experience. They were divided into two groups: a control group (G1) and an experimental group (G2). These patients were evaluated clinically using the HHIE for adults and HHIA for elderly people, before and after system implementation. A third web group was formed with users who were invited through social networks for their opinions on using the system. A questionnaire evaluating hearing complaints was given to all three groups. The study hypothesis considered that G2 would present greater auditory perception, higher satisfaction and fewer complaints than G1 after the auditory training. It was expected that G3 would have fewer complaints regarding use and acceptance of the system. RESULTS. The web system, which was named SisTHA portal, was finalized, rated by experts and hearing aid users and approved for use. The system comprised auditory skills training along five lines: discrimination; recognition; comprehension and temporal sequencing; auditory closure; and cognitive-linguistic and communication strategies. Users needed to undergo auditory training over a minimum period of 1 month: 5 times a week for 30 minutes a day. Comparisons were made between G1 and G2 and web system use by G3. CONCLUSION. The web system developed was approved for release to hearing aid users. It is expected that the self-training will help improve effective use of hearing aids, thereby decreasing their rejection.

Introduction

Sensorineural hearing loss is a chronic disease that can have an impact on individuals' daily lives[1]. To minimize the day-to-day impact of such a disease, there is a need for hearing aids to be adapted for adults and elderly people with hearing loss. This population often does not adapt well to using hearing aids and these individuals often discard them. It has been shown[2,3,4] that auditory training helps users improve their discrimination and comprehension of speech sounds. Simply recalibrating the hearing aid does not help regarding users' auditory quality. Specific auditory training techniques are needed in order to positively influence the auditory processes of neuronal plasticity in these individuals.

In Brazil, there is no web-based system aimed towards adult and elderly users of hearing aids similar to the one proposed in this study which exists. This system provides an original application, and specific tools for auditory training, management and analysis. Likewise, there are no references in the literature relating to any system that addresses all of the skills relating to the mechanism and processes of the auditory system: sound detection, sound discrimination, auditory recognition, recognition of the temporal aspects of hearing and auditory performance in relation to competing acoustic signals and in unfavorable acoustic situations. This study is aimed to make it possible to ascertain whether an intervention through information technology (using a web-based system in the subject's home) enables the improvement of the user's auditory skills and adherence to hearing device use.

The objective of this study was to develop and evaluate a web-based system for the auditory training of adult and elderly users of hearing aids. This study formed part of the academic activities of the Health 360 research group (Saúde 360, saude360.com.br) a research group focused on consumer healthcare information technology, clinical decision support systems, e-health processes and evaluation, ontology for healthcare, knowledge discovery, data mining and big data. This group is part of the postgraduate program on Healthcare Management and Information Technology, Federal University of São Paulo (UNIFESP), Brazil.

Methods

The method used in this study was based on the construction and evaluation of a web-based system for the auditory training of adult and elderly users of hearing aids. This study was developed in the Department of Healthcare Information Technology, Paulista Medical School (EPM), UNIFESP, in partnership with the Department of Speech Therapy, University of São Paulo, Bauru (FOB-USP). Data was gathered in partnership with the Auditory Health Division (DSA) of the Craniofacial Abnormality Rehabilitation Hospital (HRAC-USP), in

Bauru. This study was approved by the Research Ethics Committee of EPM-UNIFESP, under procedural number 26949/2012, and the Research Ethics Committee of HRAC-USP, under the number 569743/2014.

The web-based auditory training system has two modules: (1) an information module based on guidelines for using hearing devices; and (2) an auditory training module based on different lines of auditory skills. Both modules were developed in PHP: Hypertext Preprocessor language (php.net). MySQL DBMS version 5.0 (mysql.com) was used for data storage and management.

The system was evaluated by five speech therapy specialists and two individuals with hearing deficiencies who were hearing aid users. They answered a questionnaire that evaluated layout requirements, content and system usability. These requirements were assessed based on a five level scale (very poor, poor, fair, good and excellent). The top three levels (fair, good and excellent) were considered to have indicated approval and that the two lowest levels rejection.

The population sample consisted of two groups of individuals who were selected according to the following inclusion criteria: age over 25 years; bilaterally symmetrical sensorineural hearing loss of mild to moderate degree; new users who had been bilaterally fitted with hearing aids featuring digital technology in accordance with the protocol of the Brazilian National Health System (SUS); literate; experience of web browsing; and available to undergo auditory training lasting 30 minutes a day for five days a week, over a four-week period. Initially, 100 individuals were selected. They were separated into a control group (G1) and an experimental group (G2). G1 did not have access to auditory training through the web-based system, while G2 had access to the auditory training module. A third experimental group named the web group (G3) was set up to assess system use and acceptance. G3 had access to both modules of the SisTHA portal, but the inclusion criterion established for this group was that the questionnaires should be answered before and after the auditory training. All the subjects in the groups needed to give responses to the Hearing Handicap Inventory for the Elderly (HHIE) questionnaire[5] or the Hearing Handicap Inventory for Adults (HHIA) questionnaire[6] and a questionnaire on hearing complaints, before and after application of the research protocol. The three groups are described and the functionality and usability of the web system are detailed below, in Figure 1. After the protocol had been applied, the results were analyzed. The structure of the method is shown below.

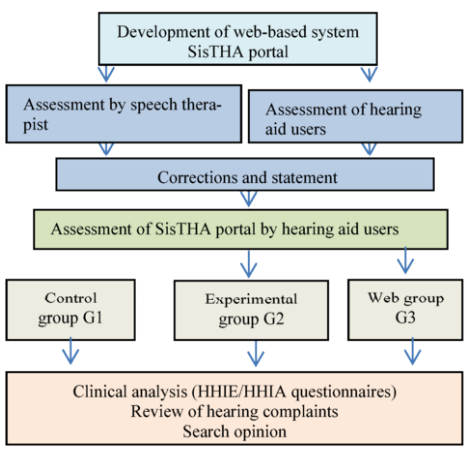

Figure 1 – Structure method for the study

Below is a diagram of the entity relationship model and database management system (DBMS) of MySQL Server ® version 5.0, furnishing a conceptual description of the data that was used to construct the SisTHA portal database (Figure 2):

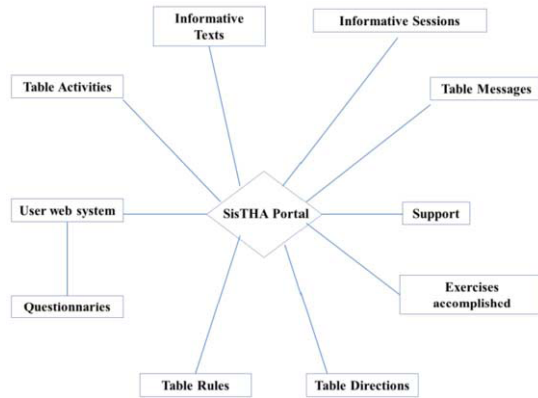

Figure 2 – Entity relationship model (ERM) of the SisTHA portal database.

Results and Discussion

The web-based system at www.sistha.com.br was finalized with two modules:

1) The information module had the aim of presenting general information about auditory health and was divided into two sections: hearing and hearing aids. These sections were composed of the following subsections: physiology of hearing; hearing loss; degree of hearing loss; the hearing aid; hearing test; hearing care; communication strategy; questionnaire on hearing complaints; importance of hearing aid; types of hearing aids; hearing aid and noise reduction; microphone of the hearing aid; battery; how to put the hearing aid on; mold and cleaning the hearing aid; how to use a telephone or mobile phone with a hearing aid. Figures 3, 4 and 5 shows the initial screens of the system relating to the information module.

(http://telemedicina6.unifesp.br/projeto/sistha/index.php?cap=Audi%C3%A7%C3%A3o&tit=Grau%20da%20perda%20auditiva)

2) The auditory training module was constructed by searching for and producing images and audio material that were coherent with each other and presented similarities to the day-to-day routines of the study population (in order to provide auditory training that would be as close as possible to the realities of the hearing aid user).

The auditory training was divided into five lines. Each of these corresponded to the stimulus of one of the mechanisms of the auditory skills of auditory processing: detection, discrimination, recognition, comprehension and auditory memory.

Each image of the auditory training module was correlated with corresponding audio material by means of the focus group method.[7,8] In this, 10 subjects presenting with normal hearing and vision assessed the images and audio material separately and then correlated them. Both the images and the audio material were selected only when there was a unanimous agreement within the focus group. The SisTHA portal presents 208 images in its database.

Audio recordings of voices were produced using the Audacity software. Recordings from twelve people were used (five men, five women and two children - a girl and a boy), with various accents and ages ranging from 9 years to 71 years. Each person was recorded while reading out numbers, words, sentences and text, which were all prepared in accordance with the daily lives of the adult and elderly subjects. The summary statistics for recorded material are listed below:

- 130 sentences;
- 200 individual words;
- 30 sequences of words, in two equal categories;
- 50 sequences of two words of different categories and lengths;
- 30 three-word sequences of equal categories;
- 50 sequences of three words of different categories and length;
- Numbers from 0 to 10;
- 40 three-digit number sequences;
- 20 texts composed of 200 to 600 words;
- Audio of news and vignettes.

The total amount of audio content produced for the content of the SisTHA portal was 10,027. However, all of this content was analyzed and selected. Through the analysis, 2,430 pieces of audio content were selected using audibility and intelligibility criteria. From these, some were selected to make up the audio overlay, in accordance with the proposal for auditory training through the SisTHA portal, for each line of the auditory training.

Currently, the audio database contains a total of 5,345 selected and finalized pieces of audio content.

The strategy of this module was to provide a sequence of exercises on the computer screen, to assist hearing aid users towards stimulating their hearing abilities. For this, the auditory training was divided into five lines. Each line corresponded to the stimulation of one of the mechanisms of hearing skills: detection, discrimination, recognition, comprehension and auditory memory.

Lines 1 to 4 of the auditory training presented three levels of difficulty (level 1 easy, level 2 medium and level 3 hard), while line 5, relating to communication strategy, had only one level of difficulty. For each level, a specific number of exercises were developed (Table 1), and were presented randomly to users, within their current stage (line and level).

Table 1– Number of exercises proposed within each line in the web-based system.

Stage	Total number of exercises	level 1	level 2	level 3
Line 1	120	40	40	40
Line 2	180	60	60	60
Line 3	156	16	70	70
Line 4	104	20	44	40
Line 5	15	15		
Line 6	Continuous/ random	Lines 1, 2, 3, 4, 5		

The difficulty of the auditory training increases as users correctly answers the exercises. When users give correct answers for 60% of the proposed exercises at each level, they move to the exercises at the subsequent level. After one line has been completed, users change stage, and so on. However, if they give wrong answers, the next exercise will remain at the level of difficulty of the previous exercise (which will be drawn within the same line and level). A running total of the number of correct answers is kept, with the aim of avoiding user frustration. It should be noted that the web-based system is dynamic and that exercises can be added at any time that is convenient.

Figures 6, 7, 8 and 9 present the screens of the SisTHA portal with examples of exercises within different lines and at different levels.

Figure 6 - Screenshot of the SisTHA portal referring to an example of an exercise within line 1 at level 1. By clicking on the "play" button, audio content is presented to the user, who has to choose the correct image associated with the audio.

Figure 7 - Screenshot of the SisTHA portal referring to an example of an exercise within line 1 at level 2. By clicking on the "play" button, audio content is presented to the user, who has to choose the correct image associated with the audio: the voice of a man, woman or child.

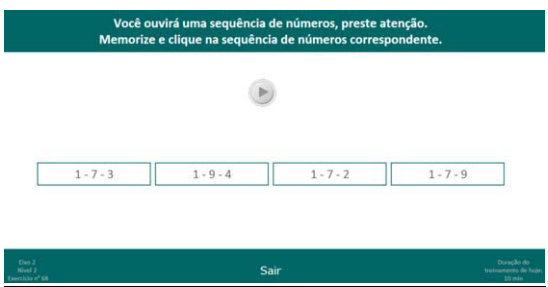

Figure 8 - Screenshot of the SisTHA portal referring to an example of an exercise within line 3 at level 3. By clicking on the "play" button, audio content is presented to the user, who has to choose the correct image associated with the audio, with regard to comprehension and auditory memory.

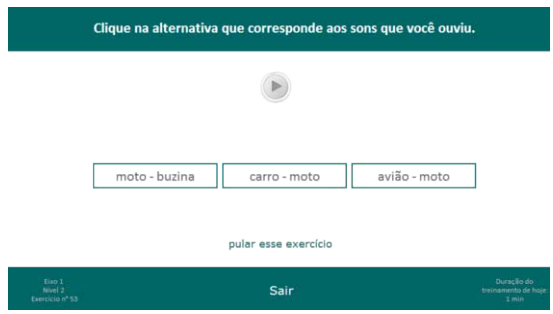

Figure 9 - Screenshot of the SisTHA portal referring to an example of an exercise within line 2 at level 1. By clicking on the "play" button, audio content is presented to the user, who has to choose the correct image associated with the audio.

As described earlier, the SisTHA portal was assessed by five volunteer specialist speech therapists with between 15 to 28 years of professional experience in the field of auditory rehabilitation. These professionals had academic qualifications as specialists in speech therapy, alongside their master's and doctoral degrees. They were working in universities and consultation offices. Evaluation of the system was also performed by two volunteer hearing aid users with bilateral hearing loss and a minimum of 25 years of hearing aid use. This evaluation consisted of a questionnaire which assessed the layout, content and usability requirements of the system. Responses were coded via a five-level scale (very poor, poor, fair, good and excellent). The top three levels (fair, good and excellent) indicated approval and that the two lowest levels indicated rejection. Responses to the questionnaires evaluating the system were analyzed by using descriptive statistics and content analysis from the perspective of Bardin.[9]

From the point of view of the speech therapists, the information module was approved with regard to the access requirements, layout, content, images, audio content and videos. The auditory training module was approved with regard to access, layout, volume adjustment, images, audio content and coherence between image and audio. Regarding the impact of the web-based system for hearing aid users, all the experts stated that the expected impact was positive. The evaluators reported that the following were important suggestions for the web system: improvement of the presentation of images, given the delays in loading them; insertion of a screen at changes in line regarding the number of correct answers per level; insertion of an incentive screen; and provision of access to screening of auditory processing before and after the auditory training to ascertain whether there was any improvement in the user's hearing abilities.

Regarding the evaluation of the web system by hearing aid users, both modules (information and auditory training) were approved in relation to all of their requirements. The hearing aid users provided a suggestion for the web system that an alternative should be included in the exercises such that users could choose not to answer the question (this option is already included in the current version). In addition, it was suggested that both a screen showing the number of correct answers per line and per level and a screen showing the change in line should be inserted.

Currently, the web-based system is at the data-gathering phase with the control, experimental and web groups until May 2015. Management and analysis of results will be carried out in June 2015.

Conclusion

A web-based system for helping in training the auditory skills of hearing aid users was constructed and evaluated for clinical use. In future clinical trials using the control, experimental and web groups, it is expected to be possible to assess whether standardized training done at home enables effective use of hearing aids, thereby giving rise to the possibility of reducing their rejection.

Acknowledgement

To FAPESP for assistance through the doctoral scholarship granted (number 2012 / 05410-0); to CNPQ for its Universal Notice with procedural number 4809 / 2011-8 in the name of Prof. Dr. Wanderléia Q. Blasca; and to the Auditory Health Division of HRAC-USP and the Department of Health Informatics, EPM-UNIFESP, for support and encouragement in the development of this study. We especially thank the speech therapists and hearing aid users who contributed to this study.

Abstract

The pervasive use of electronic records in healthcare increases the dependency on technology due to the lack of physical backup for the records. Downtime in the Electronic Health Record system is unavoidable, due to software, infrastructure and power failures as well as natural disasters, so there is a need to develop a contingency plan ensuring patient care continuity and minimizing risks for health care delivery. To mitigate these risks, two applications were developed allowing healthcare delivery providers to retrieve clinical information using the Clinical Document Architecture Release 2 (CDA R2) document repository as the information source. In this paper we describe the strategy, implementation and results; and provide an evaluation of effectiveness.

Keywords:

Electronic Health Record; CDA repository; Contingency plan.

Introduction

There is an increasing use of electronic health record, specifically the replacement of paper-based health record with Electronic Health Records (EHR) [1]. Therefore, every healthcare delivery process relies on information systems to ensure patient care. This brings up the threat of a lack of information for decision making in case of system downtime. One of the biggest risks in this scenario is inaccessibility of information needed to administer medication [2, 3].

Unexpected information technology (IT) downtime occurs more and more often with widespread adoption of electronic systems in healthcare [4]. Although the reliability of computing hardware has improved significantly, the complexity of software has escalated, especially in healthcare [4]. Risk identification and risk assessments are essential steps for developing preventive measures. Equally important is institutionalization of contingency plans as our data show that not all failures of health IT can be predicted and thus effectively prevented [5].

Most institutions had only partially implemented comprehensive contingency plans to maintain safe and effective healthcare during unexpected EHR downtimes [6]. Preparing for these unexpected downtimes should be a part of every EHR-enabled healthcare organization's overall patient safety strategy.

As most experts state, an effective contingency plan should address the causes and consequences of EHR unavailability, triggering processes and preparations that can minimize the frequency and impact of such events, ensuring continuity of care [7-9].

The objective of this paper is to describe the design, implementation, and evaluation of the IT component of a contingency plan that uses the Clinical Document Architecture (CDA) Release 2 (R2) document repository to support continuity of care during system downtime.

Methods

Settings

The Hospital Italiano of Buenos Aires (HIBA) is a nonprofit academic medical center founded in 1853. HIBA has a network of two hospitals with 750 beds (250 for intensive care), 800 home care patients under care, 25 outpatient care centers, and 41 operating rooms. There are more than 2,800 physicians, an equal number of medical team members and 1,900 administrative and support staff. During 2013-2014 there were 45,000 admissions, 3 million outpatient visits and 45,000 surgeries (half of them ambulatory).

In 1998 HIBA began the gradual implementation of a Healthcare Information System (HIS) developed in-house, from data capture to analysis. It includes a web based, modular, problem-oriented and patient-centered EHR. This EHR is known as Italica and allows inpatient, outpatient, home care, and emergency care records. Italica also allows users to order ancillary tests, prescribe medications and view results including imaging through an integrated picture archiving and communications system (PACS).

The EHR has a relational database record and also a CDA R2 document-based repository, which is digitally signed by professionals participating in healthcare delivery. This repository is used to interoperate with payers and other EHRs, and to make information portable for patients or other external healthcare providers. The system architecture for sharing medical information is based on HL7 CDA and a repository/registry XDS (Cross Enterprise Document Sharing) model defined by IHE (Integrating the Healthcare Enterprise). The document repository currently contains 36.4 million CDAs [10].

This repository allows the organization to operate without need for paper records, because information exchange between actors or systems is facilitated by these documents. For instance, for ancillary systems like imaging or laboratory, order is no longer paper-based but a digitally signed CDA R2. Likewise, result reports are not printed, but reviewed directly in the EHR through a CDA R2 sent by the ancillary service.

Since 2012, and based on this implementation, all procedures and communications for healthcare continuity while systems recover from a meaningful interruption have been redesigned, mainly for the inpatient setting. Two levels of contingency were identified:

- Level 1 is the application level, when only the EHR is not available. Causes might be a problem with the deployment of a new version or server issues. The rest of the computing infrastructure is available: database, networking, electricity, etc.
- Level 2 is total impact. Usually this level of contingency occurs when the database server is down or halted during upgrades or maintenance, or during data center problems affecting the server farm or storage, network outages or natural disasters.

The decision was to leverage the redundancy generated by the document repository to support contingency processes.

Design

A laboratory function study was performed to evaluate effectiveness and 20 Level 2 contingency tests were run on different days and at varying times. Time was randomized from the last execution to the start of simulated system downtime.

This involved simulating system downtime on 20 occasions at different times of day and comparing each prescription that each patient had at the time of the simulated downtime with the current list of prescriptions in real time. For example, if the list had been generated at 12:00 am and the system went down at 12:16 am, prescriptions during those 16 minutes were compared for additions or modifications.

Results

In order to mitigate the first level of contingency, a CDA navigator was developed, having as indexes some of the elements in the CDA header (metadata).

Table 1

Document date	/ClinicalDocument/effectiveTime/@low
Document type	/ClinicalDocument/code/@code
Service	/ClinicalDocument/legalAuthenticator/assignedEntity/representedOrganization/id/@extension and /ClinicalDocument/legalAuthenticator/assignedEntity/representedOrganization/id/@assigningAuthorityName
Patient id	/ClinicalDocument/recordTarget/patientRole/id/@extension
Patient root	/ClinicalDocument/recordTarget/patientRole/id/@root
First name	/ClinicalDocument /recordTarget/patientRole/patient /name/@given [1]
Last name	/ClinicalDocument /recordTarget/patientRole /patient/name/@family

Using this index, a tree is generated, and this tree is accessed based on patient information. From the tree root (target patient), timeline for inpatient (day by day) can be navigated. After selecting a specific date, the caregiver can access all documents for the visit grouped by document type and service.

This application is deployed on a different server from the EHR, and with a different and redundant database. If by any chance the EHR is not available, the document-based EHR at least can be retrieved.

Figure 1 – CDA Navigator

The second level of contingency assumes a total lack of database support, application server support, and electricity or network connections.

In this extreme case and only for inpatient and emergency care (average 720 beds), the question of which information is most critical for healthcare delivery to minimize risk to patients was evaluated on a consensus basis.

In this regard, two elements were key: access to the patient's prescriptions (medications, dosages, etc.) and proper labeling for laboratory samples.

Based on this requirement, an application was designed that accessed the document repository every 30 minutes for the latest medication and sampling label information for each inpatient.

Each computer running the application devotes local disk space to a folder tree organized by department and inpatient location and containing every prescription CDA and label information for each location.

This temporal repository is composed of two folders. The system alternates storage of the document between them. This application runs redundantly on several computers in strategically selected locations, and can only be used in contingency situations. These computers have a local printer and connection to backup power, with uninterruptible power source (UPS) and supplies of printer paper.

In the event of natural disasters, application server downtime, database downtime, or any other contingency, these computers can be used to print prescriptions and labels so that critical healthcare delivery can continue uninterrupted.

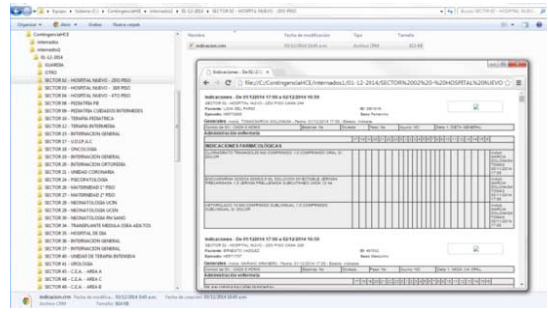

Figure 2 – File Explorer for Level 2 Contingency

Creating this backup requires querying the relational system and generates an average of 18 queries involving 44 tables for each patient. With an average of 720 beds, 12,960 queries would be needed every 30 minutes, which then would need to be turned into HTML for on screen rendering.

Using the CDA repository, only 1 query is needed, involving a snapshot of the current active inpatients or emergency care episodes, and the query to the document repository for the URL for the patient's last prescription CDA. Rendering the information only requires transformation of the XML using an XSLT stylesheet.

The downtime record between March 2012 and June 2014 is presented in Table 2. This table shows dates and times when the EHR was not available, and for how long. The column 'Type' indicates if the lack of EHR was programmed or not, and then the cause. The column "Level" indicates the severity level assigned to the cause and for each event, the quantity of pages printed.

Table 2 – Downtime Record and Pages Printed

Date Begin Time	Duration (Hrs.)	Type *	Motive	Level	Pages
08/03/12 09:15	05:55	U	EHR bug	1	365
05/04/12 23:10	02:00	U	DB issue	2	301
07/04/12 20:00	02:00	P	DB maintenance	2	10
27/04/12 09:50	06:15	U	EHR bug	1	303
12/05/12 22:40	07:50	P	Upgrade DB	2	1254
09/06/12 22:00	07:00	P	Upgrade Server memory	2	867
29/12/12 05:30	04:30	U	EHR bug	1	425
23/04/13 05:30	25:01	U	Shut-down power	2	1450
26/04/13 12:30	01:00	U	Router down.	2	23
27/04/13 18:00	03:00	P	Server maintenance	2	150
25/05/13 16:00	05:05	P	Server maintenance	2	1050
15/06/13 17:00	07:38	P	Server maintenance	2	1080
26/07/13 20:00	13:30	P	New DB cluster	2	1250
14/09/13 18:00	02:00	P	Update switches firmware	2	306
11/01/14 02:00	04:30	P	Update switches firmware	2	309
24/06/14 12:10	01:10	U	DB issue	2	124

*Type: U: Unplanned - P: Planned

As an example, a change of servers' operating system produced downtime of 13:30 hours. In this contingency, all prescriptions were printed, and 1,250 sheets of paper were used to print 759 prescriptions in 1 hour 15 minutes.

In the contingency Level 1 case, even though the CDA browser was used, the critical care units and emergency care areas preferred to print out the prescriptions in order to be able to make written notes of instructions and any other changes.

Details of each test simulation are presented in Table 3, including the time elapsed since last generation (mins), the number of inpatients at that moment, records that matched at the simulated downtime and the differences found.

Table 3 - Evaluation Cases

Case #	Minutes elapsed since last generation	Inpatients at down-time	Matches	Diffe-rences
1	2	654	650	4
2	10	695	667	34
3	18	712	668	44
4	25	730	666	64
5	5	759	723	36
6	12	759	707	52
7	26	762	686	76
8	5	771	759	12
9	5	721	697	24
10	15	678	630	48
11	14	699	643	56
12	10	712	680	32
13	17	734	686	48
14	5	723	707	16
15	15	745	709	36
16	13	711	671	40
17	22	733	657	76
18	5	732	712	20
19	1	722	722	0
20	25	745	673	72
		14,497	13,713	784

The differences were evaluated in each case: how many were caused by a patient being admitted or discharged, how many were caused by a change in medications. Medications for newly admitted patients and missing updates were deemed errors. New inpatients with no medications and discharged patients still in the contingency system were not deemed errors.

For example, for the second case, 34 differences were found, 22 of them due to patients admitted during the 10 minutes from the listing generation but with no prescription, 6 patients with their prescriptions updated, 13 patients discharged and 3 patients had new prescriptions. The evaluation result is presented in Table 4.

Table 4 – Evaluation Results for Contingency Listing

Case #	Diff.: New Admission	(1) Diff. Medication Change	Diff.: Discharged patient	(2) New patient with prescriptions	Errors (1) + (2)
1	1	1	2	0	1
2	12	10	6	6	16
3	22	6	13	3	9
4	34	10	17	3	13
5	18	3	15	0	3
6	26	4	20	2	6
7	8	10	55	3	13

8	6	3	3	0	3
9	12	3	9	0	3
10	22	2	20	4	6
11	29	6	19	2	8
12	16	5	11	0	5
13	23	10	6	9	19
14	8	2	6	0	2
15	17	5	12	2	7
16	20	7	13	0	7
17	39	17	16	4	21
18	10	3	7	0	3
19	0	0	0	0	0
20	36	9	23	4	13
	359	116	273	42	158

The results show that printed prescriptions concur in 98.91% (14,339/14,497) of those registered in the EHR.

The relationship between the time elapsed since the last generation and the differences found after downtime are presented in Figure 3.

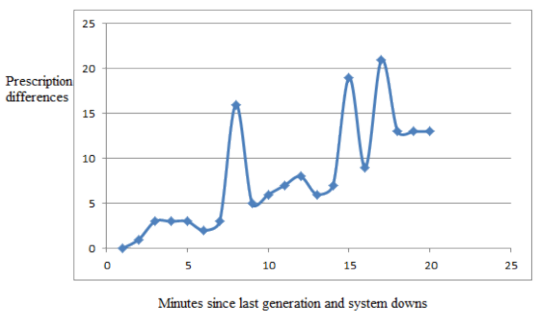

Figure 3 – Differences (Time)

Discussion

This architecture allows information to be available from all delivery care locations, and allows every actor requiring the information to access it.

The printing process has a predefined sequence for the various locations, prioritizing critical care units, emergency care, pediatric care, and then other services.

The more time elapses between the generation of the latest list and the EHR unavailability, the greater the difference in the prescription record. Although the medical staffs understand that any changes made in less than 30 minutes could be re-prescribed, they are aware that the nurse work based on the lists received and these should be corrected manually after the EHR disruption.

In the real scenario, other times should be evaluated because doctors do not make decisions on every patient immediately after the system goes down. Other changes could have been made during the downtime and will not be represented in the print version (prescriptions, bed changes, etc.). So we have two mechanisms that generate gaps between the information documented and the reality: gaps between the last local backup and the down time and gaps between the down time and the moment at which the caregiver uses the print version.

This study evaluated the differences between Point 1 and Point 2. The effectiveness of this architecture at Point 3 is pending evaluation and will be the subject of a future study.

The alternating folder strategy was required because in one of the tests if network connectivity or power was interrupted just when the folder was being generated, its structure could be corrupted. If this happens, the other folder can be accessed.

Prescription printed forms are used mainly by the nurses to ensure care continuity for patients. They continue recording their actions there in order to update the EHR when the system comes back, or scanned as part of the care record.

One limitation, as shown by the evaluation of the results, is that not all the information is available because there can be changes between the executions of the refresh process: patient transfers, new prescriptions, admissions or discharges.

No other experience in creating this kind of repository was found in the literature, either as a redundant repository or for use on a contingency basis.

Conclusion

Downtime in information systems, both planned and unplanned, is inevitable, even in the healthcare environment, where systems need to be available 24-7-365. Implementing tools such as the one presented in this paper provides contingency plan support and helps mitigate many risks that threaten information availability at the point of care.

Abstract

The treatment of patients with pituitary adenoma requires the assessment of various patient data by the clinician. Because of their heterogeneity, they are stored in different sub-information systems, limiting a fast and easy access. The objective of this paper is to apply and test the tools provided by the openEHR Foundation to model the patient data relevant for diagnosis and treatment of the disease with the future intention to implement a centralised standard-based information platform. This platform should support the clinician in the treatment of the disease and improve the information exchange with other healthcare institutions. Some results of the domain modeling, so far obtained, are presented, and the advantages of openEHR emphasized. The free tools and the large database of existing structured and standard archetypes facilitated the modeling task. The separation of the domain modeling from the application development will support the next step of development of the information platform.

Keywords:
Patient data modeling, pituitary adenoma, archetypes, openEHR.

Introduction

A Pituitary adenoma is a kind of tumor that is located in the sella region of the brain. Usually, the tumor is benign, but it can affect the normal production of hormones, such as the sexual or growth hormone. These dysfunctions are responsible for example for infertility, erectile problems or enlargements of the extremities (hands, nose, ears) and of the internal organs (heart, kidneys) causing premature death. Because of the proximity of the pituitary gland with the optic chiasm, which is the region where the optic nerves cross, large pituitary tumors can moreover affect the vision of patients.

The diagnosis of the presence of a pituitary tumor is primarily performed based on MR imaging (figure 1). The position of the tumor in the pituitary gland and its size are estimated based on the image data. However, additive examinations, especially eye examinations, and blood tests which measure the quantity of hormones, provide complementary information about the kind of tumor. All these features strongly influence the choice of therapy [1].

Figure 1 – MR data of patient revealing a large adenoma (white arrow) in the pituitary gland.

More generally, the treatment of diseases requires nowadays the acquisition and interpretation of a large amount of patient data of various formats, including image data, results of laboratory tests, findings or medical reports and letters. At hospitals, these patient data are digitalized in so-called electronic health records (EHR) and stored within a centralized database called hospital information systems (HIS) [2]. The history and all data of patients are therefore available at anytime for all clinicians within the hospital. However, the main drawbacks of these systems for the every-day use by clinicians are their heterogeneity and ,therefore ,their complexity of use.

Since patient data occurs in various data formats, different sub information systems constitute usually the HIS. Image data acquired within the hospital are stored in a Picture Archiving and Communication System (PACS) and are visualized and interpreted by the clinicians through a computer interface, a DICOM-viewer. Results of laboratory tests are also commonly managed within the specific software, specially designed for such particular data. External medical letters and findings are scanned and stored in specific databases accessible through their unique user interfaces. It becomes clear that it can be very complex for clinicians to find the relevant patient information among the available patient data distributed in the different software components of the HIS. The access to the patient data can moreover be very slow. Finally, the management and maintenance of such systems is very complex.

To overcome this situation we intend to implement a centralized and standard-based information platform dedicated to the treatment of patients with pituitary tumor according to the point of view of neurosurgeons. Domain modeling is a key step in such development [3]. It consists in representing and

storing the involved patient data in a suitable way. This paper focuses therefore on the modeling of the relevant patient data required for the treatment of the disease. The requirements associated with the domain modeling are presented. They form the basis to justify the choice of openEHR and associated tools. Finally, first results and experiences with the modeling are presented. In the future, the developed information platform should facilitate the diagnosis, therapy choice, treatment and monitoring of the disease by:

- Improving the access to patient data;
- Facilitating the interpretation of patient data;
- Increasing the exchange and re-use of patient data.

Materials and Methods

Selection of relevant patient data

The first step in the patient data modeling was the description of the clinical workflow for the treatment of patients with pituitary adenoma and the selection of relevant associated data. This was performed based on interviews with neurosurgeons.

Requirements for the patient data modeling

The second step consisted in representing the selected patient data according to models - to store and represent the information in the platform. This important task had to fulfill different requirements described in the following.

Definition of requirements. Content or fields of patient data models have to be determined. For example, the administrative data has to include personal information of patients, such as name, sex, birthday, address, identifier number and entry date.

Standard representation. The patient data has to be represented in a way so that it is understable to all actors. For example dates and time points need to be uniquely represented since they are differently recorded according to continents and countries [4].

Structured representation. In the context of the treatment of pituitary adenomas, a neurosurgeon makes the decision for the treatment based on images, laboratory data or information from the clinical reports provided by other clinical specialties. An unexperimented neurosurgeon is little familiar with these patient data. Structuring the information by enhancing important facts or conclusions facilitates the interpretation [5].

Interoperability. The use of existing norms and standards for modeling is a key point to improve the exchange of patient data between healthcare institutions [6].

Support for the implementation of the information platform. Patient data modeling forms the basis for the implementation of an information platform and most widely support and facilitate it [3].

openEHR

The openEHR Foundation is described on its web site (http://www.openehr.org/) as follows: “OpenEHR is a virtual community working on interoperability and computability in e-health. Its main focus is electronic patient records (EHRs) and systems.” [7, 8]. Different applications were already developed based on openEHR [9, 10], for example in the field of neonatology [11] and epidemiological studies [12]. The tools provided by openEHR have important advantages for the development of our application.

Free availability. The philosophy of openEHR is to share the knowledge in the field of patient data modeling. Several tools are available to all for free. Users are encouraged to reuse these archetypes for their applications. These archetypes are good templates for the development of new archetypes. The database is totally free available so that each one can contribute on its enlargement. A discussion forum enables support and collaboration.

Standard-based archetype database. Patient data models are called archetypes in openEHR. A large database of existing archetypes is available. They were developed based on rules and structures, now recognized as standard. For example, a large set of archetypes represents the results or findings of a medical examination. A main component of these archetypes are conclusions of the examination -that are crucial for the diagnosis of the disease. However, further information about the requester of the examination, the name of the healthcare institutions where the examination was performed as well as the data and time are also important and included in the templates in general. Moreover, it is possible to link the archetypes with existing terminologies, for example, to code some text like the modality of image data.

Archetype Editor tool. This editor aims at supplementing existing archetypes for a specific applications, at building new archetypes and at assembling archetypes for the development of an application.

Separation of domain modeling and application development. The idea of openEHR is to separate the domain modeling from the application development. Therefore, the modeling of patient data can be performed by physicians or noncomputer scientists. The tools proposed by openEHR, like the *Archetype Editor*, are intended to be easy to use. A second software tool, the *Template Designer*, was developed to join all archetypes relevant for one application. The existing archetypes include a large number of information fields -that are not all relevant for a given application. With the *Template Designer,* it is possible to define constraints on the archetypes, for example the occurrence of an archetype. Some information fields can be prohibited. An XML-document is then generated from the domain modeling, on which the computer development of the information platform is based.

We tested and applied the tools provided by openEHR for the domain modeling of the treatment of pituitary adenomas.

Results

Clinical workflow and patient data set

The clinical workflow of treatment of patients with pituitary adenoma includes mainly three phases: firstly diagnosis of the disease, secondly therapy choice and treatment, and thirdly control of treatment and monitoring of the disease (figure 2).

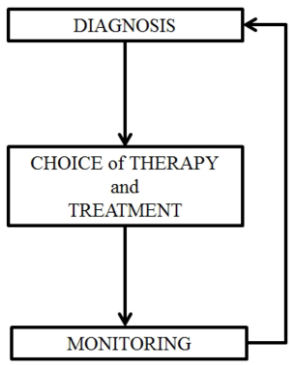

Figure 2 – Clinical workflow of the treatment of pituitary adenomas.

Diagnosis phase. During the first visit of the patient at the hospital, the administrative data of the patient are recorded. Diagnosis of the disease is primarily performed based on MR data which reveals the possible presence of a tumor and, if it is positive, provides an estimation of its size and position. Moreover, results of laboratory tests, eye examinations (more specifically the measurement of visual acuity and visual field) and clinical symptoms expressed by patients strongly influence the choice of therapy. The most common options are pharmacotherapy, surgery, observation of the disease development and combinations of them.

Treatment phase. In our application, the patient data are collected only in the pre-, intra- and postoperative phase of the surgical therapy. At the University Hospital of Leipzig transsphenoidal endoscopic operations is performed. An Endoscope and surgical instruments are inserted through the nose and the sphenoid bone till the sphenoidal sinus cavity - - to remove the tumor. The operation is assisted using a navigation system that indicates at anytime the position of the surgical instruments on CT and MR image data acquired one day before. Bone structures are well revealed on the CT image to guide the surgeon on the way to the tumor, while the MR data enhance the soft tissue, like the pituitary adenoma, in the brain area. During the operation planning, the surgeon can semi-automatically segment the tumor, especially when it is badly visible in the images. In the operating room, endoscopic video images are generated and stored for operation documentation. Postoperatively, a CT or MR image is generated in order to reveal possible bleeding or to detect possible remnants of tumor. Finally, the surgeon draws up the operation progress on a medical report.

Monitoring phase. Patient data involved in the monitoring of the treatment and of the disease are the same than those used for the diagnosis.

In conclusion, Table 1 lists patient data involved in the different clinical phases and the relevant information they provide to the neurosurgeon.

Table 1 – Patient data involved in the diagnosis, surgical treatment and monitoring of pituitary adenomas

Phase	Patient data	Relevant information
1	Master data	PID / Sex / Age
	MR data of the head	Tumor size and location
	Clinical symptoms	List of symptoms
	Laboratory tests	Hormone concentration in blood above or under normal values
	Eye examination	Measurements of the visual acuity and visual field
2	Preop. MR data	Tumor size and position (segmentation) for surgery planning
	Preop. CT data	Bone structures (visualization) for surgery planning
	Intraop. endoscopic video	Selected images for documentation
	Operation report	Documentation
	Postop. CT or MR	Presence of bleeding / Detection of remnants of tumor
3	Identical than in phase 1	

preop.: preoperative
intraop.: intraoperative
postop.: postoperative

Clinicians pointed out that four kinds of information must be attached to each archetype:

- Original text or image data
- Healthcare institution which performed the medical examination
- Date and time of the examination
- Comments of the neurosurgeon

Domain modeling with openEHR

The patient data listed in Table 1 were modeled using seven archetypes from the openEHR database and five self-implemented archetypes (Table 2). Since imaging examination are required for the three phases of patient treatment, its modeling is described in more detail in the following.

Table 2 – List of archetypes used for pituitary adenoma domain modeling

Patient data	Archetype name	OpenEHR	New
Master data	*Research study*		x
Image data	*Imaging examination results*	x	
Radiological findings	*Organisation*	x	
	Pituitary adenoma classification		x
Clinical symptoms	*Pituitary adenoma clinical symptoms*		x
Laboratory tests	*Pituitary hormones*		x
Eye examination	*Visual acuity*	x	
	Visual field measurement	x	
Choice of therapy	*Procedure request*	x	
Intraoperative image data Operation report	*Procedure undertaken*	x	
Histological findings	*Histopathology*	x	
	Pituitary adenoma histology		x

Example: imaging examination modeling

Image data and radiological findings

The existing archetype *imaging examination result* from the openEHR database, models image data with the corresponding radiological finding. The finding is structured in different sub-parts including the examination name, the examined anatomical site, the date, time and status of the given result, the radiological diagnosis and possible conclusion or comment. A link to the original text data can be specified. Moreover, the imaging examination can be documented: who requested and performed the image acquisition, when was the acquisition performed, what was the patient position. A reference image of a current view can be attached.

Usually, only selected fields are required according to the medical application. In agreement with the neurosurgeon the following fields were kept:

- "Imaging modality": possible choices were coded;
- "Conclusion": in this field can the neurosurgeon add his comments;
- "Examination result representation" includes the link to the original radiological report;
- "Name of organisation" which performed the imaging examination;
- "Image details" includes the date and time of image acquisition as well as a reference image, possibly with the tumor segmentation.

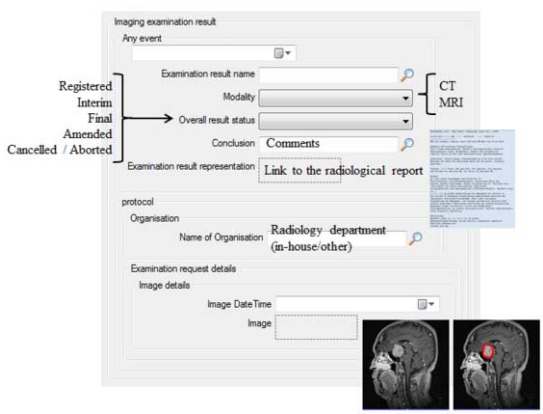

Figure 3 – Preview performed with the tool "TemplateDesigner" of the selected fields of the existing archetype "Imaging examination result".

The archetype was improved using the tool *Archetype Editor*. The choices for the field "Imaging modality" were coded using an internal code because only CT or MR data is involved. The field "Name of organisation" was linked to the existing archetype *Organisation*, which reports details of an organisation or agency.

In the tool *Template Designer*, the other fields not required for our application were set as prohibited so that they will not appear in the information platform. Moreover, the fields "Examination result name" and "Overall result status" are mandatory by definition in the archetype. A preview of the mask corresponding to the modified archetype can be generated and is shown in figure 3.

Pituitary adenoma classification

Based on the observation of the image data and on the reading of the radiological findings, the neurosurgeon infers a classification of the pituitary according to its size and location (Table 3). Since this classification is specific to our application, we developed ourself the corresponding archetype.

Table 3 – Description of the new archetype "pituitary adenoma classification"

Fields	Description	Modeling
Number of tumors	Between 1 and 4	Number
Maximum size	Maximum tumor size estimated in the three radiological directions	Quantity
Macroadenoma	Tumor size ≥ 10 mm	Boolean
Microadenoma	Tumor size ≤ 10 mm	Boolean
Localization	Tumor localization and link with adjacent structures	Boolean
Symmetrical growth	Performed in the coronal view	Boolean
Hardy classification	Classification based on tumor size and localization: Grade 0 to Grade IV	Coded text

The new archetype was developed using the tool *Archetype Editor*. Different kinds of data can be included into the archetype like text, numbers or boolean values. The unit can be attached to a data "quantity", like it is the case for the tumor size given in millimeter. It is possible to specify the range of value which are entered by the user. For example, the number of tumors was limited to four, the values for maximum tumor size must be positive. The Hardy classification [13] was coded using an internal code from Grade 0 until Grade IV. A preview of the archetype is shown in figure 4.

Discussion and conclusion

Patient data modeling is a crucial step towards the development of information systems in health care domain. The openEHR Foundation proposes free software that is well adapted to support this task. The domain modeling is totally separated from the application development. This enables a medical expert with limited experience in computer development to implement the respective domain knowledge. The large database of archetypes provided by openEHR was developed according to standards. The tool *Archetype Editor* enables to complement existing archetypes, to implement new archetypes and to specify constraints on the archetypes. Then, they are put together in the tool *Template Designer*. A preview of the web mask corresponding to the domain modeling can be generated. The model can be exported as an XML file which forms the basis for the development of the web mask. The standardisation of the models of patient data should encourage the exchange between healthcare organisations. In general, the use of the openEHR tools require experience since a documentation is available only to a limited extend or difficult to find. This can be a limitation for clinicians.

So far we implemented a prototype of the information platform based on a couple of patient data. This proof of concept project showed us the feasibility of developing an information system based on openEHR. The future objective

of this work is the development of therapeutic assistance system to support clinicians in decision making for the treatment of patients with pituitary adenomas. This requires the extraction of semantic information from patient data, whose representation in archetypes is supported by openEHR. For example adverse events concerning the patient or occurring during the treatment can strongly influence therapeutic decisions. Specific new text mining and image processing tools have to be developed in research environment and included within our information platform [14, 15].

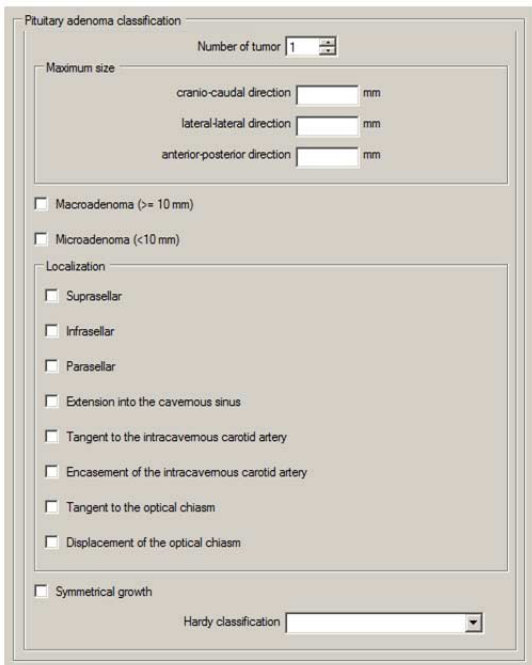

Figure 4 – Preview of the new archetype "Pituitary adenoma classification" recording the tumor classification performed based on image patient data (mask generated by the "Template Designer").

Abstract

Exponentially increasing costs in healthcare coupled with poor quality and limited access have motivated the healthcare industry to turn to IS/IT solutions to overcome these issues and facilitate superior healthcare delivery. In an environment of rapid development of new clinical informatics solutions claiming to provide better healthcare delivery, there is a paucity of systematic frameworks to robustly measure the actual value of these systems. The promised business value of these solutions has been elusive; hence, this study offers an approach for the evaluation of the business value of health IS/IT solutions based on a conceptual model, which has been validated using three clinical case studies.

Keywords:

Healthcare, Information Techonology, Information Systems, Business Value of IT, Computerized Systems.

Introduction

Healthcare spending is increasing exponentially throughout the world [1], necessitating decision makers to take action to address this dilema[2,3]. Not only are the expenses creating pressure for the healthcare industry where resources are already strained, but also increasing problems relating to heathcare quality and patient safety. According to a report by the Institute of Medicine [2], more than 98 000 Americans die annually, and more than ten times that number are injured as a result of this problematic situation. Furthermore, these figures are projected to be getting even worse. A 2010 study[3] estimates that ~180 000 Americans will die per year, and another 2013 study [4] estimates this to be between 210 000 and 440 000 patients. Clearly, this is a serious and untenable situation, not to mention the tremendous cost of all of this for the American healthcare system.

Investing in information technology has been touted as a new strategy to correct all of these issues and achieve the desired cost/quality balance (input/outcome) [5, 6]. As a result, OECD countries are now heavily investing in health information systems [7, 1]. This growth has been driven to a large extent by success stories for such investments in other sectors of the service industry such as retail, education and logistics [8]. While most healthcare providers globally have started investing in health IT, we are yet to witness the promised increased business value from these investments [8]. However, at present, too many significant failures with health IT investments permeate the literature [9]. Thus, understanding how information technology can help generate business value in healthcare becomes a priority.

The impact of information technology on the organisational performance (i.e business value of IT) has been a major theme in the research since 1992 [10]. Since this time, researchers have not stopped investigating this area [11, 12]. The scope of these studies, however, has been limited to retail and manufacturing industries, and has not covered the healthcare industry. The reason behind this could be due to the complexity of healthcare delivery, consisting of many systems and subsystems; as all of these as ecosystems must be considered if a true sense of value is to be established [13, 8].

Our exploratory study aims to examine the business value of IT in healthcare. To do so, we propose a comprehensive conceptual model that covers almost all types of IS/IT, and all levels of healthcare delivery. This model is then tested against three exemplar case studies; noted by Yin to be a prudent methodology under these conditions [14].

Business Value of IT in Healthcare: A Conceptual Model

Although the business value of IT has been previously investigated, the current literature still has several key deficits, notably a lack of understanding of the relationship between IT investments and firm performance [12, 8]. Many researchers believe that an appropriate strategy is to move from the question of whether IT creates value to how, when and why benefits occur or fail to do so [15]. To develop a conceptual model to support this line of inquiry, we look at IS/IT investments through the lens of their management objectives. This lens is derived from the work of Peter Weill, who classified IT investments into four types: informational, transactional, infrastructure, and strategic systems; which forms what is called 'IT portfolio', and in turn represents an organization's entire investment in IT [16].

Classifying IT investments in this way forms the first step toward developing a conceptual model. The second step is recognising the socio-technical aspects, a differentiating feature which represents one of the big differences between healthcare and other service industries [17]. According to this conceptualisation, healthcare delivery can be divided into four interrelated layers: healthcare ecosystem (society), system structure (organisation), delivery operations (processes), and clinical practices (people). Further, the efficiencies that can be achieved at the lowest level (clinical practices) are limited by the nature of the next level (delivery operations).

The conceptual model suggested by this research aims at reflecting the complexity of healthcare delivery and the vast range of IS/IT investments in this industry. This is done by taking both the IT Portfolio [16] and the Healthcare Delivery

Enterprise Model [17] into consideration as depicted in Figure 1.

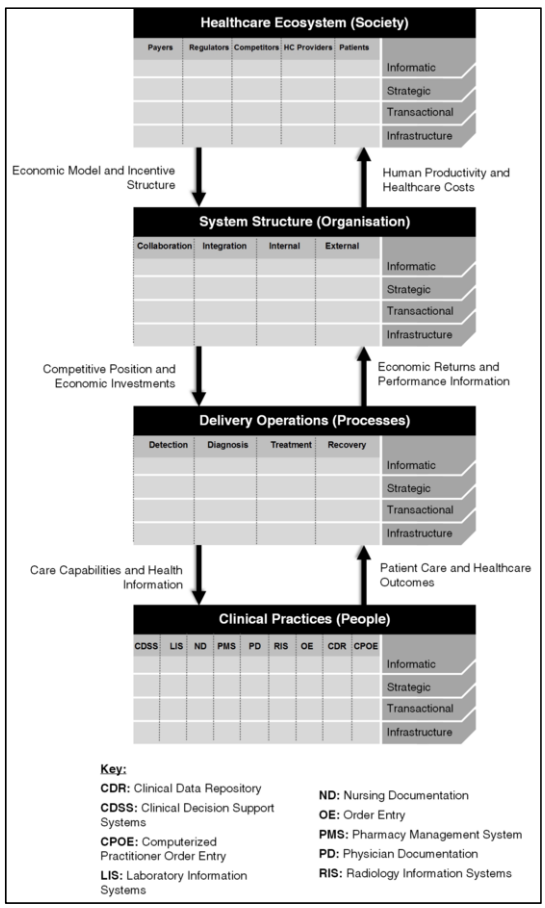

Figure 1: Business Value of IT in Healthcare: A Conceptual Model

Methods

A case study is the appropriate method to illustrate critical issues or key points in such a context [14]. For the purpose of this paper, we use three exemplary case vignettes that highlight three clinical practices in the conceptual model. The first is an Australian nursing documentation (ND) system, the second is an American computerised practitioner order entry (CPOE) system, and the third is an online second medical opinion application (MyConsult). For ND and CPOE systems, data collection took place between 2013 and 2014 in Australia. The methods used were mainly a series of 28 semi-structured interviews with the main stackholders at a leading private healthcare provider in Australia. This includes professionals from three groups: clinicals, IT and business people. All of the interviews were transcribed and qualitatively analysed using Nvivo 10. MyConsult has a 12 year history of adminstrative and clinical data collection and we focused on the last three years examining the clinical outcomes of the second opinion reports combined with administrative data. Additionally, semistructured interviews were also completed as noted with the ND and CPOE groups. These interviews were conducted with 12 department and institute chairs or their respective administrators as well as 8 members of the Distance Health and Information Technology Division and Finance Department staff at the Cleveland Clinic.

The use of three significantly different systems is intentional. The aim of having these three different systems is to test the robustness of our conceptual model and thus to be used to evaluate the business value of IT in different and distinct contexts and circumstances. Testing the model with similar cases will only serve to demonstrate the usefulness of the model in a narrow application.

We look at different IS/IT solutions in two different countries whose healthcare ecosystems are different. This enables us to test whether or not any amendments on the proposed conceptual model are needed.

MyConsult is a comprehensive online application that provides an online model for a patient to request a second opinion from experts at the Cleveland Clinic. As the only US institution offering such a comprehensive model that is secure, patient specific and incorporated into clinical practice, MyConsult offers patients, physicians and families the opportunities to remove the geographic barriers to care and receive a formal report through the online secure portal. While the consult is real, it is the visit that is virtual (please note that Ask MayoExpert and WebMD systems were not considered comparable). The MyConsult model provides an excellent example of a novel technological approach to clinical care in a specific regulatory environment using an application that has been custom designed and developed by the technical teams at the Cleveland Clinic.

MyConsult pricing, market and program research indicates that those requesting MyConsult were in fact looking for specific program attributes, a comprehensive review of general and diagnosis specific questionnaires and the data set that comprised the first opinion; all resulting in a formal written report that is shared with the patient's treating physician team in their home market. The development structure permits MyConsult to quantify the business value of the development work in conjunction with the clinical value received by patients.

All who were interviewed noted that the clinic's online second opinion system was far superior than any other system they had used or come across.

Case vignettes

Case Vignette 1: Nursing Documentation System

For the purpose of this paper, we examined a nursing documentation system that was designed and built in Australia. The developers envisage that this system will replace paper-based nursing documentation in hospital acute care wards in both private and public hospitals. The objective of this system is to allocate more time for patient care by putting smart terminals at the patient bedside, which would create more interaction between nurses and patients. The system is still under research, where a research team consisting of both nursing and IS researchers are examining the system, and providing feedback to the designers, who are, in turn, releasing new versions constantly. By making these smart terminals available by the bedside, a higher level of collaboration between ward nurses and other healthcare professionals is expected; according to the designers of this system.

Case Vignette 2: Computerised Practitioner Order Entry (CPOE) System

The studied CPOE system in this paper is part of a comprehensive information and image management system

specialised in oncology care. The vendor offers three modules of this system: radiation, medical, and surgical. In our case study, the two purchased modules are radiation and medical, while the surgical module had not been acquired.

The aim of implementing this system is to replace the manual scheduling of pateients by electronic means, which would help make the processes of admission, treatment, and post treatment care plans smoother and with less errors or delay.

The radiation module has been implemented in our case study for two years now, while the medical module has just been acquired. Globally, the system has been in use for 10-15 years. In the Australian context, it is been in use for about 7 years.

Case Vignette 3: Online Second Medical Opinion Application

The Cleveland Clinic MyConsult application removes the geographic barriers to care by providing an online second medical opinion for those diagnoses with sufficient objective data upon which a remote evaluation can be completed. The focus is to determine if the diagnosis is correct and if the patient is receiving the optimal treatment. These patients can receive a second opinion without leaving their homes. Integration with the existing IT infrastructure includes network, interface engine, LDAP, DB, upload, EMR, Security, Financial, and Materials Management. Three structural layers classified the business value discussion: first the external system to receive and organize these requests, second, the internal system to coordinate, consolidate, and organize per diagnosis, and third, geographic issues from the international, national and regional unique markets.

Results

The participants for ND and CPOE had the following demographic patterns: 46.42% of the 28 interviewees were females and 53.50% males. In terms of specialty, the interviewees were clinicians (nurses, oncologists and clinical auditors) (26.67%), IT personnel (33.33%), and executives (including clinical executives) (40%). All the interviewees had more than 15 years' experience and 89% of them had more than 7 years at the case study. Majority of the interviewees were within the age group 41-50 years (46.7%), 51-60 years (26.7%), 31-40 (13.3%), and 61-70 (13.3%).

For MyConsult, 80% of the participants were male and were comprised of 40% clinical staff and 60% administrative staff. All of the administrative staff had more than five years of experience while the clinical staff had more than 20 years of experience.

The Role of IT in Healthcare

A number of factors that help generate business value out of IT were identified during the interviews. The majority of the interviewed staff recognized the role IT can play to enhance the organisational performance of healthcare providers. From a nursing perspective, IT *"could absolutely and should facilitate the patient journey through health, generally, from the community into the acute care environment and then back into the community. Certainly, that provides the quality of continuity, but I think it also provides a safer environment for that patient"* [NAS#1]. From another clinical point of view, IT is an important part of contemporary healthcare organisations *"in that it measures what it can be measured and more importantly it facilitates processes"* [CAS#3]. Facilitating processes is not limited to clinical processes, but it also covers the business side of healthcare provision. *"not only does it reduce the cost or increase the efficiency of processes, but also it enhances the integration with other partners like the health care funds".* [CIO].

Business Value of IT: Problems and Requirements

In order for IT to generate business value there are a number of organisational and conceptual requirements that must be met. The big differenece between health organisations and other organisations is that *"healthcare in general, and hospitals in particular are not organizations in the traditional sense. They don't have hierarchical line authority from top to bottom, particularly in the private sector. They're not organizations. They're loosely affiliated groups of people trying to do the same thing".* [CAS#2]. Thus, the business value of clinical IT is hard to be montized. Asking about the reasons behind this, the interviewee suggested that the apprenticeship system through which the doctors are raised up is to be blamed: "*Generally in that sort of training, process is not a reflection. What I would call a deep reflection of what is the nature of your work process as you get with the apprenticeship training*". As a solution to this conceptual issue, the Director Clinical Order and the Group Manager Medical Services suggests that "*I suppose if we train doctors to think of themselves as part of a system rather than as independent practitioners, that would achieve that end*".

The other problem with IT investments, and especially the clinical IT systems, is that healthcare organisations tend to be solution-focused, more than problem-focused. "*so they come in solutions and then look for the problem that it's solving as opposed to what problem do I need, what actual things do I need to resolve*" [PMO#1].

Case Vignette 1: Nursing Documentation System

The system has shown high fidelity to the processes of nursing care delivery in the sense of time consumed for nursing documentation. This time fell from 15.7% to 6.4% after the inroduction of this system, freeing up over 9% of nurse time from record-keeping. This decrease has allowed an increase in the proportion of nursing activities devoted to patients assessment from 5.2% to 9.1%. The way the system was designed (smart terminals by the bedside) has increased transparency in healthcare provision. This has been achieved by increasing the nursing activities performed by the bedside by up to 48.1% since the introduction of this system, which has created better platforms for longer interaction between the nurses and the patients (23.6% of time nurses spend with patients compared to 7.95% before the system). [1]

Although maximsing the care time and minimizing the time dedicated to other nursing activities is important, it is "*much more complex than just taking some aspects of the role away"* [NAS#1], citing the the big strike back in 1980's in Victoria, Australia around non-nursing duties. Back then, nurses were continually doing duties that were not direct patient care, like some cleaning activities, supervising things that probably should have been done by housekeeping, and lots of administrative paperwork. Although a lot of those responsibilities were taken away from nursing, there has not been an evaluation that shows this has enhanced nursing care. *"I think that even with our new technology that we're testing now, nurses find other things to do"* [NAS#4].

During the interviews, our interviewees gave us the impressions that the concentration should be focused on the quality of time spent with patients not the duration of it. This is complex though, and requires a "*whole of care redesign. IT has the ability to facilitate this, but there are human factors should not be left behind*". [NAS#3].

[1] These results are the summary of a research project to evaluate the fidelity and usability of the ND system. The reference is available upon request.

Another important aspect of introducing state-of-the-art IT systems into healthcare, which is visible to the patients is the reputation, which is a *"fundamental part of the business"* [PMO#5]. Consequently, *"if patients feel that even just on face value, that the nurses are not scribbling on a piece of paper, but actually, they've got an IT system that provides confidence in the organization".* [NAS#3].

Two other problems were identified with this system. First, it is limited to ward care, and it does not fit well within the scheme of care in the hospital. *"I'm a bit concerned that you've got an end-to-end process where a patient comes in. They're booked. They're pre-admitted. They're admitted. They have an inpatient stay. In that inpatient stay, there's a section in theatre. They're then discharged and then go home, whatever. This system may be a part of that whole process. It won't do the theatre piece so when the patient goes into theatre"* [CIO]. Thus, The fit of any IS/IT system into the care strategy of any healthcare provider needs to be clearly articulated.

Second, the system is still under development, and "*health care companies don't tend to like to be at the bleeding edge*" [CIO], as "*we are healthcare business, not an IT shop*" [CCIO].

Case vignette 2: Computerised Practitioner Order Entry (CPOE) System

The studied CPOE system in this paper is dedicated to cancer care. The difference between the drug prescribing systems in cancer care and other systems in different care contexts is its complexity. "*Drug prescribing systems typically prescribe a single drug for blood pressure or antibiotics and dizzy dotted period. In the cancer treatment, there are things called chemotherapy private calls, which are often five or six drugs given at very specific individuals, specific doses for lengthy period and the prescribing function in those is quite complex because they have to be given according to certain recognized protocols".* [OAS#1]. The studied COPE system provides these complex funtions.

The introduction of this system has positively impacted the patients'outcomes. *"There's been a significant reduction in errors because we prescribe according to the protocol. These protocols are quite common and human error in transcribing is common. It's reduced legibility errors, all that sort of stuff."*[OAS#2].

The problems with implementing this specific system can be classified into two categories: the system characteristics, and the organisational characteristics.

The System Characteristics

The system is an American model. *"it is an international software that struggles with local billing practices which are different everywhere, and so are the drug protocols. It needs more domestication because it's an American product"* [OAS#1].

Second, the studied hospital has two of the three available modules of this product. These two modules were be described as: *"one really is good, the other is okay and we are trying to get them to talk to each other."* [PMO#2].

The Organisational Characteristics

The studied hospital is a private hospital, where the majority of the oncologists are visitor medical officers (VMOs). This group of knowledge workers have invested heavily (both emotionally and financially) in their own IT systems. Although there's a lot of mutual interest in IT between the VMOs and the hospital, "*they're talking about different sorts of IT. That leads to a massive amount of misunderstanding*" [OAS#1]. This misunderstanding seems to result in incompatibility between the two parties. This incompatibility is more conceptual rather than technical: *"The incompatibility between IT systems is fixable and it's mostly achieved by standards like HL7. But the incompatibility that I'm talking about between medical professional staff in hospital is a conceptually incompatibility"* [OAS#2].

The other organisational problem is that IT in this hospital is mainly controlled by a project management approach, where project managers, who report to "project sponsors", have other full day-to-day responsibilties. This results in delays in meeting the milestones, and less tangible impact of the IT system in the short-term.

Case vignette 3: Online Second Medical Opinion Application

The MyConsult application has provided second opinions to patients from over 105 countries for the past 12 years. While most of the users are consumers who locate the service through traditional search services, over 13.5 millions are provided access to MyConsult as a health care benefit from their employer. Evaluating the data streams and interviews focused on the business, administrative technology, and clinical inputs and outputs. MyConsult improves efficiency for patients, their doctors and consultants; empowers and engages patients with personalized information and the productivity enhancements substantiates the value produced in the program.

Each of the internal and external costs were evaluated as depicted in Table 1. Furthermore, these costs were classified based on the level of healthcare delivery.

Table 1- Mapping MyConsult to the Conceptual Model

Internal and External Costs	MyConsult Operational Response	Parameter	IT Layers
Working the request in individual offices	Centralized, standardized MyConsult Clinical Operations Center	Clinical Practice - Internal variability in case labor becomes standardized	Transactional Infrastructure
Customer service distributed	Trained, highly experienced team	Delivery Operations - Patient experience	Strategic Infrastructure
Physician participation and expertise matching	Institute derived participation with clinical leaders	System structure - Internal physician satisfaction	Strategic Transactional Infrastructure
Variable response format	Standardize report format	Delivery operations - Patient experience	Transactional
Readability and comprehension variable	Doctor translated into patient English	Delivery operations - Patient experience	Informatic Transactional
Conflict with other duties	Incorporated in duties	System structure, Clinical practices - Internal physician satisfaction	System structure Delivery operations Clinical Practices
Expectations from patient not always clear	General and diagnosis specific questionnaires	Delivery operations, patient satisfaction	Healthcare ecosystem Informatic
Medical record collection challenges	Offering medical record collection services	System structure, Delivery operations - Patient experience	Informatic, Strategic, Transactional, Infrastructure

Overall, the enterprise adoption and adaptation of the application was supported by the clinical leadership driving participation and diagnosis coverage, streamlining and optimizing online and clinical processes, and integrating into clinical practices and schedules. For patients, the concurrence of diagnosis approached 75% while the concurrence of treatment recommendations approached only 38%, further demonstrating value provided to patients.

Discussion

In healthcare, demonstrating business value of IT is challenging. This is largely due to the complex nature of healthcare operations, the web of players that must interact with any particular IT solution, as well as structural and organizational issues. An integrative model to assess the value of a clincial informatics solution requires consideration of the key stakeholder's perspectives of healthcare value. The use of the IT portfolio classificiations of infrastructure, transactional, informational, and strategic IT provides an excellent basis for organizing these perspectivies [16]. When combined with the

Enterprise of Healthcare Delivery Model classifications of clinical practices (people); (ii) delivery operations (processes); (iii) system structure (organizations); and (iv) healthcare ecosystem (society) [17], this model becomes a powerful tool for assessing the business value of healthcare IT.

The three case studies used to illustrate and demonstrate the fidelity of the proposed solution are taken from clinical contexts that exhibit these challenges. For example, unique structural considerations at the Cleveland Clinic include that its medical staff are salaried, while unique structural considerations for private hospitals in Australia include that their doctors are typically visiting medical officers (VMOs) and not salaried. Such structural differences severely affect the effectiveness of enterprise wide clinical IT systems such as the ones discussed in the respective scenarios, and thus also the ultimate business value of the IT that can be realized. While still under development, the proposed assessment tool is both flexible and rich enough to provide useful information to executives in all these scenarios. We believe that this is a key strength of the tool. At this stage, assessments are more qualitative than quantitative, but we anticipate developing quantitative scoring systems in the future. What is particularly attractive about the proposed tool is the generalized applicability across all healthcare IT solutions, which means that now it will be possible to carefully examine and compare relative values of different IT solutions in healthcare contexts; something which to date has been extremely difficult, if not impossible, to do.

Conclusion

As the adoption, assimilation and diffusion of IT in healthcare increases coupled with the pressure for healthcare organizations to demonstrate improvements with respect to access, quality and value for patients; the need to objectively assess the value afforded by IT investments will increase. Our research serves to begin to address this need through the development of an integrative value of IT assessment tool and has demonstrated its validity by illustrating its use in three different clinical contexts. There is a clear need for a systematic, robust framework to assess the business value of these clinical informatics solutions. Future research will focus on developing the framework further and continually testing it with the many IT solutions that are becoming available to assist in directing appropriate resources.

Conflict of Interest

There is no conflict of interest by any member of the study team or from the participants in this research.

Toward User-Centered Patient Safety Event Reporting System: A Trial of Text Prediction in Clinical Data Entry

Lei Hua[ab], Yang Gong [a]

[a] *School of Biomedical Informatics, University of Texas Health Science Center, Houston, TX*
[b] *Informatics Institute, University of Missouri, Columbia, MO*

Abstract

As a primary source for learning from lessons, patient safety event reporting systems have been widely adopted. Nevertheless, underreporting and low quality of reports pervade the system. To address these issues, the study proposed two text prediction functions as data entry aids to system users. With 52 subjects, a two-group randomized experiment was conducted to quantify the impacts in terms of the reporting efficiency, quality, and usability attitudes. Consequentially, on structured data entry, the results were an overall 13.0% time reduction and 3.9% increase of response accuracy with the functions; on unstructured data entry, there was an overall 70.5% increase in the text generation rate, a 34.1% increase in the reporting completeness score, and a 14.5% reduction on the amount of text fields ignored by subjects. Subjects' usability attitudes were slightly improved with the proposed functions according to the questionnaire results.

Keywords:

Ppatient Safety Event Reporting; Usability; Text Prediction; Performance Measurement; Randomized Experiment.

Introduction and Background

In 1999, the prestigious report "To Err is Human" released by the Institute of Medicine estimated 44,000 – 98,000 patient deaths each year due to preventable medical errors [1]. In a recently published study in 2013, the estimation was raised to 210,000 – 440,000, which made the medical errors the third-leading cause of death, behind heart disease and cancer in the United States [2]. To learn from the errors in order to improve patient safety and healthcare quality, electronic event reporting (e-Reporting) systems have been proposed and promoted nationwide. However, low-quality reports pervade the systems and undermine the user engagement of e-Reporting.

As one of the most prominent factors associated with low-quality reports, data entry has received much attention in clinical information systems, such as electronic health record and computerized provider order entry system [3,4]. Quality data in patient safety holds promise in prompting system acceptance, which in turn may form a virtuous loop in leveraging system performance, user engagement, and patient safety. In this two-group randomized study, we explored text prediction techniques for facilitating data entry in terms of quality and efficiency.

Method and Material

Subjects

The study enrolled 52 nurses from 21 clinical departments in Tianjin First Central Hospital (TFCH) in China. All nurses were female between the ages of 30 and 52 years. On average, they had 20 years of nursing experience and four years of experience with e-Reporting. All participants signed an informed consent form approved by the Ethics Committee at the TFCH (No.E2012022K). This study was also approved by the Institutional Review Board at the University of Texas Health Science Center at Houston (No. HSC-SBMI-12-0767).

Interfaces

Two experimental interfaces (control and treatment) were developed as a means of configuration control during data collection. The two interfaces were identical in terms of task and representation, requiring the completion of 13 structured multiple-choice questions (MCQs) defined by AHRQ Common Formats [5] and one free text, multiple-line comment field for reporting additional details of patient fall. A single exception between the two interfaces was the provision of text prediction functions in the treatment interface, which included a cueing list (CL) and autosuggestion (AS). As illustrated in Figure 1, part B, the CL was attached to the MCQs (4 out of 13) that had a single text field. For unstructured data entry, the comment field was equipped with both the CL (part C) and AS (part G) in the treatment interface.

All items contained in the CL and AS were manually prepared [6]. Two domain experts reviewed all testing cases, and transcribed and categorized the key elements with the colloquial language in Chinese with characters Hanzi and phonetic typing method Pinyin. Pinyin text input methods (IME) are based on the standard qwert keyboard and are the most popular in Chinese. Pinyin IME does not require additional training for those who recognize English letters.

To prepare the CL and AS, expert reviewed words, phrases, and sentences were populated into a data table serving as reminder items. The number of listed items in any CL and AS was limited to 10, based on a trade-off between inspecting efforts and predicting sensitivity [7]. In the CL, at least one of the items was considered to be more descriptive, accurate, and pertinent to the case being reported than the rest. In the AS, the display of suggested entry options relied on a Soundex algorithm (phonetic matching function) of MySQL and the reporter's initial entries. As illustrated in Figure 1, Part G, the top 10 hits were rendered in the AS list. On the treatment interface, the subjects were allowed to select mixed entries from the AS list and user-generated text input. On the control interface, subjects were not provided any AS or CL; thus, each participant had to generate his or her own text input through a regular qwerty keyboard.

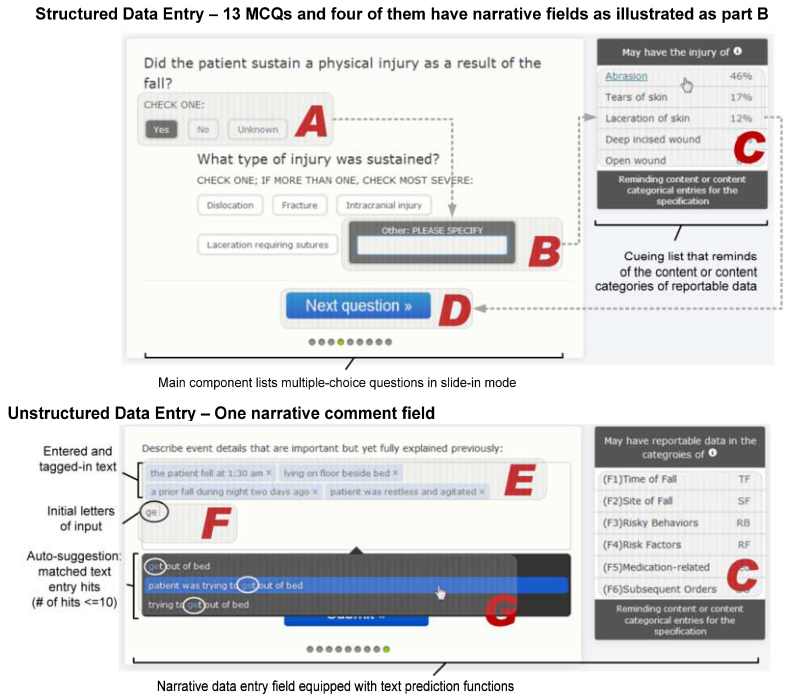

Figure 1 – The layout of interface elements is shown in English for both structured and unstructured data entries. Text prediction of *Cueing Lists* (CL, box C) and *Auto Suggestion* (AS, box G) are triggered with cursors in the corresponding fields. Box A shows the first answer triggering generated by the child's answers to questions B, C, D, etc. Box C is activated only when a single-text field (B) is open. CL reminds reporters of the content or key characteristics of reportable data associated with the event. The number of items listed in CL is <6. When pressing the button (D), a report would show an unstructured page containing boxes E, F and G. When initial letters (shown in box F) of the description are typed in, a matched list provided by AS shows up. The number of items listed in AS is <10. Matched letters and the focused line are highlighted in blue (G). Reporter may select one at a time and modify as necessary. Pressing the "Enter" button (behind G) will tag the current entry in a blue text chunk (as shown in E).

Testing Cases

In the study, each subject reported five patient-fall cases in a randomized sequence. The cases were selected from two sources —a case depository with 346 fall reports from a previous study [8] and a public database of Morbidity and Mortality (M&M) [9]. The five selected cases were translated into Chinese and rephrased by two domain experts for the purpose of quality and readability of text. A similar complexity of the five cases was agreed on by the domain experts. The following English narrative is an excerpt from one of the cases.

> *"… patient was alert and oriented X3 (person, time and location) upon assessment, and instructed on admit not to getting up without assist. He had been sleeping and attempted to get up to go to the bathroom. He forgot to call staff to have plexipulses (a device) undone, and tripped on plexi tubing and attempted to catch self on overhead bars. He landed on the floor…"*

Experimental Design

With a permuted-block algorithm, the 52 subjects were randomly assigned to two groups. 25 subjects were allocated into the group using the control interface without text prediction; 27 were assigned to the group with the treatment interface. The presenting sequence of five cases for each subject was randomly assigned. The subjects were trained through verbal instructions, and then asked to practice using both interfaces to report a sample case until each felt comfortable with the content and interface interactions. Since the training was conducted prior to grouping and the grouping procedure was blinded to both the subjects and the trainer, this design prevented confounding influences and training bias which might be delivered by the trainer.

Table 1 – The data sources and the units of analysis of key measures in the study

Measures	Data sources	Unit of analysis
Subject		
Age	Hospital nursing office	Years
Proficiency of reporting falls	Graded prior to the experiment	5 points Likert scale (1-low to 5-high)
Reporting efficiency		
Structured data entry	Accumulated time on MCQs	Seconds
Descriptive comments	Completion time on the comment field	Seconds
Text generation rate	Nominator: Letters in length of the comments; Denominator: completion time	Letters/Second*
Quality of reports		
Structured entry accuracy	Nominator: Accumulation of scores on MCQs; Denominator: Maximum of the accumulation	Percentage
Narrative completeness	The number of credited text chunks	Counts
Survey usability attitudes		
User attitudes in four dimensions	Posttest questionnaire	5 points Likert scale (1-low to 5-high)

* To count the length in letters, one UTF-8 encoded Chinese character equals three English letters in length.

In the hospital, a typical scene of event reporting is that a reporter initiates a report upon a witness's word-of-mouth information. This study simulated the natural scene by using the five cases with each having appeared on the first page of the interface. Subjects read the descriptions and answered the questions upon recall.

Pauses and pop-up questions were discouraged, except when a subject was in transition between reports. Keystroke level operations (mouse clicks and keystrokes) for each subject trial were time stamped and logged into a MySQL database. All reporting sessions were recorded using Camtasia Studio® 7 for data reconciliation. Each session was concluded with a questionnaire [10] via SurveyMonkey to reflect user attitudes in e-Reporting. The questionnaire was developed following Nielsen's Attitudes of Usability with a five-point Likert scale, wherein "1" indicated a maximal level of disagreement to the statement and "5" indicated a maximal level of agreement.

Processing of Data

The study collected ordinal and nominal data out of three data sources, including MCQs, narrative comment fields, and questionnaires. Ordinal data are the selected response items in the MCQs and questionnaires, and nominal data are the text entries in the single-line fields of MCQs and the comment field at the end of each report. We examined the ordinal and nominal data in terms of efficiency, effectiveness, and usability attitudes. Other experimental features associated with the CL and AS functions were also investigated. Table 1 lists the data sources and units of analysis of the measures.

Results

All the subjects successfully completed the experimental sessions with each subject having reported five cases, and the group consequentially generated 260 reports and 52 questionnaires. On average, each subject's session took 71 minutes, which consisted of 17 minutes in training and practice, 45 minutes in case-documenting, and 9 minutes in the questionnaire. There were 25 subjects in the control and 27 subjects in the treatment groups, accounting for 125 and 135 reports respectively. The mean ages of the subjects' groupings were 43.6 ± 5.8 (control) versus 41.1 ± 6.7 (treatment). The differences of ages and proficiency scores between the groups were insignificant ($p > 0.05$). The 260 reports contained 2,849 answers to MCQs and 238 unstructured narrative comments. As shown in Table 2, the subjects had eight significant variations between the groups indicated by an arrow ↑ (increase) or ↓ (decrease). Almost all variables, except for mouse clicks, in the treatment group showed an improved performance against the control group.

The analysis showed that the efficiency and quality of reporting can be enhanced by CL and AS for both structured and unstructured data entries. As illustrated in Figure 2, for the structured questions, the completion time was reduced by 13.0%, while the accuracy had a 3.8% increase overall. For unstructured narrative entries, the text generation rate was increased by 70.5%, which significantly increased the generation of free text data volume without an increase of time consumption between the groups. The reports generated in the treatment group were much more complete (34.2%) and richer in text (24.4%) than those in the control group.

As indicated in Table 2, the introduction of CL greatly improved the missing comments in the narrative field where the non-adherence rate dropped from 14.5% to 1.5%. CL functioned as a dynamic display when the page containing narrative comment fields slid in, as shown in Figure 1 (Part E, F & G). CL successfully drew subjects' conscious attention to the interface content. This dynamic CL signaled a compelling message to the subjects about the importance of filling the comment field.

Analytical results out of the questionnaires show potential non-adherence that may occur due to the following reasons: (1) a slip of unconscious skip of the comment field, (2) a lack of ideas of what event characteristics should be described further, and (3) that memory fades when working on the comment field.

Benefits from AS and CL also showed in keystrokes. In the reports, keystrokes were reduced by an average of 48.4%. In contrast, there was a 29.3% increase of mouse clicks. AS, in addition, showed a significant effect in generating 133 narrative comments, wherein AS was selected in 120 (90.2%) comments, totaling 460 times. Meanwhile, AS was inserted into 66.9% text chunks identified in the 133 entries. On average, AS was presented in 3.8 ± 1.9 text chunks in each report. A regression analysis showed that influential rate, defined as AS selection over total text chunks in each report, increased along the experimental progress ($p < 0.05$). Therefore, an observed learning effect amplified the efficiency along the experimental progress, as shown in Figure 4.

Fifty-two questionnaires were completed, which contained 1,300 rated answers. According to the analysis shown in Figure 5, the subjects showed overall good attitudes for the usability of both interfaces. The scores on all four dimensions slightly increased in the treatment group compared to the control group, but were not statistically significant. The text prediction functions implemented in the treatment group did not impact user attitudes in terms of learnability, efficiency, memory, and satisfaction.

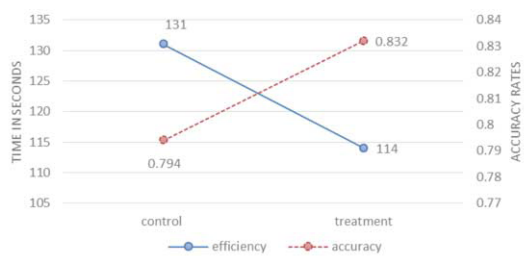

Figure 2 – Reporting efficiency and accuracy of structured data entries increased in the treatment group.

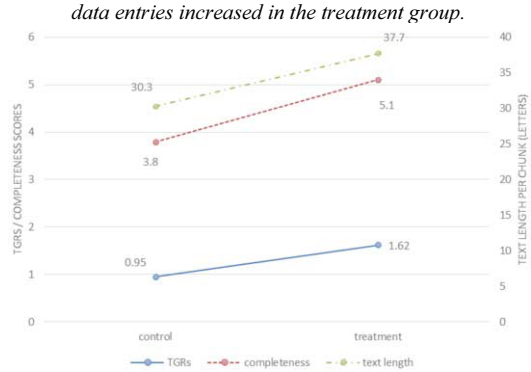

Figure 3 – Text generation rate and data completeness of unstructured data entries increased in the treatment group.

Table 2 – The subjects' performance in the reporting task.

Measure	Control Group	Treatment Group	Variation	*p*-value	Illustration
Subject					
Sample size (subjects/reports)	25/125	27/135			
Age	43.6±5.8	41.1±6.7		0.189	
Proficiency in reporting fall events (Likert scale 1-5)	3.8±0.5	3.9±0.5		0.413	
Reporting efficiency					
Time on case reading (seconds)	84.9±44.8	78.6±43.2		0.307

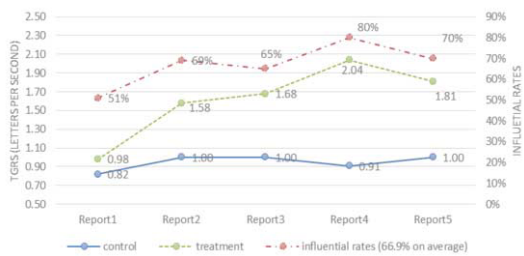

Figure 4. Text generation rates exhibit an overall increase (learning effect) over five reports in the treatment group. In contrast, such an effect does not present in the control group.

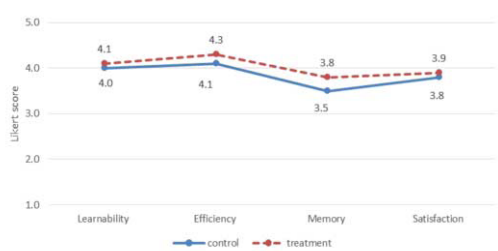

Figure 5. User attitudes of the treatment group are slightly improved than the control group.

Discussion

It is generally agreed that keystrokes could be reduced when clickable on-screen options are readily available on a user-centered interface. However, the keystroke savings alone remain inadequate in explaining the increased efficiency. Earlier research exhibits mixed, inconsistent results regarding improved efficiency of keystrokes in terms of cognitive load, eye gaze movement, and mouse clicking [11,12]. The balance between mouse clicks and keystrokes is an interesting topic in the process of developing an efficient and effective e-Reporting system. As touchscreen handheld devices are becoming pervasive in healthcare, significant keystroke savings on data entry may greatly amplify the benefits of user-centered design. This is because most touchscreen users prefer on-screen menu selection to on-screen keyboard typing.

The two-group randomized experiment proved the effectiveness of AS and CL text prediction in generating quick and high quality data entry in e-Reporting. User attitudes reflected in the questionnaires did not change significantly, but were potentially improved with the introduction of text predictions in e-Reporting. The observed effect may be generalizeable to other data entry interfaces in healthcare. Clinicians working under time pressure are expected to document in a timely manner [13,14]. Meanwhile, the quality of data has to achieve a high standard for decision-making and the creation of actionable knowledge. The solutions such as AS and CL experimented with in this study pave a way for addressing these concerns. The clinical document architecture (CDA) is a markup standard developed by Health Level 7 Internation (HL7) to define the structure of clinical documents, such as discharge summaries, progress notes, etc. Nonetheless, e-Reporting is becoming a routine documentation task where the structure is not yet well defined.

Recently, The Agency for Healthcare Research & Quality (AHRQ) created the Common Formats (CF), which are common definitions and reporting formats, to help providers uniformly report patient safety events and to improve healthcare quality. CFs include paper forms to guide the development of data collection intruments. When transforming the paper forms into electronic interfaces, designers should carefully learn from those lessons based upon the evolvement of electronic medical records.

One of the major purposes of e-Reporting is the collection of information and knowledge about patient safety events. Ironically, the e-Reporting process is not immune to human errors due to time pressure, multi-tasking, or competing priorities.

Recommendations for Interface Development in Healthcare

Guided by user-center design principles, we employed state-of-the-art and open-source techniques to rapidly prototype the dual-interfaces, one exhibited stereotypical functions in prevailing e-Reporting, the other was renovated and embeded with text predictions. The dual interfaces not only met the experimental requirements of randomization and control, but successfully demonstrated the effectiveness and effiency of the innovative design in e-Reporting. Interface design specifically for the purpose of e-Reporting requires further investigation, which would contribute to the purpose of collecting quality events, generating actionable knowledge, and sharing experience in reducing the recurrence of similar incidents.

Our design and development process is instrumental to many clinical information systems. The incremental effect on saving providers' time and improving report quality may be magnified, while evident-based estimates show 440,000 preventable events each year in the U.S. [2].

Limitations

CL offered in the interface presents a high quality contribution by domain experts. In reality, the prediction accuracy based upon an algorithm of event similarity and frequency of appearance may not match the manual effort of experts. In addition, the number of predicted items may differ in other clinical systems depending upon the richness of data entries. We did not provide an extended item list, which may be a burden for reporters' inspection. In the future, the question of whether text prediction with lower accuracy or a longer list would undermine the proven effect is worth further investigation.

It is a noteworthy dilemma that AS, designed for increasing text generation rate and accuracy, may lead to side effects, such as a subject's overdependence on the suggested items, and thus limit constructive thinking [15-17]. This is because, when provided with a predefined list of options, busy clinicians tend to recognize or ignore the options rather than specifying answers. The future development of the AS should carefully keep a balance between the strength and weakness of such protocols, and strategically address the dilemma.

Conclusion

User-centered design aimed at renovating e-Reporting demonstrated the effectiveness of text prediction in clinical data entry. This work may lay the groundwork for further research associated with text prediction in clinical information systems.

Acknowledgments

The authors express heartfelt thanks to Shen Wang, RN, Xiao Liu, RN and Ying Sun, RN at the Office of Nursing at Tianjin First Central Hospital in China who helped review and edit the testing cases, derived proper text prediction responses, scheduled the testing sessions, and graded the subjects' commentary data.

The Role of Hospital Information Systems in Universal Health Coverage Monitoring in Rwanda

Gustave Karara[a], Frank Verbeke[a,b], Marc Nyssen[a,b]

[a] *Department of Biostatistics and Medical Informatics,VrijeUniversiteit Brussel, Brussels, Belgium*

Abstract

In this retrospective study, the authors monitored the patient health coverage in 6 Rwandan hospitals in the period between 2011 and 2014. Among the 6 hospitals, 2 are third level hospitals, 2 district hospitals and 2 private hospitals. Patient insurance and financial data were extracted and analyzed from OpenClinic GA, an open source hospital information system (HIS) used in those 6 hospitals. The percentage of patients who had no health insurer globally decreased from 35% in 2011 to 15% in 2014. The rate of health insurance coverage in hospitals varied between 75% in private hospitals and 84% in public hospitals. The amounts paid by the patients for health services decreased in private hospitals to 25% of the total costs in 2014 (-7.4%) and vary between 14% and 19% in public hospitals. Although the number of insured patients has increased and the patient share decreased over the four years of study, the patients' out-of-pocket payments increased especially for in-patients. This study emphasizes the value of integrated hospital information systems for this kind of health economics research in developing countries.

Keywords:

Hospital information system; universal health coverage; monitoring health insurance; patient out-of-pocket payments; Rwanda.

Introduction

Providing universal access to health care remains a challenge for many low income countries especially because of the weakness of their health financing systems [1,6]. In the Sub-Saharan African context, Rwanda currently sustains one of the most elaborate health insurance schemes. Health care services are funded by both public and private health insurance organizations. Public health insurance schemes include the Rwanda Social Security Board (RSSB) and the Military Medical Insurance (MMI) which cover government employees and the Community Based Health Insurance (CBHI) schemes, also called Mutuelles de Santé, which cover the majority of the remaining population (according to the Ministry of Health, in 2012, more than 90% of the population was covered by CBHI [2]). Additionally, private health insurance (PHI) schemes are offered by a growing number of private health insurers. Public and private health insurance organizations have different objectives and therefore provide different levels of health insurance coverage to different groups of affiliates. CBHI schemes cover the majority of the population in the informal sector and those who are categorized as poor, very poor or indigents. RSSB and MMI schemes cover, respectively, the staff of the Public Service and staff of Security Services (Army and Police) and their beneficiaries. PHI schemes cover patients from the formal sector and liberal professionals according to the level of insurance of their choice [3].

In general, CBHI schemes cover 90% of provided care delivery costs. RSSB and MMI cover 85% and PHI coverage varies between 85% and 100%. CBHI only covers health services provided by the public health facilities while affiliates of RSSB, MMI and PHI also have access to private health care.

Rwandan health insurance companies can freely negotiate tariffs with public and private health facilities for the care deliveries they wish to cover but the Ministry of Health can always enforce fixed tariffs for essential health services. Four tariff categories are used in Rwanda: (1) CBHI, (2) RSSB/MMI, (3) PHI and (4) people without health insurance. Invoice processing, payment status tracking and health care reimbursement rules have become increasingly complex [4]; some health facilities have therefore chosen to implement a Hospital Information System (HIS) to manage these activities.

From 2007 until 2014, the authors participated in the implementation of the open source OpenClinic GA HIS [4,5] in 17 public and private clinics and hospitals in Rwanda. OpenClinic GA is an integrated hospital information management system resulting from a research project at the Vrije Universiteit Brussel (VUB) that includes most of the modules commonly found in modern HIS [5], such as:

- Patient administration
- Admission, discharge and transfer (ADT) management
- Financial information management
- Reason for encounter and diagnostic coding
- Medical record management
- Lab information management
- Medical imaging
- Reporting and statistics

The software was developed in Java connecting over JDBC to the most popular ANSI SQL 92 compliant database servers (such as MySQL and MS SQL Server) and offers an easy to use web interface facilitating HIS deployment in often challenging technological settings commonly found in developing countries [4,5]. OpenClinic GA has been built according to the GEHR (Good Electronic Health Record) architecture [4]. The data model is patient oriented.

Currently OpenClinic GA is being used in more than 500 health facilities in 84 countries and 45 of these sites in Rwanda, Burundi, DR Congo, Mali, Senegal, Gabon and Congo Brazzaville are being closely monitored by the VUB ICT4Development research group [12]. OpenClinic GA has

gradually become the first medical Open Source software project downloaded over the world [11].

Using patient insurance and financial data available in Openclinic GA systems from 6 Rwandan hospitals, and in order to determine the level of population health coverage in the hospital, this study aims to evaluate: (1) the percentage of patients with health coverage, consulting health facilities in Rwanda, (2) to what extent patients make use of the possibility to get private healthcare when this is covered by their health insurance plan, (3) the evolution of the level of reimbursement of different health service categories and (4) the evolution of patient payments for uncovered health services. This descriptive and analytical retrospective study was performed in 2 third level referral hospitals, 2 district hospitals and 2 private hospitals.

Methods

The study was conducted in 6 Rwandan hospitals:

- 2 national referral hospitals: the University Teaching Hospital of Kigali (CHUK) and the Neuro-Psychiatric referral Hospital Caraës-Ndera (Kigali) (NPH-CN).
- 2 district hospitals in the Eastern Province in the cities of Nyamata (DHNY) and Rwamagana (DHRW)
- 2 private hospitals in Kigali: La Croix du Sud Hospital (CDS) and La Médicale Polyclinic (LMED).

OpenClinic GA has been installed and implemented in these 6 hospitals since 2010 and was configured to cover all possible statuses of patients' health insurance. The financial module of the system manages the various patient health insurance schemes, care deliveries consumed by patients and all billing operations for patients and their insurers. We analyzed the health coverage information available in the HIS health insurance module for all patients treated between 1/1/2011 and 30/11/2014.

First, we isolated two patient groups from the database: those who presented to the hospital with at least one valid health insurance and those who had no health coverage. We then evaluated the evolution of health insurance coverage during the study period.

Secondly, for each outpatient visit and each inpatient admission, we determined the type of health coverage that applied. Four types of health service payments were distinguished: (1) patient direct payments (PATIENT), (2) public health insurance payments (RSSB/MMI), (3) private health insurance payments (PHI) and (4) community health insurance payments (CBHI). We then calculated the weighted average percentages for the different types of health coverage in those hospitals and compared them using the Chi² test in the Center for Disease Control's Epi Info.

Finally, we extracted the amounts paid by patients and insurers in each hospital and assessed the evolution of their proportions and the absolute amounts paid by the patients for health services (patient out-of-pocket payments).

Results

Health services coverage

We analyzed a total of 778,915 electronic records of patients who consulted the 6 hospitals. The distribution of patient numbers is shown in Table 1.

Table 1 - Number of Electronic Patient Records Analyzed

CHUK	NPH-CN	DHRW	DHNY	CDS	LMED	Total
216 389	32 128	92 907	89 218	170 852	177 421	**778 915**

The evolution of the proportion of patients who are covered by at least one health insurance scheme shows a steady increase in all six hospitals in the course of the 4 year study period, as shown in figure 1. In the Neuro-Psychiatric hospital of Ndera (NPH-CN), the health insurance coverage increased from 90% to 98% between 2011 and 2014 while at CHUK, it grew from 74% to 85%. In the district hospitals of Nyamata (DHNY) and Rwamagana (DHRW), health insurance coverage improved from 78% to 88%. Similar results were obtained from private hospitals, where health coverage grew from 63% to 72% at La Médicale (LMED) and from 70% to 76% at La Croix du Sud (CDS).

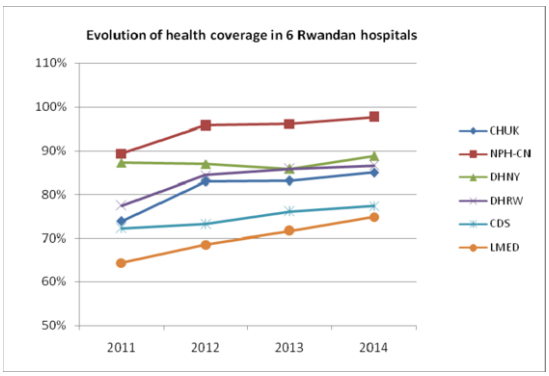

Figure 1 - Evolution of patient health coverage in 6 hospitals

Health insurance schemes in hospitals

For every out-patient encounter or in-patient admission, part of the health service costs must be paid by the insurer and the remainder by the patient, according to the patient's health coverage plan. A number of health services remain uncovered by some health coverage plans and therefore patients' out of pocket payments may vary considerably depending on the type of care that was provided. In this step, we analyzed the real reimbursement levels of different health insurance schemes over time, taking into account the uncovered parts of care.

A total of almost 2.9 million encounters (2,534,967 outpatients and 342,878 inpatients) have been analyzed, as shown in Table 2.

Table 2 - Numbers of Encounters Analyzed

	In-patient	Out-patient	Total
CHUK	92 103	639 447	731 550
NPH-CN	22 260	244 653	266 913
DHRW	110 941	224 817	335 758
DHNY	58 665	260 176	318 841
CDS	55 655	708 327	763 982
LMED	3 254	457 547	460 801
Total	342 878	2 534 967	2 877 845

The number of patients who were hospitalized at LMED is low because the use of OpenClinic GA for hospitalizations is very recent in this hospital. CHUK and CDS are 2 reference hospitals in Kigali, respectively, for the public and the private health sector. They contribute to a significant part of in- and

out-patients in our study. Figure 2 and figure 3 show the average proportion of insurance schemes coverage, respectively, for in-patients and out-patients in the 6 hospitals during the study period.

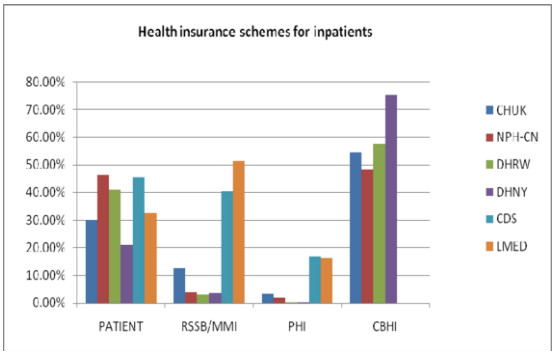

Figure 2 - Health insurance schemes for in-patients

In general, for in-patient encounters, the community based health insurance (CBHI) is the most commonly used scheme (weighted average: 60.7%) followed by public insurance (RSSB/MMI) with a weighted average of 27.7%, private insurance (PIH) for 12.9% and finally the patient directly paying for uncovered health services (PATIENT) in 37.6% of the cases. In over 45% of the in- patient encounters, patients paid directly for health care at NPH-CN and CDS due to certain care deliveries (especially hygiene supplies, specialty medicines) not being covered by the insurer. We noticed that the patient used direct payments for uncovered health services more frequently ($p<0.0001$) in the in-patient encounters in the private hospitals (44.9%) than in district hospitals (37.9%) and tertiary public hospitals (34.5%). The public health insurance coverage scheme (RSSB/MMI) is most commonly used for in-patient encounters in private hospitals (51% at LMED and 40% at CDS). There is a statistically significant difference ($p<0.0001$) between using public health insurance (RSSB/MMI) in private hospitals' (41.20%) and in public hospitals' (9.43%) in-patient encounters. At CHUK the RSSB/MMI scheme is used in 12.7% of in-patient encounters. The CBHI scheme is only used in public hospitals. It is used more frequently ($p<0.0001$) in district hospitals (64.85%) than in third level hospitals (53.38%). Finally, patients with private health insurance (PHI) are more often hospitalized in private hospitals (16.8% of the in-patients) than in the public ones (2.8% of the in-patients).

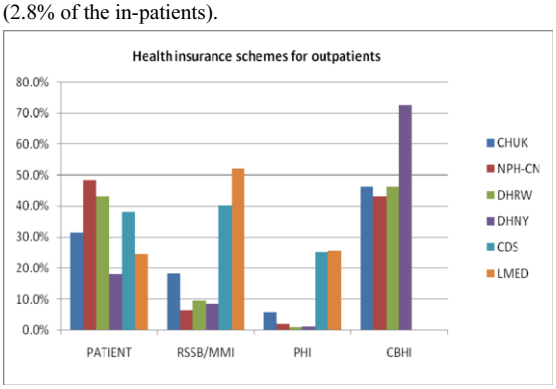

Figure 3 - Health insurance schemes for out-patients

Out-patient health coverage schemes follow a similar distribution. The CBHI scheme is more used (53.0% of the encounters) in out-patient encounters than other health insurance schemes: RSSB/MMI (38.0%), PHI (22.4%) and PATIENT (24.6%). Out-patients are facing more uncovered health services in public tertiary hospitals (37.8%) than in district hospitals (35.2%) and private hospitals (34.2%). The RSSB /MMI scheme is more used in private (45.8%) than in public health facilities (14.9%). The CBHI scheme is also more used in district hospitals (63.2%) than in tertiary hospitals (45.5%). Patients with private insurance were more likely to consult private (25.3%) than public hospitals (5.0%).

Multiple insurance schemes can co-occur in the same encounter for the same patient.

Health services payment in hospitals

Between 2011 and 2014, the proportion of patient out-of-pocket amounts paid, compared to the total amounts paid for the health service costs, has declined significantly in private hospitals: from 36.8% to 27.6% at LMED (-9.3%) and from 29.9% to 24.4% in CDS (-5.5%). This proportion also decreased at CHUK from 21.6% to 17.5% (-4.1%) but remained stable at NPH-CN (14.2%) and increased slightly in district hospitals: from 13.2% to 15.0% at DHNY (+ 1.8%) and from 17.2% to 19.7% at DHRW (+ 2.5%). Figure 4 shows the evolution of patient out-of-pocket payment proportions for health services between 2011 and 2014 in the 6 hospitals.

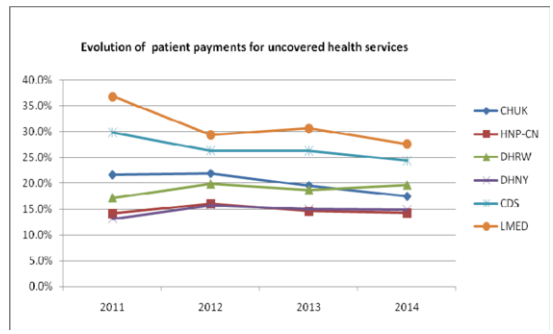

Figure 4 - Evolution of patient payment proportions for health services

The reason for the patient out-of-pocket payment proportion increase at DHRW is found in the increase of some non-reimbursable consumables (+ 2.6%), acts (+ 2.8%) and hospital stay (+ 2.6%).

Although the proportion of the amounts paid by patients has generally decreased during the study period, the absolute patient out-of-pocket payments for health services show a different trend as is demonstrated in figures 5 and 6.

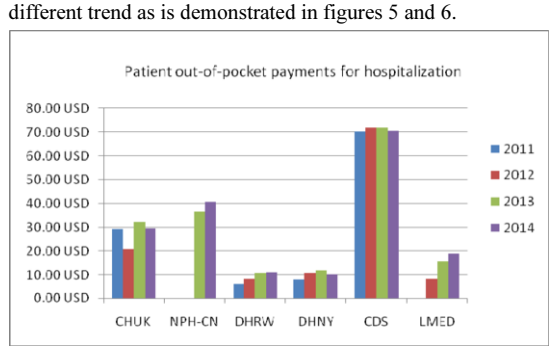

Figure 5 - Average amounts paid by the patient for health services for hospitalization

For hospitalization, the patient out-of-pocket amounts disbursed for health services at CHUK decreased the first year from 29.27USD to 20.67USD but then increased again. In 2014, the patient paid an average of 30.00USD for his hospital stay. At NPH-CN, patients' average payments for the hospitalization were 40.60USD in 2014 (NPH-CN began to use the invoicing module better in 2013). In district hospitals, patient out-of-pocket payments increased from 5.95USD at DHRW and 7.90USD at DHNY to 11.00USD and 10.15USD respectively. We noticed a large difference between patient payments in the two private hospitals: At CDS, the patient was paying around 70USD per hospitalization, while at LMED the patient out-of-pocket payments increased from 8.34USD to 18.88USD (LMED started to use the invoicing module well in 2012). The CDS experienced a period during which health care reimbursements were refused by some insurers before their accreditation as a "hospital" because their health service tariffs (especially for the hospital rooms) were too high (and the majority of the costs were not reimbursed by insurers) compared to other private hospitals and clinics.

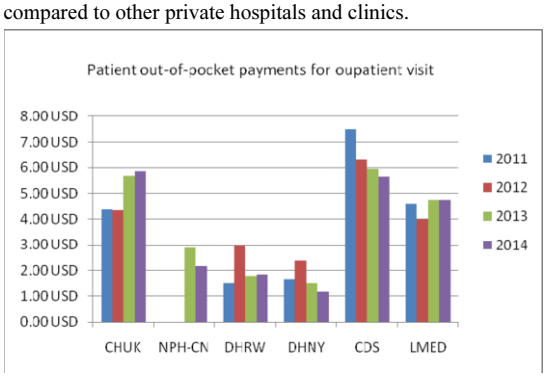

Figure 6 - Average amounts paid by the patient for health services in out-patient encounters

For out-patients between 2011 and 2014, patient out-of-pocket payments tended to increase at CHUK (from 4.38USD to 5.87USD), remain stable at LMED (around 4.50USD), and to decrease from 2012 in district hospitals (from 2.93USD to 1.83USD at DHRW and from 2.37USD to 1.15USD at DHNY), at NPH-CN (from 2.88USD to 2.19USD) and at CDS (from 7.49USD to 5.65USD). The decrease of patient out-of-pocket payments observed from the second year (2012) in district hospitals was explained by the increased number of insured patients and some consumables (gloves, syringes and needles) used during medical examinations which were initially charged to the patient and included in the global cost of the exams afterward. The decrease of patient payments observed at CDS was due to the increase of insured patients.

Discussion

This study focused on the monitoring of health coverage in Rwandan hospitals. The results showed that the health coverage in the 6 analyzed hospitals gradually increased between 2011 and 2014, reaching 98% at NPH-CN, 85% at CHUK, 88% in districts hospitals (DHRW and DHNY) and around 74% in private hospitals (LMED and CDS). Health coverage projections done in 2010 showed that in 2014, at least 92% of the population would have a valid health insurance for medical care in public health facilities [2]. This goal was reached at NPH-CN, a specialized national reference center for mental health care. Almost all patients treated at NPH-CN have a valid health insurance because the reference policy from district hospitals to tertiary hospitals enforces that insurance. In addition, difficult social cases are directly covered by the Ministry of Health. The Rwandan government pays special attention to psychiatric disorders which are often associated with higher financial risks [7,9] in a country that still faces psychological trauma consequences of 1994's genocide and war.

The high level of insured patients seen in private health facilities is explained by private health care coverage offered by public insurance schemes (RSSB / MMI) and private insurances (PHI) as shown in figures 2 and 3. Patients covered by public or private insurance which reimburse private health care are more likely to consult private hospitals where they hope to receive better quality of care [8,9].

The proportion of patients' out-of-pocket payments compared to total health service costs has declined in private hospitals and at CHUK. It remained almost stable in other hospitals (figure 4). But the average amounts actually paid by patients for health services tended to increase for in-patients and to decrease for out-patients. The decrease of patients' out-of-pocket payments is explained by the fact that the number of patients with valid health insurance has increased and insurers accept reimbursing certain health services that previously were not covered. This assertion was also confirmed by the study of Ties Boerma and colleagues [10]. However, this assertion is not confirmed for in-patients where certain health services remain to be reimbursed only partially or not at all by health insurers.

Conclusion

The use of an open source hospital information management system enabled the detailed monitoring of universal health coverage in 6 Rwandan hospitals. The results show improvement in health coverage in both public and private hospitals in the period between 2011 and 2014 due to the role of public, community and private health insurance schemes. But efforts are still needed to further reduce the patients' out-of-pocket payments.

This study demonstrates the possibility to assess the level of universal health coverage in a developing country using hospital management systems. Although we targeted referral health facilities, this experience could also be applied to first-level health facilities such as health centers through an adequate ICT infrastructure based health information management.

Abstract

A sensor network is key infrastructure for advancing a hospital information system (HIS). The authors proposed a method to provide roaming functionality for Bluetooth to realize a Bluetooth-based sensor network, which is suitable to connect clinical devices. The proposed method makes the average response time of a Bluetooth connection less than one second by making the master device repeat the inquiry process endlessly and modifies parameters of the inquiry process. The authors applied the developed sensor network for daily clinical activities in an university hospital, and confirmed the stabilitya and effectiveness of the sensor network. As Bluetooth becomes a quite common wireless interface for medical devices, the proposed protocol that realizes Bluetooth-based sensor network enables HIS to equip various clinical devices and, consequently, lets information and communication technologies advance clinical services.

Sensor Network; Bluetooth; Roaming; Hospital Information System; Clinical Application;

Introduction

A sensor network is key infrastructure for advancing a hospital information system (HIS). A sensor network enables one to plug various devices including vital sensors into a HIS and lets the devices send obtained data directly to connecting HISs. Consequently, the sensor network frees clinical staff from posting vital data into a HIS and frees patients from clinical incidents caused by misposting of the data.

The sensor network enables us to divide complicated medical equipment, such as the echogram, into functional units and embed the equipment into a gigantic computer system, which is called hospital [1]. Embedded medical equipment with tiny sensing units, such as wireless ultrsound probes, frees clinical staff from carrying heavy medical equipment or patients to move to rooms with medical equipment, and enables the clinical staff to perform measurements anywhere. As a matter of course, obtained data can be directly stored to a HIS, and the data may enable a HIS to provide certain clinical diagnostic support in proper moment. Thus, embedding medical devices into a HIS can be a silver bullet to increase clinical productivity and safety by maximizing the benefit of information and communication technologies [2].

A sensor network can be realized by any wireless communication technology, such as WiFi, Zigbee, and Bluetooth. A recent increase of social consciousness of health promotes vital sign sensors to equip connectivity with mobile information terminals, such as smartphones. The most common standard to mediate communications among personal health devices is Continua Health Alliance [3], which defines the standard connection protocol via Bluetooth. Recently, the existence of the Continua promotes clinical sensors to equip Bluetooth. Thus, once Bluetooth equips roaming functionality for enabling sensors to move around and real time location functionality to locate those moving sensors, it can be a feasible technology for emerging clinical sensor network environment.

On the other hand, the Bluetooth protocol, which is originally designed as “wireless serial bus”, is not suitable for roaming. The conventional Bluetooth protocol requires a time-consuming “pairing” process to connect a host computational device with a client terminals such as sensors. In this paper, the authors propose a method to provide roaming functionality for Bluetooth, implement the proposed method as a commercial Bluetooth sensor network system, and evaluated the developed system during daily clinical tasks at the Kyoto University Hospital.

Methods and Materials

Figure 1 shows the state transition diagram of Bluetooth. A Bluetooth module goes into “Standby” phase when it is switched on. When a CPU sends an “Inquiry” command to the Bluetooth module in standby phase, the module moves into the inquiry phase and starts to search nearby Bluetooth devices for a master communication device. Once a Bluetooth slave device such as a headset or a keyboard catches an inquiry packet from the master communication device, it responds with a Frequency Hop Synchronization (FHS) packet. After exchanging the inquiry and the FHS packet, both master and slave devices move into the “Page” phase and exchange communication parameters. Finally, both master and slave device move into “Connect” and “Transmit” phases to start data exchange.

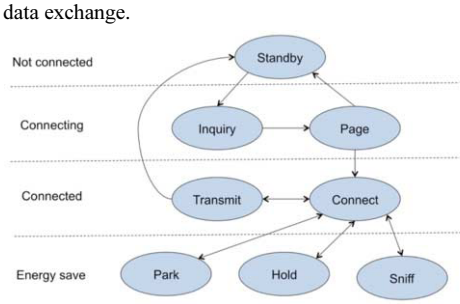

Figure 1 – The state transition table of Bluetooth

As a Bluetooth device moves into the page status immediately after discovery to wait for communication, a moving device, which is once coupled with a certain Bluetoth access point (BTAP), needs to wait for timeout to know that it is already out of reach of the BTAP. After that, the device needs to go through the inquiry process to find nearest BTAP. Moreover, the inquiry process is quite time consuming. The process requires approximately ten seconds. This limitation disables Bluetooth devices for smooth roaming under multiple BTAPs.

The authors made the master device suspend and restart the inquiry process in shorter periods by changing parameters, such as the master's inquiry interval and the slave's inquiry scan window size.When a master device suspends and restarts inquiry process every 640 milliseconds, the average response time to discover slaves becomes less than one second. As medical devices under operation in clinical environment will not move quicker than walking speed, the achieved response time, less than one second, is adequate to let devices move around.

Once a device obtains certain data to send, the device should be paired with a BTAP within a reach. As the paring process initiated by the medical device, the proposed system makes the medical devices act as the master nodes during inquiry mode. On the other hand, to enable a BTAP to accept connections from multiple devices, the BTAP needs to act as the master node of the particular connection to keep slave channel open to accept incomming connection request.

Figure 2 shows the detailed protocol of the pairing process. In this diagram, a new comer (DEV3) tries to connect to a BTAP, which is connected with two devices (DEV1 and DEV2). In the beginning, DEV3 works as a master Bluetooth device to repeat the inquiry process as Figure 2(a) to keep finding nearest BTAP. When DEV3 obtains certain data to send, DEV3 immediately connects with the BTAP through the standard Bluetooth protocol as shown in Figure 2(b), then swaps their roles with the BTAP as shown in Figure 2(c). As a result, the BTAP keeps its slave channel open to accept an incoming device as shown in Figure 2(d).

The BTAP keeps connection with DEV3 until DEV3 sends a termination code, an expected (pre-defined) data communication is finished, or the the BTAP detects timeout (Figure 2(e)). When DEV3 fails finishing communication, DEV3 goes back to inquiry process to find the nearest BTAP to restart the communication.

Results and Discussion

The authors developed and commercialized a Bluetooth-based sensor network system. The system provides a virtual serial port for a server to connect with Bluetooth devices over WiFi and Ethernet as shown in Figure 3. Figure 4(a) shows the developed BTAP (Takebishi Corp.).

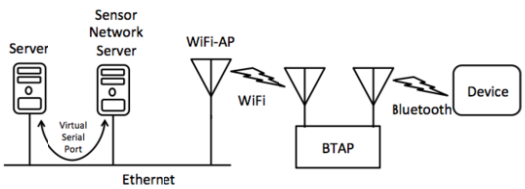

Figure 3 – Diagram of the developed Bluetooth-based sensor network system

(a) (b)

Figure 4 – The devices introduced to the hospital. (a) BTAP antenna (Takebishi Co.). (b) Barcode Reader (KoamTac Inc.).

Kyoto University Hospital [4] introduced the developed Bluetooth-based sensor network system with approximately 400 BTAP in 2011. The main target device was a Bluetooth-based barcode reader (KoamTac Inc. KDC 300, Figure 4(b)) for auto-ID / barcode enabled medication administration (ABMA) system [5]. Kyoto University Hospital introduced 1500 barcode readers. Each nurse and resident has a barcode reader for performing approximately 2700 safety checkups for transfusions and injections per day. Since January 2011, when the system was put into operation, the hospital has not experienced any major issues caused by lost communication, including roaming trouble, to the moment that this paper was written (April 2015).

The authors investigated all the comunication errors of the ABMA system on a standard business day, Thursday, October 9th, 2014. 2260 checkups were performed on the ABMA, and 32 communication errors occurred.

Figure 5 shows the basic communication protocol of the ABMA system. As the connection should be always initiated by the barcode device, the atomic communication of the system always consists of four messages, that is, barcode data, ack from server, response from server, and ack from the reader. During this atomic communication, no barcode device can change communicating BTAP.

As the ABMA checkup process consists of two atomic communications as shown in Figure 5, eight packets are needed to be sent to fulfill safety checkup. If any single packet within an atomic communication is lost, the ABMA system asks the clinical staff to re-read the barcode again. Therefore, the error rate of the observed day was $32 \div ((2260 + 32) \times 8) \times 100 = 0.17\%$.

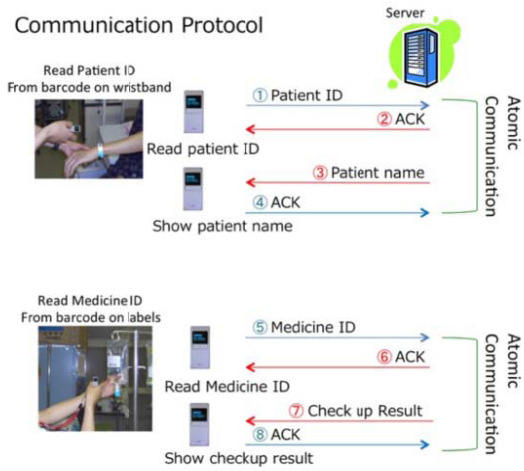

Figure 5 – Communication Protocol of the ABMA system

Additionally, packet can be lost during any connection between the device and the sensor network server. As shown in Figure 3, the communication is mediated by Ethernet and WiFi as well as Bluetooth. Thus, it is not the case that all observed error was caused by the roaming error of the developed system.

Thus, the developed roaming system worked quite well in the real clinical setup of Kyoto University Hospital, and provides clear efficiency for nurses to enable with their daily safety checkups with single tiny device. As a matter of fact, the average number of performed checkups per day increased from 1825 (January 2011) to 2260 (December 2014) after the introduction of the Bluetooth-based ABMA system. The number increased eight percent (from 1825 to 1973) in the first five months. This quite steady increase tells that the reliability of the ABMA system, supported by the realiability of the proposed Bluetooth roaming, earning the clinical staff trust. This fact clearly confirms the effectiveness of the proposed roaming mechanism.

As the proposed method realized by slight modification of the Bluetooth protocol, slight customization of firmware enables any Bluetooth-equipped devices, including the barcode reader introduced for Kyoto Univrsity Hospital, to connect to the developed sensor network.

The proposed protocol assumes that the connecting sensors send data intermittently. As the most of the vital sensing devices used in a standard hospital ward, such as blood pressure meter, body temperature meter, and weight meter, produce small size packets intermittently, just as the ABMA system implemented on the proposed sensor network that exchanges four short messages and four ACK packets. Therefore, the Bluetooth-based sensor network based on the proposed roaming mechanism may be able to accept most of such sensor devices.

On the other hand, in order to make the sensor network be enabled for continuous sensing devices, such as electrocardiogram (EKG) or oxygen saturation monitor (SpO2), certain compensation mechanism, such as buffering at the device side, should be considered.

Conclusion and Outlook

This paper proposed and implemented a method to provide roaming functionality for Bluetooth to realize Bluetooth-based sensor network for healthcare industries. The introduction of the developed Bluetooth-based sensor network system for daily activities in a university hospital with approximately 1000 admitted patients per day for five years clearly confirms the effectiveness and the availability of the proposed approach.

As the Bluetooth becomes a quite common wireless interface for medical devices, the Bluetooth-based sensor network may enable HISs to equip various medical and non-medical devices. Consequently, the sensor network expands capability of information communication technology to advance clinical services.

Acknowledgments

The research is partly funded by the Ministry of Internal Affairs and Communication of Japan, and JSPS Grant-in-Aid for Scientific Research (B) number 2580106. The authors would like to thank Takebishi Corp., Shimadzu System Development Corp. and IBM Japan for their precious support in developing, commercializing and implementing the developed sensor network and ABMA system.

On Building an Ontological Knowledge Base for Managing Patient Safety Events

Chen Liang, Yang Gong

School of Biomedical Informatics, University of Texas Health Science Center at Houston, TX, USA

Abstract

Over the past decade, improving healthcare quality and safety through patient safety event reporting systems has drawn much attention. Unfortunately, such systems are suffering from low data quality, inefficient data entry and ineffective information retrieval. For improving the systems, we develop a semantic web ontology based on the WHO International Classification for Patient Safety (ICPS) and AHRQ Common Formats for patient safety event reporting. The ontology holds potential in enhancing knowledge management and information retrieval, as well as providing flexible data entry and case analysis for both reporters and reviewers of patient safety events. In this paper, we detailed our efforts in data acquisition, transformation, implementation and initial evaluation of the ontology.

Keywords:

Medical error; Patient safety; Ontology; Knowledge management

Introduction

The increasing high rate of medical errors indicates that patient safety is a prominent issue [1, 2]. A recent study reported that preventable medical errors cause annual deaths of 210,000 to 440,000 in the United States [3]. The magnitude of these medical errors, as well as near misses and unsafe conditions, has raised public awareness on patient safety and interest in research. For the purpose of preventing error occurrence, much attention has been drawn into reasoning about systemic factors that contribute to the errors, while the road block appears to be the disclosure of patient safety events [1]. It is documented that the major obstacle to disclosing patient safety events and proposing systematic solutions is due to limited functionalities of a reporting system [4]. The core functionality of a reporting system is thought to be collecting, analyzing and learning from the existing mistakes [5-7]. Therefore, the systems should include functional modules such as data acquisition, knowledge management, information retrieval, and beyond.

Reporting systems are pervasively used in the United States [4, 8], Australia [9], United Kingdom [10] and other countries. Nevertheless, debates on the effectiveness of such systems still remain. So far , there has hardly been any study that reports a decrease of medical errors, mortality or morbidity directly due to the intervention of a reporting system [4]. Obviously, more efforts are needed to prove the value of the reporting systems. A first-line question is why the reporting systems are unsuccessful in demonstrating the value. Among various reasons, data quality is thought to be a major concern. Patient safety reports containing detailed narratives are helpful in replicating the incidents and further translating into improved patient safety. The narratives are different from other data types stored in generic health information systems, such as electronic medical record (EMR) data and clinical notes. Reporting systems collect a variety of data ranging from structured to unstructured formats and therefore may cause a data inconsistency issue, which leads to incompleteness and inaccuracy of the data entry [11]. For example, a reporting system with a structured data entry can oftentimes force the reporters to choose “other or miscellaneous” when they are asked to categorize a patient safety event [12]. In contrast, unstructured data (free text) are unconstrained in offering detailed information but they are not immune from issues. An obvious pitfall for the use of unstructured data in the reporting system is time efficiency. Many reporters are working under time pressure or in a multi-task mode and thus they may not have sufficient time to provide a complete and detailed report to the systems [11]. A recent study using a text prediction method intended to mitigate the abovementioned problems [13]. With this method, the system provides prompting information (suggested words/phrase to use) to the reporters at the time when they are typing free text into the data entry portal. The text prediction technique provides insights into extracting and organizing the semantic information based on the free text with the only limitation being that the prediction list was manually prepared by domain experts. Another pitfall for the use of unstructured data appears in data processing. Similar to clinical notes, typos, abbreviations, and nonstandard acronyms are typically intertwined with free text data. These have become barriers for data pre-processing, such as de-identification, and classification by natural language processing (NLP), and thus cost extra time for reviewers in understanding the data.

Taxonomies have been used to address these problems as they intend to manage patient safety events as a knowledge base. The taxonomies used to document and classify patient safety reports can be traced back to 1987 when the Australian Patient Safety Foundation (APSF) originally reported the Australian Incident Monitoring System [14]. Later on, a series of well known taxonomies were put into use, which include the JCAHO patient safety event taxonomy [15], the National Coordinating Council for Medication Error Reporting and Prevention (NCC MERP)’s taxonomy of medication errors [16], the Neonatal Intensive Care system (NIC) [17], the Pediatric Patient Safety taxonomy (PED) [18], the Preliminary Taxonomy of medical errors in Family Practice (PTFP) [19], the Taxonomy of Nursing Errors (TNE) [20], and the Adverse Event Reporting Ontology (AERO) [21]. While these taxonomies served primarily as domain specific knowledge bases, the rapid increase of patient safety data calls for a sharable knowledge base organized by a unified language system.

In sum, more efforts are needed for improving data quality, sharing and learning from patient safety events across the individual systems. A significant challenge to increase data

quality remains in the development of a unified domain knowledge base and the effective use of the data. To explore solutions to the problems, we aim to build a semantic web ontology (Medeon) using W3C open standard Web Ontology Language (OWL). The Medeon serves as a unified knowledge base for organizing patient safety events, and as a supporting component that facilitates the user end applications towards enhancing data entry and data quality.

Materials and Methods

Semantic Web Ontology

A taxonomy as a controlled vocabulary in hierarchy has been used in patient safety reporting for years. Ontologies are explicit specifications of conceptualized definitions and relationships where these specifications define a taxonomy of the knowledge [22]. Specifically, an ontology models the real-world knowledge by encoding the entities and the relationships among the entities. We aimed to develop an ontology to replace the role of a taxonomy because the ontology can provide a broader application over taxonomies. We chose OWL and semantic web technologies because they jointly provide a unique advantage for machine understandable semantics and descriptive logic reasoning. OWL has an advantage that allows us to identify unique patient safety terminologies or concepts that may appear under different names or originate from different sources. This advantage largely reduces the ambiguity in medical terminologies, and may advance the knowledge management of patient safety events.

Previous work on building ontologies for patient safety events employed various methodologies (i.e., techniques, tools, procedures and guidelines) [23-25], yet these approaches are lacking computer understandable representations. In the present work, we refer to the *Semantic Web for the Working Ontologist* for theories and general guidelines commonly employed in developing OWL ontologies [26]. Protégé (V4.3.0) was employed to implement the ontology.

learning across the reporting systems through a unified language serving as a common denominator. With this view, the Common Formats (v1.2) developed by the Agency for Healthcare and Research Quality (AHRQ) were employed as the taxonomy where we extracted and encoded semantic knowledge into Medeon. Recognized as a unified standard of reporting patient safety events, the Common Formats are designed to specify and collect event information, which range from general concerns to frequent occurrences and serious types of events. We borrowed the hierarchical structure in the Common Formats to build the OWL classes and rephrased the narrative data in the Common Formats to construct OWL incidents and objective properties. At the top level, four OWL classes consist of *Circumstances_of_Event, Patient_Information,Reporting_Reporter_and_Report_Information,* and *Type_of_Event*, with the maximum depth of four. Figure 1 shows the visualization of expanded classes. The OWL Object Property was defined as IsA property, for example, *Inattention IsA Human_factors*.

Data Acquisition

At an initial stage, all the entities and relationships implemented in Medeon were extracted from the Common Formats. Healthcare event reporting form (HERF), patient information form (PIF), and summary of initial report (SIR) in the Common Formats are regarded as a comprehensive and relatively complete collections of entities that can represent patient safety events. Therefore, a direct translation was performed in order to encode those entities from the Common Formats to Medeon. To obtain high quality data in the Common Formats, we followed a set of principles as guidelines [27]. Table 1 provides a brief description on the principles. We borrowed eight principles that were separated into three dimensions to guide the rephrasing of the language used in the ontology. Note that we did not include 'social quality' from the Dimensions in the original literature since this dimension measures the ontology comparing it to the existing ontologies and emphasizes the utility of the ontologies which are not applicable to the project. When the

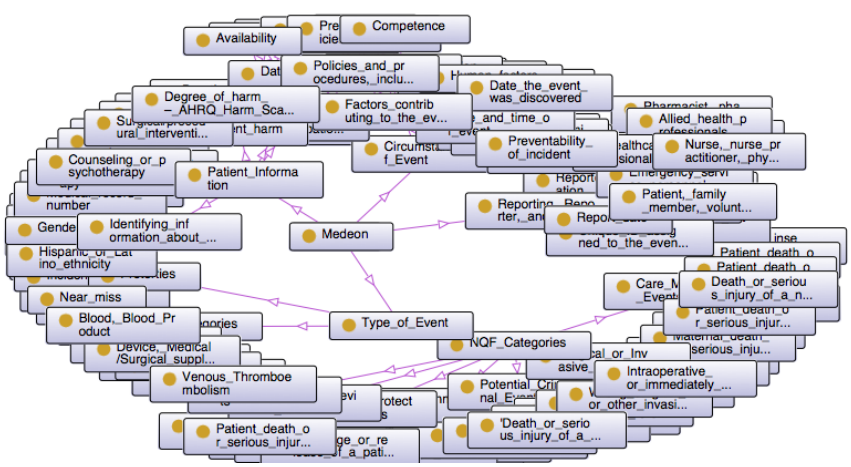

Figure 1 - OWL Class Visualization by OntoGraf (V1.0.1) in Protégé (V4.3.0).

The Meta Ontology

Patient safety taxonomies have been used as a reference where hierarchies, entities, and relationships can be used as candidate materials [23]. While these taxonomies served primarily as standards of domain specific taxonomies, the rapid growth in medical information needs a knowledge base for sharing and

translation of entities was completed, we imported those entities into Medeon via Protégé. Data consistency was checked through Protégé build-in modules to ensure that no logical conflict existed in the ontology.

Evaluation

The evaluation is intended to provide a comprehensive report pertaining to the effectiveness and validity of ontology in multi-dimensions. Our evaluation design included the assessment of the ontology itself and the user experience. We designed a questionnaire with a 5-point Likert scale to collect the measurable data from domain experts interested in using the ontology in their daily work.

Below we enumerate a set of questions in the questionnaire. Each question is equipped with answers to a 5-point Likert scale (i.e., 1=very disappointed; 2=disappointed; 3=neutral; 4=good; 5=very good).

1. The phrases used in the vocabulary are well formed and the words are well arranged.
2. The terms used in the vocabulary can explain the meanings of real-world concepts.
3. The terms that appear in the vocabulary are clear.
4. The vocabulary represents the designated domain and provides sufficient knowledge to the user.
5. The claims the vocabulary makes are reasonable.
6. The vocabulary can satisfy your requirements when you use it to categorize the case you are reviewing.
7. Please rate the overall satisfaction based on your experience using the vocabulary.

To make sure that the questionnaire reached the confidence level on effectiveness and validity, we employed a pre-measurement to assess the content-validity and inter-rater reliability to guide the final revision of the questionnaire. The content-validity measures to what extent the designed questions subjectively reflect the tasks they purport to measure. The inter-rater reliability measures the degree of agreement among raters. Three domain experts used the pre-measurement to validate the questionnaire where randomly selected patient safety reports were provided in the task.

The questions listed below were used for measuring content-validity. Each question was instructed to be answered on a 4-point scale (i.e., Not relevant; Somewhat relevant; Quite relevant; Highly relevant)

1. "The phrases used in the vocabulary are well-formed and the words are well-arranged."
   Does the scale purport to measure "The correctness of syntax."?
2. "The terms used in the vocabulary can explain the meanings of real-world concepts."
   Does the scale purport to measure "The meaningfulness of terms."?
3. "The terms that appear in the vocabulary are clear."
   Does the scale purport to measure "The clarity of terms."?
4. "The vocabulary represents the designated domain and provides sufficient knowledge to the user."
   Does the scale purport to measure "The comprehensiveness of the vocabulary in a certain domain."?
5. "The claims the vocabulary makes are reasonable."
   Does the scale purport to measure "The accuracy of information."?
6. "The vocabulary can satisfy your requirements when you use it to categorize the case you are reviewing."
   Does the scale purport to measure "Whether the vocabulary specifies agent's specific requirements."?
7. "Please rate the overall satisfaction based on your experience using the vocabulary."
8. Does the scale purport to measure "The overall satisfaction to the vocabulary."?

Results

Upon the completion of Medeon, we obtained a semantic web ontology in OWL format. The ontology represented, with necessary conceptualization and translation, the entities and relationships of patient safety knowledge that were extracted from the Common Formats. The ontology was constructed in a hierarchy with four top-level classes where each contained sub-classes with a maximum depth of four levels. An example of OWL individuals is shown in Figure 2. As in the preliminary stage, these individuals may be incomplete yet they represent the most frequently used concepts and terminologies appearing in the Common Formats. Note that OWL classes and individuals, as well as the OWL properties, are open to expand. That being said, the knowledge we borrowed from the Common Formats serve as building blocks for further development without limiting patient safety ontology.

Two domain experts participated in the pre-measurement. The results showed a 100% agreement for the inter-rater reliability and 100% for content validity.

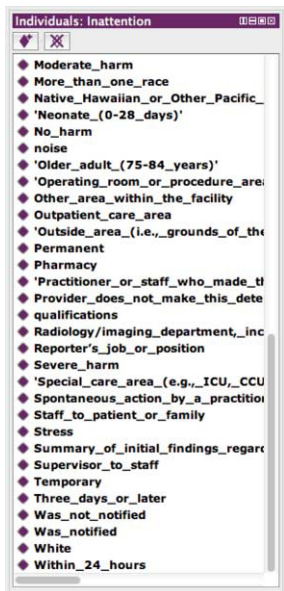

Figure 2 - OWL Individuals in Protégé (V 4.3.0).

Discussion and Future Work

The ontology primarily serves as a knowledge base to model the taxonomies broadly used for patient safety reports. With this role, the proposed ontological approach aims to meet the challenges in the development of reporting systems. Among the many factors fundamental for a successful reporting system, data quality has been a major concern. An outstanding reporting system should be able to collect quality data that link to the procedures and factors threatening patient safety in a timely manner. Nevertheless, a great number of reporting systems are suffering from low quality data due to inefficiency and ineffectiveness of data entry [11, 28, 29]. To improve the data quality, much effort has been made in increasing the number of reports, but the increase in quantity does not improve the system performance since the very crux of the

problem remains in knowledge management. In fact, the reporting systems in use generate a great volume of patient safety reports, which on the contrary are becoming a burden for data processing.

The ontology is what we believe is a suitable approach in patient safety reporting. Given a patient safety report, oftentimes it needs to be labeled with multiple categories in a hierarchical knowledge base. Neither plain reporting forms nor patient safety taxonomies can easily solve this problem during the submission of a report to the system or retrieving a report from the system. For example, a case being labeled under 'lighting' may be also labeled under 'contributing factor', 'environment', and 'patient fall', assuming that 'contributing factor' and 'environment' are the super classes of 'lighting', while 'patient fall' is under the other super class yet has certain associations to 'lighting'. It could be time consuming when reporting such a 'lighting' case in plain reporting forms and it could be difficult to extract the association between 'lighting' and 'patient fall', since they belong to different classes or different hierarchical levels. Fortunately, an ontology can contribute to these aspects since it encodes all the relationships among entities and is able to query via path expression.

Ontology provides insights into an efficient and user-friendly data entry framework. Researchers have found close associations between data entry and the system performance in terms of the completeness and accuracy of patient safety reports [30, 31]. The majority of patient safety reports are recorded in free text. Although the free text might be an efficient and natural means for users to deliver an informative case, it could be costly to turn the raw information into a cognitively organized and manageable format for professionals to utilize . Applying semantic web ontology to organize the text data can support effective data entry. Such a use case includes web portals where ontology is used for defining terminologies and concepts (meanings) for an area of knowledge. For example, 'patient fall', 'female', 'slip', and 'emergency room' are terminologies that can be found in the patient safety ontology. The ontology can also define a concept like 'All female slips in emergency room are considered as patient falls.' This provides an interesting angle to look into; the latent yet important information in the patient safety reports since a few distributed semantics (terminologies and relationships) appear to be sufficient for representing the most significant meanings in a report.

To our best knowledge, the use of AHRQ Common Formats as the source taxonomy to build semantic web ontology is an initiative. Patient safety reporting systems never lack taxonomies, but a universal and computer understandable knowledge base. The Common Formats provide a compatible format that includes patient safety events ranging from a series of general concerns, frequent occurrences and serious types of events andmore importantly, the implementation of the Common Formats in an ontological framework offers an open environment to aggregate and share the patient safety knowledge base by cooperating with other data sources and ontologies.

Our design and implementation have challenges and limitations. When building the ontology, it is most challenging in mapping between discrepant data sources due to the distinction among existing taxonomies in terms of the hierarchical structures and synonymous terminologies. We envision the use of NLP techniques and automatic classifier (i.e., k nearest neighbor) could facilitate the process, as we will expand Medeon in the next step. Also, a view on a unified coding system, such as Unified Medical Language System (UMLS), is definitely helpful. On the other hand, debates regarding validity and effectiveness are always in ontological studies Therefore, we must continue the evaluation study of the present ontology.

Table 1 - Design Principles for High Quality Ontologies.

Dimensions	Attributes	Description
Syntactic quality	Lawfulness	Correctness of syntax
	Richness	Breadth of syntax used
	Interpretability	Meaningfulness of terms
Semantic quality	Consistency	Consistency of meaning of terms
	Clarity	Average number of word senses
	Comprehensiveness	Number of classes and properties
Pragmatic quality	Accuracy	Accuracy of information
	Relevance	Relevance of information for a task

Conclusion

The development of a knowledge base for patient safety reporting systems is imperative for both practice and research. With the aim of establishing a comprehensive knowledge base, we employed a semantic web ontology that plays a key role underlying the reporting systems. The present ontology built on the Common Formats serves as the building blocks towards a unified knowledge base, with which the reporting systems are expected to support comprehensive data entry and increase the data quality. We envision that utilizing a semantic web ontology would facilitate information retrieval and reuse of the narrative data for expert review, clinical decision-making and education. Moving forward, the swift growth in aggregate data requires a sustainable knowledge base to keep abreast with the latest reporting events. Our design must be open-minded to glean knowledge from the most recently reported data and tremendous amount of historical data.

Acknowledgments

This project is supported by a grant from AHRQ, 1R01HS022895 and a patient safety grant from the University of Texas system. We thank Dr. Jing Wang for her invaluable comments in designing the evaluation questionnaires for the ontology.

[a] *College of Biomedical Engineering & Instrument Science, Zhejiang University, China*

Abstract

openEHR is a flexible and scalable modeling methodology for clinical information and has been widely adopted in Europe and Australia. Due to the reasons of differences in clinical process and management, there are few research projects involving openEHR in China. To investigate the feasibility of openEHR methodology for clinical information modelling in China, this paper carries out a case study to apply openEHR archetypes to Clinical Data Repository (CDR) in a Chinese hospital. The results show that a set of 26 archetypes are found to cover all the concepts used in the CDR. Of all these, 9 (34.6%) are reused without change, 10 are modified and/or extended, and 7 are newly defined. The reasons for modification, extension and newly definition have been discussed, including granularity of archetype, metadata-level versus data-level modelling, and the representation of relationships between archetypes.

Keywords:

Archetype, openEHR, Clinical Data Repository, Chinese hospital.

Introduction

A Clinical data repository (CDR) is a repository that stores the clinical data integrated from various kinds of clinical information systems for analysis and research. An increasingly larger demand for clinical research and application has drawn international initiatives' attention and propels institutions such as the Mayo Clinic [1], Intermountain Healthcare [2], Stanford Medical Center [3], Massachusetts General Hospital [4] and Columbia University Medical Center [5], to build CDRs.

As healthcare is a highly complicated and rapidly developing domain, the flexibility of the data model in CDR is rather indispensable. Being an open architecture for Electronic Health Record, openEHR advocates a dual-level methodology to conduct data modelling for clinical information [6]. It also provides a flexible modeling methodology to adapt to the evolution of clinical concept and knowledge. The architecture of openEHR includes reference model and archetype to separate clinical knowledge from clinical information. The reference model defines the data type, data structure, basic framework of EHR and represents the global characteristics of health record entries [7]. The archetype is a conceptual model, which is built on the base of clinical knowledge by clinical experts and specifies constraints on the reference model.

Although openEHR methodology has been widely carried out and implemented in Europe and Australia [8-10], only a few researches studies utilizing openEHR have been conducted in China. Most of the existing publications in China were limited to the introduction or translation of the basic principles and concepts of openEHR [11-13]. Only few were related to openEHR implementation in the area of research [14], while none of them focuses on data modeling in clinical settings. The possible obstacles are the differences in clinical process of hospital and the healthcare management mechanisms between countries. To implement openEHR in China, an investigation of the feasibility of using openEHR methodology to model clinical data in China is a necessity. This paper introduces a case study of applying the openEHR archetypes to CDR in a Chinese hospital.

Methods

The selected tertiary class A hospital in the case study has deployed several information systems including HMIS (hospital management information system), CIS (clinical information system), PACS (picture archiving and communication system), RIS (radiology information system), and LIS (laboratory information system). The clinical data has been scattered in these silo systems, and the physicians have to access different patient data in corresponding system respectively. It is crucial to build a CDR to integrate all the clinical data from these heterogeneous information systems and provide real-time data access services for applications to browse the complete set of patient data in data viewing applications. To achieve this target, the CDR needs to contain all essential clinical data including domains of patient demographics, encounters, medication, imaging examination, and laboratory test. The authors have designed a 6-step method to model the data in CDR via openEHR.

1. Analyze MOH standards

The data requirements of the CDR are first analyzed with regard to several standards. Chinese MOH (Ministry of Health) has published a set of standards related to healthcare data sets to facilitate information collection, storage, and exchange, such as "WS 363-2011 Health data element dictionary" (WS 363-2011) and "WS 445-2014 Basic dataset of electronic medical record" (WS 445-2014). "WS 363-2011" defines the identification, naming, meaning, data type, representation, and value set for all the data elements in healthcare domain. The purpose of this standard is to provide the standardized definition of data elements for all applications in healthcare domain. "WS 445-2014" specifies the typical business model and clinical documentation of the electronic medical record (EMR) together with the data sets under this architecture. The data elements used in this

standard conform to "WS 363-2011", except for some that are further constrained to adapt to the EMR context.

Firstly, the standards of "WS 445-2014" and "WS 363-2011" were analyzed according to the requirements of the CDR scope, content, and data elements. The coverage of standards for the requirements is listed in Table 1 and Table 2.

To be more specific, for each CDR data requirement, we need to find the corresponding data sets of "WS 445-2014" and refer to "WS 363-2011" for collecting the necessary data items in CDR, "none" indicates that the CDR requirements are not included in standards. For instance, the imaging examination requirements in the CDR refers to three data sets of "outpatient and emergency medical record", "examination and laboratory test record" and "inpatient progress note" in "WS 445-2014". After that, the relevant imaging examination data items can be found within "identification", "assistant examination" and "healthcare organization" in "WS 363-2011".

Table 1 – CDR requirements and WS 445-2014

WS 445-2014	CDR requirements
1) medical record summary	patient demographics, encounters
2) outpatient and emergency medical record	imaging examination
3) outpatient and emergency prescription	medication
4) examination and laboratory test record	imaging examination, laboratory test
5) general therapy and treatment record	medication
6) delivery record of therapy and treatment	none
7) nursing operation records	none
8) nursing valuation and plan	none
9) informing information	none
10) home page of inpatient medical record	none
11) home page of inpatient medical record summary of TCM	none
12) admission record	encounters
13) inpatient progress note	imaging examination
14) inpatient order	medication
15) discharged brief	encounters
16) transfer record	encounters
17) medical institution information	none

Table 2 – CDR requirements and WS 363-2011

WS 363-2011	CDR requirements
1) identification	patient demographics, encounters, medication, imaging examination, laboratory test
2) demographics and social economics characteristics	patient demographics
3) health history	none
4) health risk factor	none
5) chief complaint and symptom	none
6) physical examination	none
7) assistant examination	imaging examination
8) laboratory examination	patient demographics, laboratory test
9) diagnosis	encounters
10) medical assessment	encounters
11) medical plan and intervention	encounters, medication
12) health expenditure	none
13) healthcare organization	patient demographics, encounters, medication, imaging examination, laboratory test
14) health personnel	none
15) drug and material	medication
16) health management	none

2. Analyze existing database schemas

The data items defined in the standards can only cover part of the CDR data requirements, and the schemas of the existing heterogeneous information systems should also be taken as a source for collecting the necessary data elements in CDR as shown in Table 3. For example, the data items of imaging examination can be found from Exam request, Exam item, Exam procedure, Image, and Report four tables in the existing database schemas.

Table 3 – CDR requirements and existing database schemas

CDR requirements	Information systems	Table schemas
patient demographics	HMIS	Patient
encounters	CIS	Visit, Inpatient admission
imaging examination	RIS	Exam request, Exam item, Exam procedure, Image, Report
laboratory test	LIS	Test request, Test item, Report, Sample
medication	CIS	Medication order

3. Merge data items

Data items collected from the above two steps are merged into the final data set for CDR. If the data type, value set, or coding for same data element is not compatible in the standards and the database of existing systems, the one from the standards was used. After merging, 217 data elements were finally defined in a structured format and ready to be used as shown in Table 4. The data items of imaging examination is composed of 38 items among which 13 items came from standards and 25 items came from information systems.

Table 4 – Number of data items collected from standards and information systems

CDR requirements	Standards	Information systems
patient demographics	18	21
encounters	16	45
imaging examination	13	25
laboratory test	10	17
medication	16	36

4. Organize data items into concepts

Since each archetype models only one distinct concept, the data items should be organized into concepts before modeling. Although the data items are classified into basic data sets in the standards, the classification is mainly clinical documentation oriented and the data sets often contain a number of distinct concepts. For example, the data sets in "part 4) examination and laboratory test record" of "WS 445-

2014" contain two sub-domains of laboratory test and examination, and there are concepts about request, result, report, and specimen in each sub-domain. The data elements in "WS 363-2011" are just listed in a row one by one. On the other hand, the data schemas from different information systems are heterogeneous and overlapped. To organize the data items from both standards and data schemas of different systems, an entity-relationship concept modeling process is carried out and results in a group of 26 concepts. Semantic overlapping between concepts is avoided to our best to comply with the single archetype for single concept principle. The derived clinical concepts are shown in Figure 1.

5. Map concepts to archetypes

To achieve maximum reusability, the public archetype repository Clinical Knowledge Manager (CKM) is searched for matching archetypes with each derived concept with the name or other key words. The candidate archetypes filtered by searching are analyzed in details. If all the data items of the clinical concept are covered by the existing archetype, this archetype can be directly adopted without any modification. If only part of the data items of clinical concept is covered by the existing archetype, this archetype needs to be modified and extended. If more than one matching archetypes exist, the most semantically suited one was selected and then checked for whether it could completely cover or partially cover the concept. If there is no matching archetype for the clinical concept, a new one is defined. For archetype modification and extension, several operations are illustrated in the openEHR specification [15] such as revision, specialization, and new version.

6. Model relationships between concepts

After mapping concepts to archetypes for the CDR, the relationships between the concepts also need to be modeled. There are two general methods to express relationships between archetypes, archetype slot and link. Archetypes can be composed to express valid possibilities for larger structures of data from different levels of ontological hierarchy of the reference model. Such compositional connections are termed as 'slots'. For example, "Section" and "Entry" archetypes can be composed through slots to represent the structure similar to clinical document with head, body, and content. Currently, almost all the archetypes in CKM use slots to express relationships between archetypes. "Link" is an attribute root in the deep architecture of the openEHR reference model and can refer to many other archetype structures.

Results

26 archetypes are identified to cover all the data requirements of the CDR, shown in Figure 2. 9 archetypes, listed in Table 5, are from CKM and can be directly reused without any modification, which account for 34.6% of all 26 archetypes. 10 archetypes, listed in Table 6, are modified and extended, among which 2 are revisions by replacing compatible data types with some data items, 8 are modified by adding data items, no specialization and no new version archetypes. 7 archetypes, listed in Table 7, are newly defined since not all the clinical concepts are covered by the existing archetypes, which include 2 for laboratory test, 2 for examination, 2 for medication orders, and 1 for transfer management.

So far, the 26 archetypes have been used to implement the CDR based on the relational database that provides data access service in the hospital. Clinical data has been integrated from the heterogeneous systems into the CDR and a clinical data viewer for clinicians has been developed and used in the clinical practice.

Discussion

Although all the clinical concepts retrieved from the CDR of Chinese hospital can be modelled using the openEHR archetype approach, several issues were encountered and discussed below.

Immaturity of archetype modification operations

openEHR specifies three operations for archetype modification: revision, specialization, and new version [15]. Other than these three operations, there is another operation with subtle differences. So far, the only way to add data items to existing archetypes is through specialization. Since each archetype represents a concept, this requires creating a new specialized archetype, which represents a new concept. There is no way to add these data items to existing archetypes. Since the archetype development is still an ongoing process, there are great demands for this requirements. We define a new operation for this situation named extension shown in Table 8.

Table 8 – Operations for archetype modification

Operation	Modification	Compatibility
Revision	Modify description part	Ensure backward compatibility
	Expand attributes, range of value sets, terminology	Data created by pre-revised archetype is compatible with the revised version
Specialization	Strengthen the constraints	Ensure the new specialized archetype must create data that conforms to the parent
	Redefine and add nodes	
	The range of value sets and semantics of nodes conform to the previous archetype	
New version	Change mandatory item to optional	Modifications are incompatible with the previous archetype
	Adjust value range or coded term set	
Extension	Add missing data items to existing archetypes	Compatible with the original archetype
	Use semantic version as the naming rule	

To take an example, if two data items of memo and report identifier need to be added in the archetype INSTRUCTION.request-imaging_exam.v1, it can be easily versioned as INSTRUCTION.request-imaging_exam.v1.1 through the "Extension" operation.

With the extension operation, archetypes can be clearly managed using the semantic versioning mechanism. Applying archetypes to local context will be much easier since there is no need to figure out a proper name each time to add data items through specialization.

The granularity of archetype

Differences in the granularity of archetypes between the CDR data requirements and CKM archetypes can cause problems of information representation in clinical practices. Take imaging examination sub-domain as an example. The concepts extracted from the CDR include Request, Request Item, Result, Report, DICOM Study, and Image shown in Figure 3a. Two coarse-grained archetypes (a) INSTRUCTION.request-imaging_exam.v1 which contains Request, Request Item and (b) OBSERVATION.imaging_exam.v1 which contains Result, Report, DICOM Study, Image are found in CKM and analyzed to extract corresponding concepts in Figure 3b. By comparing Figure 3a with Figure 3b, several important relationships between concepts are missing or improper, such as ③ one-to-many relationship between Report and Request Item, ⑤ one-to-one relationship between Request Item and DICOM Study, improper relationship cardinality between ④ Report and DICOM Study. The problem is that OBSERVATION.imaging_exam.v1 contains multiple concepts and the relationships between these concepts are greatly limited and not suitable for the CDR requirements. These differences result in structural modifications and reorganization of the archetypes which are demonstrated in Figure 3c. To represent ④, OBSERVATION.imaging_exam.v1 is split into two archetypes, (c) OBSERVATION.imaging_exam_report.v1 for Result and Report and (d) OBSERVATION.imaging_exam_image_series.v1 for DICOM Study and Image.

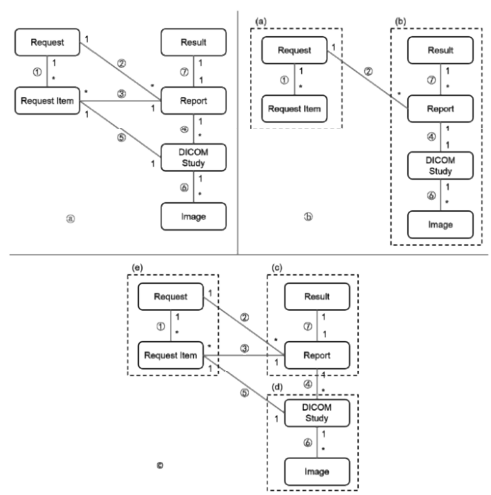

Figure 3 – Imaging examination concept relationships.

Bearing the principle of one archetype for one clinical concept in mind, with more and more clinical requirements appended, fine-grained archetypes is more flexible and easier to represent concepts and its relationships, and will improve the modelling capability of archetypes eventually.

Metadata-level versus data-level modelling

Problems are also encountered due to mismatches between metadata-level modelling and data-level modelling which happen in candidate archetypes and the CDR data requirements. For instance, all the results of the laboratory test have the similar structure, which consists of test item, test value and unit. In comparison to the clinical practice, for each laboratory test subject, such as full blood count and liver function, there is an archetype that contains certain data items of that subject. There are over 200 laboratory test subjects in the CDR, while only 19 of which have been defined with archetypes. Given the low scale of archetype coverage to clinical concepts, it is necessary to use an archetype that has the common structure for the general concept of laboratory test results.There is a OBSERVATION.lab_test.v1 archetype in CKM as the basis for all the laboratory test archetypes. We define a specialized archetype OBSERVATION.lab_test_single.v1 with data items test item, result, and result unit to represent the general strucutre of the laboratory test results.

Representing archetype relationships

Most of the archetypes in CKM use archetype slots to represent relationships between archetypes, but it has significant limitations that it can only express relation between certain types of archetypes. For example, archetype slot is not allowed between Entry based archetypes. The semantics of archetype slot is the major obstacle in this paper, and we choose links to express relationships between archetypes. For example, among imaging examination archetypes in Figure 3c, to relationship ④, a link node Image series is added to OBSERVATION.imaging_exam_report.v1 to refer to OBSERVATION.imaging_exam_image_series.v1. For ③, a node Report identifier is added under node activities to (e) INSTRUCTION.request-imaging_exam.v1.1. For ⑤, a link node Examination requested is added to OBSERVATION.imaging_exam_image_series.v1. Although link is a general method to represent relationships between archetyps, the usage of the link is not well explained in openEHR specifications and there are few examples. As relationship is an important aspect in information modelling, flexible relationship representation can greatly facilitate the application of the archetype approach to clinical practice.

Conclusion

This paper is the first research that builds a CDR and develops a clinical application with the openEHR methodology in clinical practice in China. A 6-step archetype modeling method was proposed, which refers to the MOH standards and exisiting database schemas for collecting required data items in CDR. It provides an important lesson for including experiments with the openEHR approach adoption in China, which also facilitates the openEHR adoption.

Although the feasibility of the openEHR methodology has been verified by the case study, some limitations of openEHR when implemented in China have also been identified, including immaturity of archetype modification operations, the granularity of archetype, metadata-level versus data-level modelling and representation of archetype relationships. The findings of the case study will facilitate the openEHR adoption in China.

Abstract

Consequences of the computerization of laboratory and radiology information system (LIS and RIS) are not well documented. The aim of this study was to evaluate the impact of computerization of LIS and RIS of four hospitals on performance and quality of care. The study was divided into three phases. First, the subprocesses and information flows of LIS and RIS were described. Then, a literature review was performed in order to identify the indicators used to assess the impact of computerization. Finally, comparisons were made between 2 hospitals. Using the initial framework, each partner described its process mapping concerning LIS and RIS. The review identified a wide panel of indicators. Only 41 were useful to assess the impact of information systems. For each two by two comparison, lists of relevant indicators have been selected from the identified indicators and according to the process mapping comparison. Two by two comparisons have to be completed. Eventually, these indicators may be integrated in the quality process of hospital information systems.

Keywords:

Hospital information systems; process assessment (health care); quality indicators, health care

Introduction

Health information systems (HIS) have been widely studied in order to evaluate their effectiveness [1-4]. Benefits of HIS have been shown on the improvement of hospital productivity, coordination of care and quality of care [5]. The use of HIS also has a positive impact on the prevention of medication errors and the reduction of adverse effects [6]. However, most published studies are descriptive ones, and are performed in a monodisciplinary context. They do not provide the analysis of the consequences of the computerization implementation in a system involving multiple participants in the care process [7].

One important part of HIS is the computerization of laboratory and radiology services, from the prescription to the report of the exam results to the health professional. The computerization of laboratory and radiology services started many years ago [8], but still varies widely between health establishments [9].

The aim of this study was to: 1) describe the computerization of the subprocesses of a laboratory information system (LIS) and a radiology information system (RIS) of four hospitals; 2) identify indicators of the impact of computerization on performance and quality of care; 3) evaluate the impact of computerization on performance and quality of care using the pre-defined indicators.The same methodolody was applied to the three steps of this study, for LIS and RIS.

Methods

This study is part of the EVALSI project, led by a multidisciplinary consortium including four departments of biomedical informatics (Rouen, Paris, Lille and Nice), an engineer school (Mines ParisTech Graduate School) and a social sciences research centre (Research centre for the study and observation of life conditions).

The great variety of computerization between hospitals allowed us to build a global methodology based on comparisons between hospitals. This methodology was chosen in order to limit the risk of bias of before and after studies, following the advice of the scientific committee of the DHSO.

The study was divided into 3 phases. To date, phases 1 and 2 have been completed.

Phase 1: Process mapping

For each hospital, a detailed description of processes and information flow in the HIS of medical biological and imaging services was performed. For each process or sub process, the computerization level, the inter-step data flow, and the data that could be used for the measures of indicators were described. An initial framework was originally built from two hospitals (Lille and Rouen), and then used to obtain the final process mapping.

Phase 2: Identification of performance and quality of care indicators

In order to identify the indicators used to evaluate the subprocesses of medical biological and imaging systems, a literature review was performed. We used systematic search processes to identify all published studies concerning our topic. We searched the PubMed database, and selected articles in English and French. Detailed queries are available at: http://www.chu-rouen.fr/cismef/papers/Detailed_queries_used_for_the_literature_review.pdf. Inclusion criteria were studies performed in hospitals, concerning performance and quality indicators, used to evaluate the impact of HIS. The selection of articles was performed by two authors (JP and CP) and controlled by three others (MS, NG and SJD). We also systematically searched the reference lists of all the included studies and relevant reviews. Disagreements were resolved by consensus.

Phase 3: Evaluation of the impact of computerization on performance and quality of care

A list of performance and quality indicators was extracted from the literature review. Indicators that will be used for evaluation have been selected by five physicians (PM, MBJ, MS, NG, SJD), using 3 criteria: their applicability disregarding the level of computerization of subprocesses, their measurability disregarding the hospital and their relevance. Disagreements were resolved by consensus. Some data will be directly extracted from the HIS. Other data will be manually collected in laboratory and radiology services and in clinical wards (medicine and surgery). Comparisons will be made between 2 hospitals, process mapping of which showed a difference in the level of computerization in one subprocess.

Results

Phase 1: Process mapping

This phase has already been completed, and the results have been published. The result of the description of processes and subprocesses, using the previously developed framework, is a process mapping that allows for comparison between all the involved hospitals. Indeed, all participating hospitals described the same list of processes and subprocesses.

The following subprocesses have been described for the LIS: ordering, request filling, sample labelling, transmission of the request, sample delivery to the laboratory, registration of the request in the LIS, reconciliation of the request and the sample, technical validation, biological validation, report of the result, result awareness.

The following subprocesses have been described for the RIS: ordering, request filling, transmission of the request, appointment scheduling, organisation of the transport of the patient, registration of the patient in the RIS, production of the images, recording of the report, redaction of the report, transmission of the report, result awareness.

This process mapping allowed us to identify the steps where methods or levels of computerization were different between hospitals, and for which we may be able, using the indicators, to assess the impact of computerization (e.g presence of a ScanBack in hospital A vs. none in hospital B). The interested reader may refer to the publication for more information [10].

Phase 2: Identification of performance and quality of care indicators

Respectively, 446 and 986 articles were retrieved by the bibliographic queries for biology and radiology. Respectively, after reading the titles and abstracts (and the full texts in case of a doubt), 109 and 64 papers met our inclusion criteria (see figure 1).

Indicators for biological systems

The literature review included 109 articles. Examples of indicators reported in the literature are listed below by type.

- Delay indicators
  - Turnaround time and associated measures
  - Time between report of the result and reading of the result
  - Time between report of the result and consequential therapeutic change
  - Length of stay
- Quality indicators
  - Quality of the exam request filling
  - Proportion of samples that cannot be analyzed
  - Error rate in exam result reports
- Management indicators
  - Workload of the staff
  - Satisfaction of the staff, feeling of efficiency
  - Utilization rate of the machines
- Cost indicators

Indicators for imaging systems

This literature review included 64 articles. Examples of indicators reported in the literature are listed below by type.

- Delay indicators
  - Turnaround time and associated measures
  - Time between report of the result and reading of the result
  - Time between report of the result and consequential therapeutic change
  - Length of stay
  - Length of stay in medical imaging ward
- Quality indicators
  - Irradiation dose
  - False diagnostic rate
  - Rate of unread reports
  - Rate of lost reports
- Management indicators
  - Satisfaction of the staff, feeling of efficiency
  - Compliance rate with guidelines
  - Enhanced patient flow
- Cost indicators

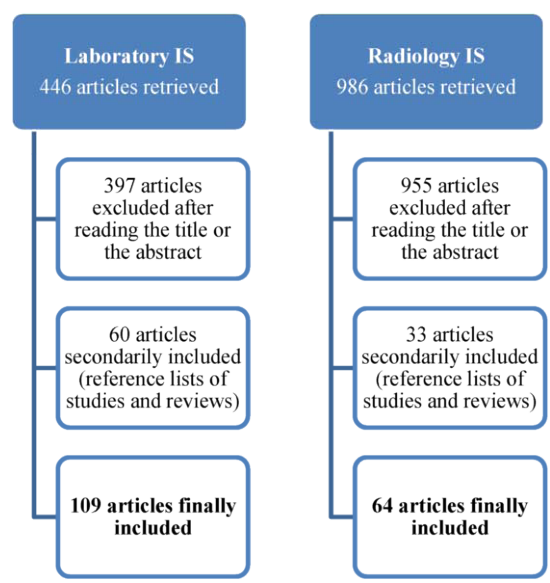

Figure 1 – Inclusion flow-chart

Phase 3: Evaluation of the impact of computerization on performance and quality of care

From the wild list of performance and quality indicators extracted from the literature review, two short lists of indicators for laboratory information and radiology

information systems were selected. Some activity indicators were also included in this selection. As a global indicator, turnaround time (TAT), which has been recognized in the literature as a key indicator [11], was impacted by all the subprocesses. Therefore, it has been decided to divide TAT into several sub-indicators. All the selected indicators are listed in tables 1 for biology and 2 for medical imaging.

Table 1 – Indicators selected for laboratory information systems (n=17)

Indicator type	Indicators
Activity indicators	Number of analyses over a given period
	Mean number of analyses per patient and per day
	Mean number of analyses per physician and per day
	Mean number of blood samples per hospital stay
	Mean number of blood samples per day of hospitalization
	Number of analyses per patient and per hospital stay
Performance indicators	Rate of cancelled analyses over a given period
	Rate of analyses rejected as non-compliant over a given period
	Time between sample collection and report of the result (TAT)
	Time between sample collection and arrival in the lab
	Time between arrival in the lab and start of analysis
	Time between start of analysis and technical validation
	Time between technical validation and biological validation
	Time between start of analysis and report of the result
	Time between the report of a drug dosage result and the consequential therapeutic change
	Time between the report of a hyperkalemia and the consequential therapeutic change
	Time between report of the result and reading of the result

Each indicator was precisely described, including all the data necessary to measure it. For each subprocess, indicators potentially impacted were identified. This allowed us to define the relevant indicators to perform each two by two comparison for LIS and RIS. Partial examples of the obtained matrixes are summarised in Tables 3 and 4, respectively.

In most cases, indicators were impacted by several subprocesses. The selection of indicators for each two by two comparison was automatically deducted from:

- the process differences between hospitals
- the potential impact of the computerization of subprocesses on the indicators.

The computerization of some subprocesses could be similar between two hospitals, for example, in Table 3, the ordering and sample labelling. The indicators only impacted by these subprocesses (eg: the rate of cancelled analyses over a given period) should be used as controls. Therefore, there should be no difference for these indicators between these two hospitals.

Table 2 – Indicators selected for imaging services information systems (n=24)

Indicator type	Indicators
Activity indicators	Number of exams over a given period
	Number of exams per patient and per stay relative to the length of stay
	Number of exams relative to the number of physicians
	Number of exams relative to the number of radiologists
	Number of exams relative to the number of available machines
Performance indicators	Number of redundant exams per hospital stay
	Compliance rate of exam requests with guidelines
	Proportion of exams requests modified by radiologists
	Proportion of images viewed by requesting physicians
	Proportion of reports read by requesting physicians
	Proportion of lost exams in patients files
	Absorbed radiation dose per patient
	Time between prescription and report of the result (TAT)
	Time between prescription and receipt of the request in the radiology service
	Time between receipt of the request and appointment schedulling
	Time between appointment schedulling and execution of the exam
	Timer between the scheduled time of the exam and the actual time of the exam
	Exam length
	Time between the end of the exam and the availability of the images for the requesting physician
	Time between the end of the exam and the availability of a first report for the requesting physician
	Time between the availability of the report and taking into account the results of the exam
	Time between the end of the exam and the availability of the final report for the requesting physician
	Patients waiting time in the radiology services
	Report writing time by the radiologist

In the case that one indicator was impacted by several subprocesses, and the difference in the computerization between two hospitals concerned only one of theses subprocesses, the above mentioned indicator should be considered as relevant to assess the impact of computerization of this subprocess. For example, in Table 4, the time between ordering and reception of the request in the medical imaging ward was potentially impacted by ordering, request filling and

Table 3 – Examples of computerization differences of several LIS subprocesses between Rouen and Paris hospitals, and their respective impacted indicators

Subprocesses	Rouen Hospital	Paris Hospital	Impacted indicators
Ordering	Computerized step (use of the LIS test catalogue)	Computerized step (use of the LIS test catalogue)	Number of analyses over a given period, mean number of analyses per patient and per day, number of cancelled analyses over a given period, number of analyses rejected as non-compliant over a given period, time between sample collection and report of the result, time between sample collection and arrival in the lab
Request filling	Paper application form	Computerized step	Time between sample collection and report of the result, time between sample collection and arrival in the lab
Sample labelling	Label identifying the patient	Label identifying the patient	Number of cancelled analyses over a given period, number of analyses rejected as non-compliant over a given period, time between sample collection and report of the result, time between sample collection and arrival in the lab
Transmission of the request	Physical transmission	Electronic transmission after validation	Time between sample collection and report of the result, time between sample collection and arrival in the lab

Table 4 – Examples of computerization differences of several RIS subprocesses between Rouen and Lille hospitals, and their respective impacted indicators

Sub processes	Rouen Hospital	Lille Hospital	Impacted indicators
Ordering	Computerized step (use of the RIS exams catalogue)	Paper prescription	Number of exams over a given period, number of exams per patient and per stay relative to the length of stay, number of exams relative to the number of physicians, number of exams relative to the number of radiologists, number of exams relative to the number of available machines, number of redundant exams per hospital stay, compliance rate of exam requests with guidelines, time between prescription and report of the result, time between prescription and receipt of the request in the radiology service
Request filling	Paper application form	Paper application form	Compliance rate of exam requests with guidelines, time between prescription and report of the result, time between prescription and receipt of the request in the radiology service
Transmission of the request	Physical transmission	Physical transmission	Compliance rate of exam requests with guidelines, time between prescription and report of the result, time between prescription and receipt of the request in the radiology service
Appointment scheduling	Partially computerized step	Manual registration	Number of exams over a given period, compliance rate of exam requests with guidelines, rate of exams requests modified by radiologists, time between prescription and report of the result, time between receipt of the request and appointment schedulling, time between appointment schedulling and execution of the exam

transmission of the request. Ordering is the only subprocess that differs between Rouen and Lille hospitals. Therefore, for the Rouen vs. Lille comparison, the time between ordering and reception of the request in the medical imaging ward was relevant to asses the impact of ordering computerization. Nevertheless, and still considering one indicator impacted by several subprocesses, if the difference in the computerization between two hospitals concerned more than one subprocess, the measures of the indicator should be hard to interpret, and could be useless.

Discussion

Using the initial framework, each partner described its process mapping concerning laboratory and imagery information systems. The literature review allowed us to identify a wide panel of indicators. Most of them were relevant to assess the quality of biological and medical imaging exam processes, but only few of them were useful to assess the impact of IS in our context. From the indicators identified and the process mapping, lists of relevant indicators have been defined to perform two by two comparisons.

TAT, and its subindicators, seemed to be well fitted to assess the impact of IS [11], and were considered quality indicators, especially in the biological domain.

Our study has several limitation.The standardized framework was quite basic. On the one hand, two quite different processes can be described in the same way. Therefore, it was necessary to have good knowledge of the process in order to avoid a false comparison. On the other hand, the framework facilitated the description of processes in hospitals as it did not require advanced skills for the description process. Moreover, the resulting process mapping was easy to compare as they shared the same format. The framework was adopted well by the four hospitals. Furthermore, only university hospitals were included in this study. This might be a possible concern for external validity. Nevertheless, their HIS profiles were quite different and many interesting comparisons could be made. A few subprocesses were similarly computerized. Obviously, this prevented the evaluation of the computerization of such processes, however, as indicators were impacted by multiple subprocesses, this strengthened the interpretation of indicators. The consortium validation of each step is a strength of this study: the validity of the overall process should be considered as strong.

These indicators will be integrated in the quality process of the Rouen LIS and RIS, and more generally in the Rouen computerized provider order entry and other involved applications of the HIS. Several other steps are already planned, in particular the extension of this quality process evaluation framework in other types of health facilities, eg: proprietary hospitals and nursing homes.

Abstract

Identifying patients with Fibromuscular Dysplasia (FMD) at the international level will have considerable value for understanding the epidemiology, clinical manifestations and susceptible genes in this arterial disease, but also for identifying eligible patients in clinical trials or cohorts. We present a two-step methodology to create a general semantic interoperability framework allowing access and comparison of distributed data over various nations, languages, formats and databases.
Methods: The first step is to develop a pivot multidimensional model based on a core dataset to harmonize existing heterogeneous data sources. The second step is to align the model to additional data, semantically related to FMD and collected currently in various registries. We present the results of the first step that has been fully completed with the validation and implementation of the model in a dedicated information system (SIR-FMD). We discuss the current achievements for step 2 and the extensibility of the methodology in the context of other rare diseases.

Keywords:

Information Systems; Health Information Exchange; Semantics; Vocabulary; Fibromuscular Dysplasia.

Introduction

Fibromuscular dysplasia (FMD) is a heterogeneous group of idiopathic, non-atherosclerotic, relatively rare vascular diseases, leading to the narrowing of medium-sized arteries, mostly the renal and internal carotid arteries [1], [2]. The etiology and pathogenesis of this disease are unknown and there is no biochemical test for the condition. The diagnosis and classification of FMD relies today on angiographic findings. These data are collected in heterogeneous databases at different points of care. Moreover, additional data about patients are often associated with these findings but not routinely. For instance information about "Anisuporia / non-reactive pupils" is collected in the American registry (FMDSA[1]) [3], but not systematically collected in other databases. Beside this, the large diversity of cultures, laws, regulations and operational implementation regarding personal health data processes (access, gathering, sharing, etc.) across countries induces variation in the nature of the data that are collected. For instance the "race" information will be systematically present in USA registries while in European ones, the information will be "geographical origin of the parents".

Frameworks accessing and comparing distributed and heterogeneous data with consistent semantics are needed to enable cooperative research and progress in the comprehension of the disease. Our main challenge is to develop such a framework that includes an e-registry collecting standardized FMD data across Europe and that gives access and reuse of existing local FMD registries in other regions. E-registries have been developed by the authors in other domains [4][5].

We have designed a generic two-step methodology to set this framework in the context of FMD based on current Information Technology paradigms.

Nowadays, semantic interoperability is a broadly used paradigm to approach the problem of sharing data from heterogeneous data sources [6]. Many semantic interoperability platforms have been developed in various projects to apply this paradigm for data analysis by querying heterogeneous and distributed data sources. Examples are given by the EHR4CR European project [7] and the DebugIT European project [8]. The rationale of such systems is to define the intended meaning (semantics) of the data to ensure coherent interpretation by humans and processing tools, even when data are not coded the same way [9]. Some existing frameworks are based on an ontology to unify structural models and terminologies together with relevant mapping sets. This approach has been tested in the context of the EU Framework Program 7 TRANSFoRm project [10].

In the following, we describe the two-step method to develop a framework that comprises first, a European e-registry based on a pivot multidimensional model to merge existing local FMD databases in France and second, mapping resources to make the registry usable at the international level by sharing data semantics with the USA FMD registry. We present the resulting multidimensional model and the current status of the project.

Finally, we discuss some issues raised by this two-step methodology and its generalisability.

Materials and Methods

Material

Since 2006, the French authorities have implemented a network of 131 rare disease centers of expertise in the country. The reference center for FMD is located in the "Georges Pompidou European Hospital" (HEGP), Paris, France. In collaboration with the Hypertension Unit of HEGP, the reference center started the collection of FMD data in 2009. Clinical and biological data are collected at the first visit. For patients referred to the center after FMD has been diagnosed elsewhere, clinical and biochemical data are collected at the first visit in the center if it occurred within 1 year of the diagnosis of FMD and if there had been no renal artery intervention during this period.

A French network of nephrologists, neurologists, radiologists and specialists in hypertension is responsible to document phenotypic and genetic traits of the disease and the progression of FMD lesions in patients with renal and/or cervical artery FMD. Information regarding >500 patients with FMD is currently scattered in several non-standardized, redundant databases (Figure 1).

1. The FMD local database of the HEGP reference center in Paris contains about 400 cases described each by *300 items*.
2. A database validated by the HEGP reference center and dedicated to activity reporting at the national level includes about *50 items* mostly redundant with the local database.
3. The ARCADIA/PROFILE program[2] was completed in October 2014. A specific Case Report Form was defined in this programme. The resulting database contains 500 patients with renal artery or cervical artery FMD from 12 different clinical sites (including HEGP) and described each by *200 items*[3].

In 2007, the Fibromuscular Dysplasia Society of America (FMDSA) decided to begin a registry to better understand the disease and its treatment. A template has been defined to collect *318 items*. Clinical data include elements such as date of diagnosis, types of tests conducted and results of these tests, past medical history, family history, subsequent clinical events and any clinical outcomes [2].

Besides this, several smaller studies exist in Europe to answer specific questions concerning the patients and reported in scientific papers. For these studies, specific databases, most of the time Excel files, are locally built for data management and analysis [1]. Such databases are redundant with ARCADIA/PROFILE but may include interesting additional items.

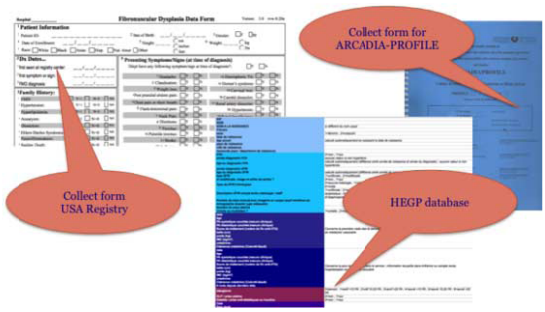

Figure 1 – Heterogeneous databases to collect FMD patients in France and USA

The HEGP FMD center wants to propose a national French e-registry based on the Case Report Form used in the ARCADIA/PROFILE cohort. It also aims at extending this registry to European countries and to making it compatible, as far as possible, with the USA registry.

Methods

Ideally, data from multiple sources are converted to standardized formats using well-characterized data vocabularies. Such approach currently requires huge efforts from experts to reach a consensus about the semantics of the domain and the standard vocabulary. It is for instance the case with the National Database for Autism Research[4] who reaches consensus about the semantics of the data.

In the first step of our methodology, a multidimensional model is set for the definition of a standard European FMD e-registry through a close collaboration between clinical experts and ontologists. This model is based on the identification of a set of core data elements for which a consensus is reachable with reasonable efforts. The second step consists of mapping all the items of the local database to the USA model. Figure 2 draws the two-step methodology.

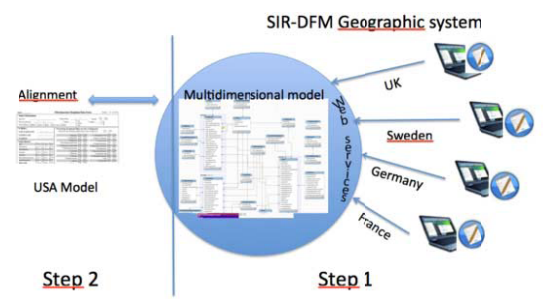

Figure 2 – The two-step methodology to set the framework

A bottom-up approach to build a multidimensional model

A data set includes data elements (DE) corresponding to some specifications which stipulate the sequence of inclusion of the DEs, whether they are mandatory, what verification rules should be employed, and the scope of the collection. A core data element (CDE) is a DE that is used in various data sets and recognized by the experts as a standard information. A specific DE (SDE) is a DE specifically defined for a given purpose (eg, the "race" is a SDE used as a public health indicator in the US) [11].

The US Office of Rare Diseases Research (ORDR) developed a set of CDEs at a national level as a tool for global collection of rare disease patient data [12]. In France, a minimum dataset

[2] ARCADIA, Assessment of Renal and Cervical Artery DysplasIA
[3] PROFILE, PROgression of FIbromuscular Lesions; Programme Hospitalier de Recherche Clinique, French Ministry of Health 2009-2014

[4] http://ndar.nih.gov. Accessed January 28, 2014.

for rare diseases has been set to respond to public health and epidemiological queries across all rare diseases [13]. These initiatives demonstrate the value of building CDE data sets. In [13], the authors argue the necessity to define core minimum data sets for each group of rare diseases in order to continue the efforts to make data interoperable for research.

Excel files and paper-based clinical Research Forms were identified and analysed by both FMD experts and ontologists to reach a consensus on a conceptual model for FMD descriptions. The target FMD model is a fixed set of CDEs. In terms of standardisation, the coding of the medical domain values can be adapted to a country's existing practices. For example, the rare disease diagnosis can be coded in Orphanet[5], OMIM, or SNOMED CT depending on the context and the required granularity of the coding. In France, diagnostic coding relies on Orphanet codes and is done by clinicians. Academic portals such as UMLS[6] or CISMeF[7] provide alignments between coding systems.

We built a set of fake cases, each case corresponding to a virtual patient, and asked a physician to describe the case using the model in order to confirm its accuracy. An information system implementing the model has been developed and is currently routinely used to feed the e-registry (Figure 2, step 1).

Using reference terminologies to align SDEs

One limit of using CDE come from the fact that, very often, data are collected at a local level for specific studies and may include specific data, semantically related to FMD but not explicitly expressed in the multidimensional model. For instance, the item "Summary_Smoking" is collected in [1] to answer a given query, it is semantically related to the item "number-of-cigarettes_daily" of the multidimensional domain but some alignment is needed. In this case, semantic interoperability can be achieved through data integration guided by an ontology [9] and in particular the approach of the type "global as view" in which an overall ontology is used as a source of mediation. However, and although there are starting efforts in the field, a domain ontology does not exist yet for FMD. In this situation, reference terminologies developed by Standard Development Organisations may be used to explicit the semantics of the data. The important initiative CTS2[8] is a specification for representing, accessing and disseminating terminological content. Moreover, many services exist to provide correspondences between these reference ressources [14].

Such an approach is used in the second step of our methodology to define mappings between reference terminologies and local interface terminologies used in local registries.

Results

Step 1 : e-registry

A standardized set of Core Data elements

The design of the methodology resulted in the following steps: (i) collecting a flat list of items as the union of the data elements and data values available from the material; (ii) performing a systematic review of the items by a group of experts; (iii) setting the different tables and value sets corresponding to the items and (iv) standardization by the eHealth team using Standard Development Organisations resources to support semantic interoperability and facilitate data re-use.

This step allows us to update the FMD nomenclature (e.g. unifocal vs. multifocal.) and to standardize the definition of FMD and FMD subtypes in order to harmonize clinical practices and enable cooperative research for this pathology.

Several face-to-face meetings were conducted with experts to reach a compromise and obtain the set of CDEs. The USA registry items were considered during this process in order to cover as many items as possible that were collected from the material. The CDE set is composed of 194 items.

The standardization of the data elements consists of:

1. Identifying concepts in reference terminologies that correspond to the items. This allows us to standardize the value sets associated to the items.
2. Choosing the prefered terms for the items and the elements in the value sets.

For example, the item "Artères" is linked to the concept "Set of Arteries" in the FMA reference ontology[9] and all elements in the value set of "Artères", such as "Coronaire Droite" are also associated to concepts in FMA (see Figure 3).

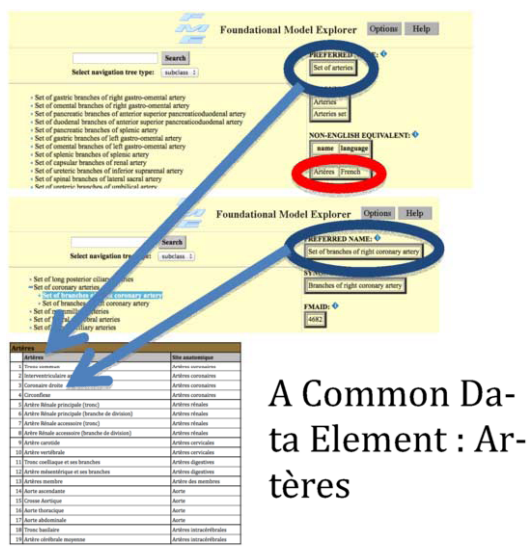

Figure 3 - Example of a common Data Element "Artères" resulting of an experts consensus and standardized with FMA concepts

The resulting multidimensional model is composed of three fact tables corresponding respectively to "Diagnosis", "Past Medical History" and "Current Situation". It is composed of 20 dimensions which are: Patients, Geographical Origin; Link; Symptoms; Signs; Vascular Events, Vascular Event Origin; Vascular Risk Factors; Type of FMD injury; Type of FMD histology; Surgery/Intervention; Type of intervention; Type of exam; Imagery Interpretation; Anatomical site, Arteries; Localisation; Drug Family; Drugs; Physical Exam; Biochimie, Familial History. Two groups of items have been designed in addition (exams; therapies) to take into account temporal and iterative information.

The Figure 4 highlights the table Diagnosis and the relations with the other tables.

Development of the e-registry

The SIR-FMD information system was developed in 2013 with the "MetaSurv" generator described elsewhere [15]. It implemented the multidimensional model described above. A secure platform has been made available as an evaluation platform since the beginning of November 2013. On the user side, SIR-DFM relies on existing local Internet networking facilities. Via a web browser, the user connects to the interface, which is connected to the databases. This application is organized into multiple specifications that provide access to intelligent electronic forms. These electronics forms are scalable, i.e., it is possible at any time to add new items that can be used for any other patients.

SIR-DFM fulfils several requirements: scalability, portability, reliability, accessibility and cost-effectiveness oriented toward non-proprietary software. After the validation of the model, medical records of 471 patients from the databases presented in the Material section of this paper were included and are accessible through a secure user account. Users are organized into a collaborative group, and can access patient groups. The system has been presented recently in the context of the international Fibromuscular Dysplasia Research Network symposium in Cleveland, Ohio USA [16]. At first, this platform is only accessible by members of the French network, but by design, the extension of this registry to European countries is possible and depends only on the adoption of the multidimensional model at the European level.

Step 2 : Alignment process for SDEs

The proposed e-registry model includes a set of Core Data Elements with unambiguous definitions. It would be complex, due to legal and regulatory differences between Europe and USA, to settle on a single international e-registry. Some items present in the USA forms are not present in the FMD e-registry, like for instance, race or religion. One important aspect is to be able to query both data sources (to include patients in a cohort for instance) and then to establish meaningful alignments between items of the different databases that are not in the CDE dataset.

Automated schema alignment approaches have been released to avoid spending time on manual alignment to detect similarity between data elements[10]. The way to classify these alignment approaches may differ in the literature [17][18]. In our current context, the alignment cannot be automatic due to the lack of an Ontology in the FMD domain. We have analysed the potential alignments on a case by case basis. Some propositions, like the "race" item in the USA and the "geographical origin" item in France,are identified as semantically linked. At first, we manually fixed ad-hoc the similarity degree between the identified correspondences.

The mapping process has three levels of correspondences: 1) the table section (21 sections in France and 10 sections with a lot of sub-sections in USA); 2) the items level with almost double items in the USA registry; 3) the value sets.

Figure 5 shows an example of the mapping effort at the level of items and value sets. We followed the methodology described in [18]. The work is in progress and accounts for the building of the semantics of the domain.

Discussion and Conclusion

Fibromuscular dysplasia is a heterogeneous group of rare vascular diseases, leading to the narrowing of medium-sized arteries, mostly the renal and internal carotid arteries. Patients data are today collected in heterogeneous databases at different points of care. In order to enable cooperative research and progress in the comprehension of the disease, our challenge is to develop a framework to access and compare such distributed and heterogeneous data with consistent semantics. We propose a generic two-step methodology to

[10] ISO/EIC 11179 s Information technology - Metadata registries (MDR) - Part 3:Registry metamodel and basic attributes, Third edition 2013-02-15

develop this framework. We have fully completed the first step of the methodology. A multidimensional model was developed from existing material and working sessions with experts and ontologists. An information system was implemented, SIR-FMD, based on this dimensional model to set an e-registry. Currently, all pre-existing patients from the ARCADIA/PROFILE program are included in the e-registry. A prospect of this work is to extend this e-registry to European countries as they will increase their use of the SIR-FMD platform [19]. One important further step will be to support the integration of EHR data in the SIR-FMD platform.

The second step is in progress and needs a large group of experts. A collaboration between the French team and the FMDSA team started recently with two objectives: 1) validate the correspondences between SDEs proposed by the French team and 2) agree on semantics. More work has to be done at the level of the SIR-FMD platform to integrate all needed alignments for performing new research queries across the European e-registry and the FMDSA registry.

Finally, the methodology can be easily extended in other contexts. For instance, we are currently developing an international cohort for the ehlers danlos syndrome, a different rare disease, re-using the methodology and the "MetaSurv" generator.

Acknowledgments

We thank *Jeffrey Olin*, Professor of Medicine at the Icahn School of Medicine at Mount Sinai Hospital and Director of Vascular Medicine and the Vascular Diagnostic Laboratory in the Zena, New York, as well as *Pam Mace*, President of the Fibromuscular Dysplasia Society of America for giving us access to the USA FMDA questionnaire.

Micro- and Macrointegration Profiles for Medical Devices and Medical IT Systems

Raluca Pahontu[a], Angela Merzweiler[b], Gerd Schneider[a], Björn Bergh[a]

[a] *Center for Information Technology and Medical Engineering, Heidelberg University Hospital, Heidelberg, Germany*

Abstract

Collecting, saving, and providing patient data are essential processes of documentation in a hospital. Many IT systems have evolved to provide solutions in this area. The automatic transfer of medical device data to these information systems is a new challenge for hospital IT systems. Some vendors are focused on the integration of medical IT systems and medical devices. They provide great solutions with magnificent features. Nevertheless, those integration solutions are proprietary and isolated, limiting the operator's selection of his medical devices and medical IT systems. Standardizing communication processes within the operating room and between medical devices and medical IT systems brings benefits for both patient and hospital staff. This work identifies and proposes micro- and macrointegration profiles as a basis for new IHE Integration Profiles for both medical IT systems and medical devices of the operating room.

Keywords:

Standardization; IHE; healthcare; medical devices; interoperability; Hospital IT Systems.

Introduction

The ongoing spread of technology in the healthcare domain increases the necessity of connecting medical devices and clinical information systems. In healthcare, interoperability is the ability of different information technology systems and software applications to exchange data and to interpret these data in the same way as defined in the HIMMS Dictionary of Healthcare Information Technology Terms, Acronyms and Organizations [1]. Semantic interoperability between medical devices and clinical information systems will permit mixed-vendor data transfer and comprehensive secure data acquisition, and it will enable innovations to improve patient safety, treatment, and workflow efficiency, reducing medical errors and healthcare costs to the benefit of patients [2].

The main goals of the OR.NET [3] project–funded by the German Federal Ministry of Education and Research (BMBF)–are the development of semantically interoperable, standardized, certifiable, secure, multi-vendor networking solutions for medical devices and clinical IT systems for the operating room and clinic. In order to achieve technical, syntactic, and semantic interoperability, OR.NET supports the Integrating the Healthcare Enterprise (IHE) initiative. IHE is an initiative of healthcare professionals and system vendors focused on improving the way computer systems share information [4]. IHE supports established standards such as Digital Imaging and Communications in Medicine (DICOM) [5] and Health Level Seven (HL7) [6] to address specific clinical needs, focusing on real-life integration problems. Providing specifications on implementing existing standards, tools, and services for interoperability, IHE establishes a guideline for a standardized communication in several clinical domains like IT infrastructure, radiology, patient care devices, and much more. It addresses aspects like security, patient privacy, and safety and shows how required data can be exchanged across different actors. Even if existing standards address some communication needs, they cannot close all interoperability gaps. This paper identifies gaps of the standards and promotes micro- and macrointegration profiles modelling communication needs between devices of operating rooms and clinical information systems.

Materials and Methods

The development of new IHE Integration Profiles usually consists of four steps [7]:

1. Clinical and technical experts define critical use cases for information sharing.
2. Technical experts create detailed specifications for communication among systems to address these use cases, selecting and optimizing established standards.
3. Industry implements these specifications called IHE Profiles in hospital information systems (HIT).
4. IHE tests vendors' systems at carefully planned and supervised events called Connectathons.

During the OR.NET project, various methods were used to identify communication needs in the operating room and clinic.

As a first step, we collected various clinical and technical use cases describing clinical and technical workflows between the operating room and medical IT systems in a standardized manner. Each use case should be characterized by the following information: author, involved actors, triggering events, preconditions, postconditons, invariants, standard workflow, alternative workflow, and temporal requirements of the arrival of transferred data. Temporal requirements range from closed-loop control of interconnected medical devices requiring real-time communication to archiving of patient images which is not critical in terms of time. Furthermore, each use case was linked to corresponding exchanged data in a communication matrix. All partners of the project (physicians, IT system vendors, medical device vendors, etc.) were involved in this process. We collected about 150 use cases.

As a further step, we developed a communication matrix template to investigate which devices or IT systems should communicate with each other. Medical devices and medical IT systems were classified in these categories:

- Anesthesia Devices: Anesthesia Machine, Ventilator, Infusion Pumps, Syringe Pumps, Heat Preservation Mats, Patient Monitoring, Neurophysiological Monitoring, Anesthesia Workstation
- Imaging Devices: Ultrasound Device, X-Ray, CT Scanners, MRI Scanners, Surgical Microscope Camera Ceiling
- Navigation: Navigation System, Tracking Camera
- Other Tools: Irrigators, Aspirators, Foot Pedal, Surgical Table
- Building Utilities: Ambient Light, Displays, Air Cooling
- IT-Systems: Clinical Information System (CIS), Documentation System, Patient Data Management System (PDMS), Picture Archiving and Communication System (PACS)

These categories are represented by the x and y axis of our communication matrix.

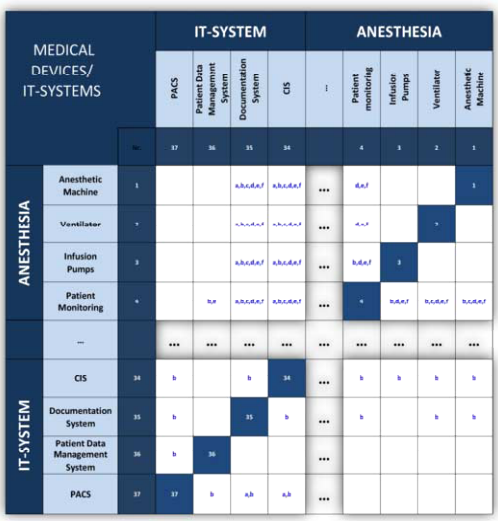

Figure 1 – Fragment of communication matrix

Furthermore, we classified possible exchange data in order to investigate which kind of data should be exchanged by these devices and systems. Therefore, we classified data into:

- Patient-related data
  - Streaming Data: Video (e.g. Endoscope-, Laparoscope videos); Measured values (e.g. heart rate, blood pressure, patient temperature); Navigation data
  - Non-Streaming Data: Patient administration data; Images (e.g. model data, segmented data); Discrete measured values (e.g. heart rate, blood pressure, patient temperature, medical report, laboratory findings, surgical planning data)
  - Alert data: like ventilation pressure is too high
- Non-patient-related data
  - Streaming Data: Room temperature; Medical device's status information; Navigation data (e.g. device position in the room); Device configuration parameters
  - Non-Streaming Data: Discrete measured values (e.g. 30% brightness, table's tilt); Medical device's status information; Device configuration parameters
  - Alert data: like technical alarms

Different project partners, such as research organizations, IT system developers, medical device vendors, and physicians, filled the matrix template with specific patient-related and non-patient-related data. As a result, we aggregated 16 filled matrices in one communication matrix. Figure 1 shows a fragment of the aggregated matrix.

Based upon the 150 concrete use cases and the communication matrix we derived four abstract microintegration profiles (MIP) describing four main communication types between clinical IT systems and medical devices or between medical devices. Each microintegration profile consists of the involved actors and a name for the transaction. The four microintegration profiles can be composed to one abstract macrointegration profile (MAP).

As a fourth step, we performed a literature research on existing IHE profiles to map identified communication needs to existing IHE transactions.

Results

The following results were obtained from the communication matrix:

- We identified the medical devices and IT systems that need to communicate with each other. In IHE terms, those also represent the actors of the microintegration profiles.
- We identified the kinds of data that are exchanged by those devices or IT systems
- We clustered all identified communication needs [8], resulting in four main MIPs and an abstract MAP. These profiles are described separately below.

MIP "Communicate Worklist"

The first MIP addresses the transfer of universal worklists to medical devices within an operating room. Thus, users are able to access and manipulate work items (e.g. orders, tasks, requests) originating from various IT systems, such as an operation planning system. The universal worklist can be accessed via a user interface that can be customized so that users can get only the most important information about the execution of the tasks displayed. For example, physicians can query all of the day's upcoming surgery orders and patient names. This worklist could then be used to select a patient for documentation. In order to communicate the worklist we need a worklist provider and a worklist consumer. In terms of IHE, those will represent the actors of the transaction called Communicate Worklist as shown in Figure 2.

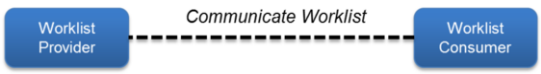

Figure 2 – MIP Communicate Worklist

MIP "Communicate Patient Demographics"

Since not every system provides the functionality of communicating a worklist, we propose a fallback mechanism if the universal worklist is not available. Therefore, the patient's demographic data have to be digitally transmitted from the clinical information system to the operating room as shown in Figure 3. In this case, the two actors will be a patient demographics provider and a patient demographics consumer. "Communicate patient demographics" is the needed transaction.

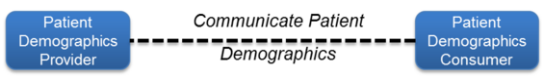

Figure 3 – MIP Communicate Patient Demographics

In our scenario, the microintegration profiles Communicate Worklist and Communicate Patient Demographics mainly refer to a communication between the operating room and medical IT systems.

MIP "Communicate Results"

During surgery medical devices deliver both patient-related and non-patient-related data. Those result data are relevant for the involved devices as well as for clinical subsystems like an operation planning system or a clinical information system. This communication path is displayed in Figure 4.

Figure 4 – MIP Communicate Results

For the MIP Communicate Results we first classified the results that should be communicated in:

1. Multimedia results like images, videos etc.
2. Alphanumeric results like diagnostic data, examination parameters etc.

Depending on the storage target, results should be available in raw, filtered, and aggregated form. Medical devices and IT systems may implement both actors: a result provider and a result consumer. For example, a PACS provides multimedia objects like patient images and saves images from imaging devices as a result consumer. A patient monitoring system may provide vital data and consume patient demographics from a patient demographics consumer actor.

MIP "Communicate Technical Operation and Control Parameters" (TOCs)

Some clinical use cases also address communication in the operating room between medical devices like the communication of technical operation and control parameters. TOCs can, for example, represent the current status of medical devices like light on/off or control parameters like light endoscope brightness increased by 30%. The communication of TOCs between an ultrasound dissector (USD) and a surgical microscope is one of OR.NET's use cases. In this scenario the physician can view and modify USD parameters via the user interface of a surgical microscope. Here we distinguish between read operations like data visualization, read/write control, and closed-loop control. Closed-loop refers to the feedback interconnection between two medical devices, meaning that a medical device action is dependent on the deviation between the measured and desired performance. Read, read/write control, and closed-loop control have various temporal requirements that imply different communication transport media. While for visualization data and read/write control Ethernet network technology may satisfy the corresponding temporal requirements, a real-time network technology is mandatory for closed-loop control data so that patient safety can be guaranteed every time. Therefore, this MIP has two specifications depending on the required network technology: Communicate TOCs in non-real-time and Communicate TOCs in real-time. Figure 5 shows the abstract MIP Communicate TOCs.

Figure 5 – MIP Communicate Technical operation and control parameters

Figure 6 shows one macrointegration profile (MAP) as a result of the combination of the four MIPs.

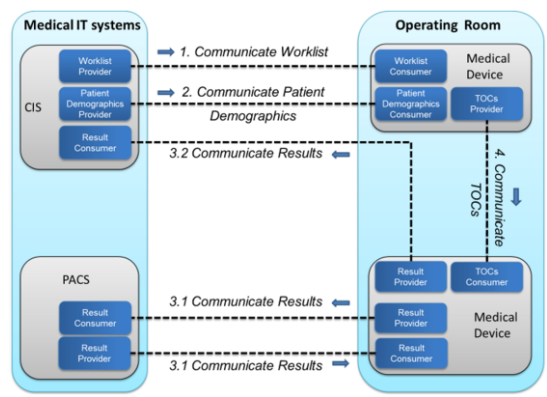

Figure 6 – Macrointegration profile

This abstract MAP includes the following microintegration profiles.

- MIP Communicate Worklist
  - Alternative: MIP Communicate Patient Demographics
- MIP Communicate Results
  - Multimedia results
  - Alphanumeric results
- Optional: MIP Communicate TOCs in non real-time
- Optional: MIP Communicate TOCs in real-time

Depending on the clinical scenario or the imminent surgery, the microintegration profiles can be variously combined, respecting the process data flow like starting with patient identity data, communicating results to medical devices and to medical IT systems. As an example, one specific MAP based on the communication between CIS, PACS, the Möller-Wedel GmbH & Co KG surgical microscope, and Söring GmbH

USD is described: at the beginning of each surgery, the user can enter patient data or select one patient from the worklist at the human machine interface (HMI) of the surgical microscope.

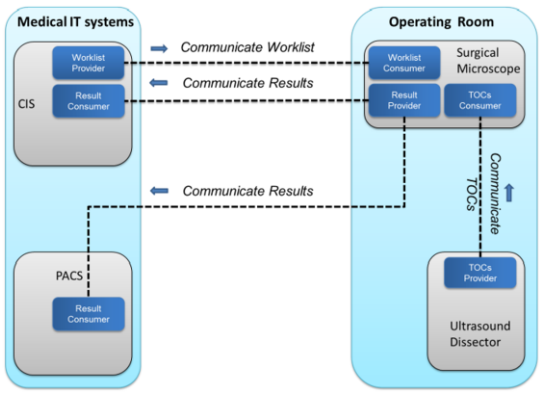

Figure 7 – Macrointegration profile for use case surgical microscope and ultrasound dissector

In the second case the worklist has to be queried from the worklist provider. This communication represents our first microintegration profile Communicate Worklist with CIS as a worklist provider and the surgical microscope as a worklist consumer. Patient data preview is supported by the HMI of the microscope. The second use case describes the triggering of USD functions, the use of USD parameters, and signaling USD error warnings over the HMI of the surgical microscope. For that the surgical microscope and the USD have to be previously configured. Using only one user interface for both devices would simplify handling both at the same time and provide better overview. For safety and security reasons, both USD parameters and functions must still be set, read, and triggered in the USD independently of any control by the HMI of the microscope. Settings on the USD always take precedence over conflicting settings on the HMI of the microscope. Using the HMI of the surgical microscope, current settings of the USD parameters can be visualized and changed on the microscope. The user can trigger USD functions over the HMI of the microscope and is warned when he exerts too much pressure with the USD instrument. Those communications are represented by the fourth microintegration profile Communicate TOCs. In this case, the surgical microscope represents the TOCs Consumer and USD the TOCs Provider. At the end of the neurosurgery, all stored patient data can be archived in medical IT systems. Picture and video recordings can be archived in a PACS and patient-relevant data are stored in the clinical information system. The microscope acts here as a result provider, and CIS and PACS act as result consumers. Thus, microintegration profiles can be combined to accomplish needed communication requirements for specific surgery and user requests.

Based on a literature search of existing IHE profiles, we identified existing IHE transactions that can map our communication needs. For each of the first three MIPs the identified IHE transactions are described below.

MIP "Communicate Worklist"

For this MIP the IHE Radiology domain provides a mechanism for communicating a DICOM Worklist in the Scheduled Workflow Integration Profile. An Acquisition Modality actor like a CT Scanner receives a DICOM Worklist after querying it from the Order Filler actor using the IHE transaction Query Modality Worklist [RAD-5]. This transaction may be used by medical devices with a DICOM interface to receive a DICOM Modality Worklist. In general DICOM interfaces are provided from medical imaging devices. One of the physicians' requirements is to provide a universal worklist via HL7 for medical devices having no DICOM interface, but having an HL7 interface. At the moment IHE provides no transaction for communicating an HL7 worklist. One mechanism to handle this missing transaction is to provide a component that listens for appropriate HL7 messages like order messages, stores the information in a local database, and answers queries from various devices.

MIP "Communicate Patient Demographics"

For this MIP we identified the IHE Integration Profile Patient Demographics Query (PDQ). Applications can query a central patient information server and retrieve patient demographics. One can query partial or complete patient name, patient ID, date of birth, bed ID, etc. The Patient Demographics Query [ITI-21] transaction is triggered by the Patient Demographics Consumer actor and addressed to the Patient Demographics Supplier actor. If visit information is also required, one can use the Patient Demographics and Visit Query [ITI-22] transaction. The Patient Administration Management (PAM) profile is an alternative to PDQ. While the transaction Patient Identity Feed [ITI-30] provides the same category of data in push mode (notification/acknowledgement), PDQ operates in pull mode (query/response).

MIP "Communicate Results"

For communicating multimedia results, the IHE Radiology transactions Query Images [RAD-14] and Retrieve Images [RAD-16] can be used. During surgery the physician can display images with those DICOM-related transactions from an Image Archive actor. Intraoperative images can then be stored at the Image Archive/Manager actor with the Modality Image Stored [RAD-8] and Storage Commitment [RAD-10] transactions.

For communicating alphanumeric results between, for example, physiological monitors, ventilators, infusion, and medical IT systems, the IHE Patient Care Device (PCD) domain provides the Device Enterprise Communication (DEC) Integration Profile. Device settings, device alarm state, and technical data from a medical device such as its battery charge status data can be transferred with the DEC profile. The Device Observation Reporter (DOR) actor sends device data to the Data Observation Consumer (DOC) actor by the HL7 based transaction Communicate Device Data [PCD-01] in compliance with IEEE 11073 terminology mapping. This allows semantic interoperability.

MIP "Communicate Technical Operation and Control Parameters" (TOCs)

For communicating TOCs between medical devices in the operating room, no IHE integration profile could be identified.

Figure 8 shows the abstract macrointegration profile after the mapping to existing IHE Integration Profiles, whereat the actors of the individual IHE transactions were adopted.

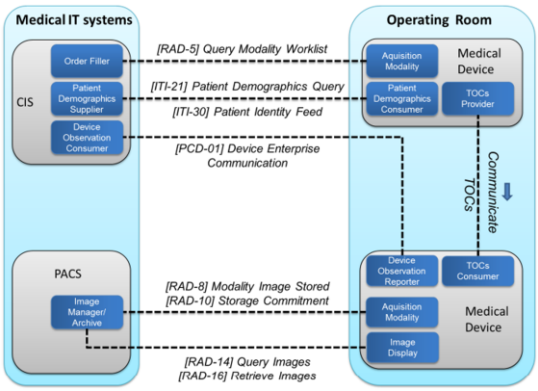

Figure 8 – Macrointegration profile with existing IHE transactions

Discussion

Since patient demographic data are essential for an upcoming surgery, they have to be automatically transferred to the operating room in an accurate way. These data can be transferred using established standards like HL7 and DICOM.

During surgery, medical devices deliver relevant data for medical IT systems. These data are mostly transferred by proprietary protocols. For communication of device data to medical IT systems, IHE provides the HL7-based integration profile Device Enterprise Communication as a first profile within the IHE Patient Care Device domain [9]. Connectathon results show that 51 vendors of medical devices and medical IT systems already implemented this integration profile, and 18 of them implementing both actors: the Device Observation Reporter and the Device Observation Consumer [10].

Since IHE does not provide integration profiles for the communication between medical devices in the operating room, this paper provides basic microintegration profiles as a first step towards new IHE integration profiles. As a next step, the identified actors and transactions have to be specified on a technical level, including communication protocols, data model, and the semantics of exchanged data.

Gathering and sharing medical device information with other devices using communication standards opens new ways in an Internet of Things (IoT) era. As IoT becomes relevant for the healthcare domain, further investigation is required in order to examine how standardizing efforts in healthcare and IoT interact.

Conclusion

This work identifies communication needs between medical IT systems and the operating room as well as between medical devices. Identified communication needs could be reduced to four abstract communication paths formulated as MIPs. Furthermore, a conceptual MAP was presented. According to the literature, the transactions of the conceptual MAP could be mapped to existing IHE transactions, except for the transaction “Communicate TOCs”.

Product-based Safety Certification for Medical Devices Embedded Software

José Augusto Neto[a], Jemerson Figueiredo Damásio[a], Paul Monthaler[a], Misael Morais[a]

[a] *State University of Paraíba – UEPB, Campina Grande, Paraíba, Brazil*

Abstract

Worldwide medical device embedded software certification practices are currently focused on manufacturing best practices. In Brazil, the national regulatory agency does not hold a local certification process for software-intensive medical devices and admits international certification (e.g. FDA and CE) from local and international industry to operate in the Brazilian health care market. We present here a product-based certification process as a candidate process to support the Brazilian regulatory agency ANVISA in medical device software regulation. Center of Strategic Technology for Healthcare (NUTES) medical device embedded software certification is based on a solid safety quality model and has been tested with reasonable success against the Class I risk device Generic Infusion Pump (GIP).

Keywords:

Medical Devices; Embedded Software Certification; Safety Certification; Certification Process.

Introduction

The software embedded in medical devices introduces new features and defines competitive differences among same-class equipment. Despite this benefit, the presence of software, and its intense interaction with electrical and electronic components, implies new malfunctioning risks and potential harm to patients and healthcare professionals who interact with it. In the last decade, the US regulatory agency (FDA) has published information concerning fault cases on medical devices and the reports show 1,154,451 cases of damage, as well as the need for 5,294 recalls [1]. The same study points out that software is still largely responsible for recalls in medical devices, and is directly involved in 33.3% of recalls for Class I (high risk) equipment, 65.6% of Class II (medium risk) and 75.3% of Class III (low risk).

The FDA provides some guidance to the industry on the general principles of software validation. In a specific document [2], the FDA specifies that software must meet a set of rules on the production process, as defined in the 21 CFR §820.70 law [3]. The legislation in Brazil is less specific on medical device embedded software, but recently the Brazilian regulatory agency ANVISA exposed a new norm to public consultation [4] which, in short, proposes to comply with the FDA production-based approach.

Overall, the current certification models are mainly based on ensuring that the production processes follow international standards such as ISO 14971 [5] and ISO 80002 [6]. Promising alternatives are known, such as the argument-based approach, where manufacturers provide safety cases and certification authorities assess them individually, and the safety quality model approach, in which quality questions are provided to guide assessors to decide whether a software product is safe or not [7]. This work extends the NUTES-IESE/Fraunhofer Software Safety Quality Model [7] with a safety certification process based on it.

The Product Certifier Body (OCP in Portuguese) is the group appointed by ANVISA that have expertise to audit medical device production processes. However, to the best of our knowledge, there is no OCP accredited to perform specific certification for embedded software in medical devices, even if the focus is on the production process.

NUTES Quality Model and the Certification Process Model

The Center for Strategic Technologies in Healthcare (NUTES) was created in 2011, as result of a partnership between the State University of Paraíba (UEPB – www.uepb.edu.br) and the Brazilian Health Ministry, aiming to develop products and technologies to support the Brazilian medical device industry, as well as the regulatory agencies that supervise it.

In 2013 and 2014, the NUTES technical team, in cooperation with the German institute IESE/Fraunhofer-Kaiserlautern, developed a safety quality model for medical device embedded software totally centered on the final product, instead of the manufacturing best practices. The basis of the NUTES Quality Model is a strong theoretical framework of safety engineering, combined with the Fraunhofer background, which has been accumulated through many years of providing services to industries in which embedded software is critical, such as automotive and the airline industry [8].

The NUTES Quality Model proposes asking a set of quality questions against the software documentation; those questions precisely define what is considered safe software in a medical device [7]. In spite of that, the model does not include a process for how these questions should be asked, nor does it provide a step by step tutorial to check whether a software is safe or not.

This paper presents a structured process used at NUTES to certify embedded software in medical devices. The process is original to Brazil and is not production-based, but rather product-based. It uses the NUTES Quality Model and, as a consequence, it is reusable and adaptable to any software-intensive medical device. This is possible due to the quality model structure, based on general safety cases, which in turn refers to requirements, architecture, testing, and code aspects (common to every software product).

The certification process presented in this work can be, for didactic purposes, split into three phases: 1) the initial customer interaction; 2) the documents acquisition to support the certification realization; and 3) the software analysis. Particularly for phases 2 and 3, we list the input and output artifacts. We also present the criterion of division in 5 subareas of technical knowledge (safety, code, tests, architecture and usability), and the aggregation rules between areas, which produces a quantitative and qualitative outcome of the certification.

The provided process is compatible with the technical requirements demanded by ANVISA, and is continuously evolving to stay aligned with technical requirements

Pilot Evaluation

Manufacturers resist collaborating in experimental assessments since NUTES certification exposes classified product features. Moreover, ANVISA still does not require a local software certification. As an alternative, we performed a pilot evaluation of the process applying it to certify the Generic Infusion Pump (GIP) [9]. The GIP is a project developed by the FDA Software Engineering Laboratory in cooperation with the University of Pennsylvania.

The GIP failed the NUTES certification process, mostly because we could not satisfy part of the quality model, either by lack of documents or due to real product safety issues. At the end of this document, we present a proper discussion on the results, implications and limitations of this approach.

Methods

Theoretical Background

The process described here results from a bibliographic review of documents provided by regulatory agencies that describe the main product certification steps [10, 11]. Moreover, the NUTES certification team is working on the ISO 17025 [12] certification pipeline; and in planning the next step, the ISO 9001 [13].

The process described next is documented within a full quality management system, compliant with international standards. We built the process assisted by an ISO consulting company. The interaction between NUTES and this company was formal, and occurred during eight months in 2014, from March to November. Furthermore, there are several direct and indirect contributions of members of the FDA and ANVISA to the current version of the certification process. The latter is much closer and especially important since many ANVISA members also act as professors at NUTES Postgraduate Program in Science and Technology in Health. The result of this effort is a structured model, presented in Business Process Modeling Notation (BPMN), and a list of documents that support its execution.

We executed the GIP certification process in September 2014, in a 15-day period, and it was attended by the NUTES Software and Safety Engineering Research Team. Currently, this team is composed of PhD Computer Science faculty members with relevant contributions in the software engineering field [7, 14, 15, 16]. The team has been through a two-year safety-focused training by means of a cooperation with the experienced IESE/Fraunhofer Kaiserlautern.

Evaluation Method

We primarily evaluated the process in a pilot experiment for the GIP certification. We consider the infusion pump choice adequate for the following specific reasons:

1. The FDA claims [1] that infusion pumps are a continuous source of safety problems;
2. The GIP in an open specification. This is interesting for future evaluation and replication of the efforts in next phases of this work. Some obstacles could emerge if we had opted for a proprietary device.
3. The GIP is a robust project of a regulatory agency and its documentation works as benchmark for both manufacturers and the academic community.
4. It is a popular project, cited in more than 10 academic papers.
5. Its conception is safety-focused, therefore directly addresses the requirements of this work.

We used the GIP publicly available documentation [17] as input to the certification process; it includes articles, models and code. Complementary documentation was required and produced by means of NUTES internal efforts [18]. As a result, we present an argument-based validation and discuss the impact of the input documentation on the process.

Results

Certification Process Model

The certification process entails three distinct and sequenced phases: **Phase 1 (Business agreement)** – contains the customer-NUTES interactions up to hiring the certification. In this phase, negotiation and contract signature occur; **Phase 2 (Document submission)** – comprises the actions performed with the purpose to acquire the artifacts required to execute the certification process. This phase is interactive and incremental (i.e., we held document evaluation rounds and additional documentation is requested when necessary). The last phase takes place when the interactions end and the documentation is complete; **Phase 3 (Software analysis)** – the main certification phase. We share the documentation among the teams in charge of subareas of certification. The subarea certification is performed, and the individual results are composed into a final certification result.

The brief description that follows summarizes the knowledge recorded in 19 operational processes and 15 document templates. The big picture of this work includes the link between this certification process model and a quality management system, together they configure the minimum elements required by ISO 17025 and ISO 9001, for which NUTES is to be submitted.

Figure 1 details the certification process using BPMN. Notice that Phase 1 is not present in the flow since it is all about commercial interaction between NUTES and the product manufacturer, or ANVISA (both are potential clients for embedded software certification). This interaction includes defining the risk class of the equipment and the embedded software under certification, as well as the milestones and deadlines, specially related to the current specification of the NUTES technical team.

Composing the Certification Dossier

The certification process starts in Phase 2, in which the software documentation is requested from the client. This request specifies deadlines and delivery orders for the documentation. We analyze all documents received and depending on its completeness for the type of device under evaluation, we decide whether the received documentation meets the process needs; if it does not, we send a new request. The input software documents for certification are:

1. Test Plans – a document that guided the execution of different categories of tests in the system;
2. Test Logs – a detailed record that includes time marks of the execution tests results;
3. Test Reports – a formal document that describes the tests results, where successes and failures are presented;
4. Architectural Document – a high-level view of the system. It uses text and architectural models to

explain the system in a macro vision (e.g.: which module interacts with the alarm module);

5. Functional Specification – presents the system expected behavior;
6. Safety Requirements Document – this document lists the body of functionalities directly related to guarantee the safety of the system;
7. Software Design – it describes the system in a still abstract perspective, but in a much lower level than the architecture (e.g.: how small code unities the interaction that occurs inside the alarm module);
8. Software Source Code and Support Libraries – the system itself, coded in a known programming language;
9. Usability Engineering Document – it describes the decision behind the way the interaction between system and user is considered;
10. User Manual – a document addressed to the final user. It explains the correct way one should act in order to interact with the system;
11. Alarms Specification – it describes the events that might happen, and how they fire observable notifications to the user;
12. Risk Management File – an important document, suggested by ISO 80002 [6], which exposes every safety aspect of a device and how they are considered (e.g.: known risks, fail occurrence chance for different categories, etc.).

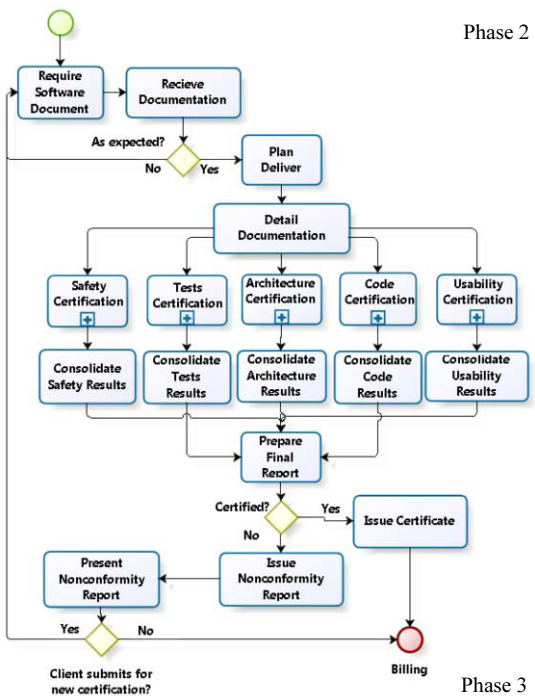

Figure 1 – The certification process for medical devices embedded software

Notice that these documents are a subset of those required by the FDA. This indicates that their production is typical, and does not impose drastic changes to the way that the software industry currently works. Moreover, in the case of certifying a real software instead of an open specification, the manufacturer is provided with "The NUTES Guide for Certification of Embedded Software for Clients". The guide goes into detail on each required document and also presents sample documents with the completeness level expected for the certification process.

Phase 2 takes at least one day and at most a week; this variation depends on the customer documentation availability. Once documentation is accepted, the third phase starts.

In Phase 3 we establish a delivery plan for each team (i.e., safety, test, architecture, code and usability) involved in the certification. This plan takes into account the certifications in progress and the teams' availability. Next, the full documentation body is detailed and shared (with possible copies) for the subareas. Finally, they generate specific reports.

Figure 2 presents the process executed in each subarea. The first task is about receiving documents and checking if the documentation is complete. At this point, any team can make requests for additional documentation to the certification manager who controls the documents originally received in Phase 2.

The subarea planning certification represents the first interaction with the NUTES Quality Model. The first step is about defining the set of questions that apply to the device under certification. At this point, teams should select questions and classify each of them as mandatory, desirable or optional according to device's risk class. In the second step, we define deadlines for the execution and report delivery. All steps, including the choice of questions and their classification, demand prior technical background and should be endorsed by a previous certification executed at NUTES.

The execution task refers to the assessment of available documentation seeking answers to the selected questions. For certification purposes, the NUTES Quality Model's questions must receive positive answers. Negative responses indicate a possible non-compliance of the software.

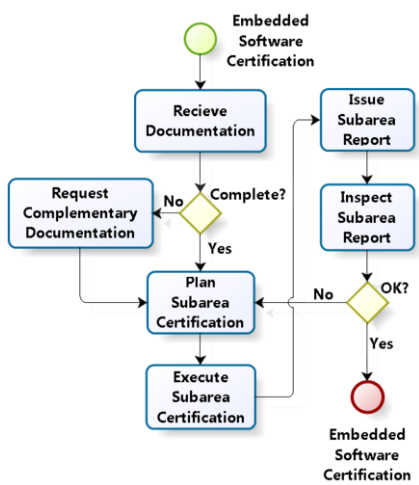

Figure 2 – The subarea certification process for medical devices embedded software.

In the end, each area produces two reports: a qualitative description of the product, and a quantitative result of the subarea certification. The first shows the assessed documentation, and presents a textual argument about the strengths and weaknesses of the product, highlighting nonconformities that led to negative answers (if any). Finally,

if the software fails the certification, the report suggests modifications to the software, such as new features to enable a better score on future certifications. The quantitative report describes the number of positive answers for each class of questions in comparison to the maximum score per class. Figure 3 shows an example of part of a quantitative subarea report. We express the number of positive and negative responses for each class in both textual and graphical representations.

Mandatory		Desirable		Optional	
Yes	No	Yes	No	Yes	No
15	0	3	2	1	1
100%	0%	60%	40%	50%	50%

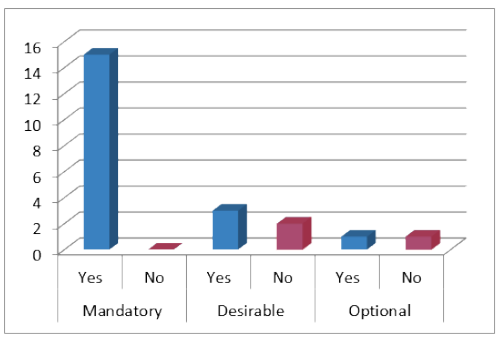

Figure 3 – Subarea quantitative results showing the total number of positive and negative answers for each class.

Finally, the team leader inspects the subarea report looking for mistakes or inconsistencies. If the team members finds any divergence, they must revisit the whole subarea process.

Returning to the main process, the certification manager analyzes each subarea report and produces the final report. The final report consists, first, of all subareas qualitative observations presented in a coherent outline. Next, it includes the subareas quantitative reports in a summarized table, with both "Yes" and "No" responses for each class of questions. To achieve the final result, the following aggregation rule is applied: questions related to mandatory safety features have a limit of zero negative answers allowed. Questions related to optional and desired safety features have an upper limit for negative answers according to the device's risk class. For the GIP, two is the limit for negative answers in desirable questions, and a varying number of negative answers is acceptable for optional safety features related questions. Each area specialist, based on international standards practices and individual expertise, defines those bounds.

Once the report is ready, one of the following situations occurs: 1) A certification is assembled and sent to the customer if it is compliant (i.e.: negative answers did not go over the limits) and therefore the embedded is considered safe; or 2) The customer is told the software failed the certification and is provided with the report that clarifies the problems that led to the negative result.

Pilot Evaluation

We applied the certification process to the GIP and the results show that the device, as currently described in the public specification, is not safe as a software intensive medical device is required to be according to NUTES Quality Model and its 300 safety-related quality questions.

However, due to confidentiality reasons, we cannot elaborate on the real results for any subarea but Safety. Such restriction does not influence the certification process comprehension, the main goal of this work. Table 1 presents the quantitative results, where only Safety results are accurate while others are slightly modified. We altered these results in a way that conclusions are the same from the original report, as follows.

Table 1 – Quantitative result of GIP certification against NUTES Quality Model questions

Subarea	Mandatory		Desirable		Optional	
	Yes	No	Yes	No	Yes	No
Usability	3	10	12	16	14	1
Safety	20	5	1	0	0	0
Architecture	5	10	17	1	2	10
Requirements	18	3	36	5	6	20
Code	15	0	4	1	1	1
Test	4	36	11	6	3	3
Total	65	64	81	29	26	35

A full "Yes" score is a must for Mandatory questions on every subarea; for the Safety subarea (real result), GIP's 20 "Yes" out of 25 questions is enough to fail the certification. The illustrative numbers used for the remaining subareas show that we address Usability, Architecture, Tests and Requirement's safety issues properly, and Tests holds the weakest safety treatment. On the other hand, Code alone had the best result, mainly because GIP's code was a good source, where we found positive answers for all questions.

Discussion

The GIP project is largely different from conventional software. Its documentation derives from multiple academic works, while conventional documentation is generally produced in sequence, and each document is clearly related to others during the software engineering process. In this paper, we have claimed that we used all the available documentation for GIP. The first problem is that the documentation found was not enough to fill out the required list. For example, we used the Hazard Analysis [19] and a document of Risk Analysis [18] to address the lack of a Risk Management File. Therefore, from the 64 negations for mandatory question, only 14 were based on real evidence. The other 50 were explained in terms of "No evidence in the documentation".

In a real product scenario, the information scarcity is also possible, but we would be able to ask the customer for extra documentation. Another aspect is the documents internally produced by NUTES team to reach the documentation required by the process, we believe that the certification scores could be higher if extra effort was placed in better composing of mock documents. Additional in-depth considerations, specifically for the Architecture subarea, can be found in another work [14].

Conclusion

The regulation for embedded software in medical devices in Brazil is currently based on international certifications, such as the FDA or CE. These certifications focus on the audit of manufacturing processes, assuming that well-executed processes will generate safe products, but this approach has problems. In this work we presented a certification process focused on the product, supported by a quality model that provides a general safety case for embedded software in medical devices.

We applied the designed process to the GIP and the results point to the high standards to which a software-intensive medical device must comply with to be considered safe, and therefore certified. We have fully executed the process, but real product certifications are necessary to better validate and improve the process proposed here. First agreements with industry partners have already taken place, and we intend to execute new rounds of the process on commercialized products soon.

The certification process is currently undergoing ISO 17025 certification, and shall be submitted to the ISO 9001 soon. A first internal audit phase for ISO 17025 has already been accomplished. This step fulfills accreditation requirements to NUTES be able to provide ANVISA with a local software certification service to Brazilian and global manufacturers.

Acknowledgements

This research is directly supported by NUTES/UEPB and several of its researchers, who have made multiple contributions in the pilot evaluation results. We also thank Dr. Kleber Nobrega and his team at Perceptum, who offered strong methodological support for us to create and refine the certification process presented here.

Abstract

Medication errors are responsible for most inpatient adverse events. Medication reconciliation emerged as an effective strategy to decrease these problems, enhancing patient safety. Electronic health records with reconciliation tools could improve the process, but many aspects should be considered in order to reach expected outcomes. In this paper we analyzed how a compulsory, electronic reconciliation application was used at Hospital Italiano in Buenos Aires, through admission and discharge processes. We evaluated all medications that were reconciled during patient admission and discharge since its implementation, from February to November 2014. During that period, there were 78,714 reconciled medications regarding 37,741 admissions (2.08 reconciled medications per hospitalization), of 27,375 patients (2.88 medications per patient). At admission, 63% of medications were confirmed and the remaining were paused or deleted. At discharge, 41% of all medications were reconfirmed. In the creation of the best possible medication history, the use of an electronic reconciliation tool would clean overloaded lists, but at the same time medications could be erroneously deleted.

Keywords:
Electronic Health Record; Inpatient Data; Cross sectional study; Medication safety

Introduction

Medication errors (ME) are the main cause of inpatient iatrogenesis, followed by postoperative complications and hospital acquired infections [1,2] Up to 20% of hospital adverse drug events (ADE) take place at admission or discharge and are related to poor inter-professional or patient-professional communication [3]. More than 50% of the inpatient population has one or more unwarranted discrepancies between their prescription list and the actual, taken medications [4]. These shortfalls can lead to omission of crucial chronic medication, therapeutic duplication and names or doses mistakes. Almost 60% of these errors could potentially cause serious health risks for the patient [5,6]. Medication reconciliation (MedRec) is "a process of identifying the most accurate list of all medications a patient is taking,… and using this list to provide correct medications for patients anywhere within the healthcare system,"[7] thus, preventing ME especially during transition of care. A comprehensive achievement of the best possible medication history (BPMH) is particularly important [8].

Electronic tools could help to perform MedRec, consequently improving patient safety [9,10]. The introduction of an electronic reconciliation application showed a 28% relative risk reduction of potential ADEs [11]. However, effective implementation of MedRec has proven to be challenging, and clinical endpoints are currently subject to further studies [12,13]. There have been studies showing less than 20% adoption of optional electronic MedRec applications [14]. However, there is little information about the use of compulsory tools [15]. In 2014, Hospital Italiano of Buenos Aires (HIBA) implemented a mandatory electronic MedRec tool at patient admission and discharge. The objective of this paper was to analyze how an EHR-based mandatory reconciliation tool at admission and discharge was used, in the creation of the best possible medication history.

Methods

Study Design

A cross sectional, descriptive study, with secondary analysis of a de-identified clinical database was performed.

Population

We included all of the 1) hospitalized patients at HIBA from February to November 2014, 2) medications that were reconciled during admission and discharge processes, and 3) physicians involved in the processes.

Setting

HIBA is a non-profit health care academic center founded in 1853, with over 2,700 physicians, 2,700 other health team members (including 1,200 nurses) and 1,800 administrative and support employees. HIBA has a network of two hospitals with 750 beds (200 for intensive care), 41 operating rooms, 800 home care beds, 25 outpatient clinics and 150 associated private practices located in Buenos Aires and its suburban area. It has an insurance plan (Plan de Salud - PS) that covers more than 150,000 people and also coordinates insurance for another 1,500,000 people who are covered by affiliated insurers. Between 2013 and 2014, over 45,000 inpatients were admitted to the hospital, with 45,000 surgical procedures (50% ambulatory) and 3 million outpatient visits.

HIBA is a teaching hospital, with over 30 medical residency-training programs and 34 fellowship programs. There are currently 400 residents and fellows in training.

HIBA runs an in-house developed Health Information System since 1998, including clinical and administrative data. Its Electronic Health Record (EHR), called Italica, is a unified, modular, problem-oriented, and patient-centered system that works in different environments (outpatient, hospital, emergency, and home care). Italica allows computer physician order entry (CPOE) for medications and medical tests, and storage and retrieval of test results, including images through a picture archiving and communication system (PACS) [16].

Analysis Plan

For this study, we analyzed: 1) the number of inpatients, gender, age, health insurance, time since first hospital contact, primary care physician (PCP) assignation; number of hospitalizations, number of admissions per patient, length of stay, admission and discharge diagnoses; 2) the number of confirmed, paused and deleted medications at admission and discharge; 3) the age, gender and specialty of physicians, seniority, authoring of admission and discharge documents.

Admission and Discharge

Before 2014, the admission and discharge documents were filled in plain text, including medical history and medications. To start the project we reviewed the literature, finding examples of electronic applications [17-21], and we worked within an interdisciplinary team (medical informaticians and computer-user interaction specialists) to reach an enhanced prototype of admission and discharge modules. A final version, implemented in early 2014, included a multiple-step wizard to fulfill information requirements for both processes, including MedRec.

In the admission *module* (Figure 1), there is a step to verify ambulatory medications to create the best possible medication history (BPMH), by checking the patient's home medication (from EHR) with direct patient interviews.

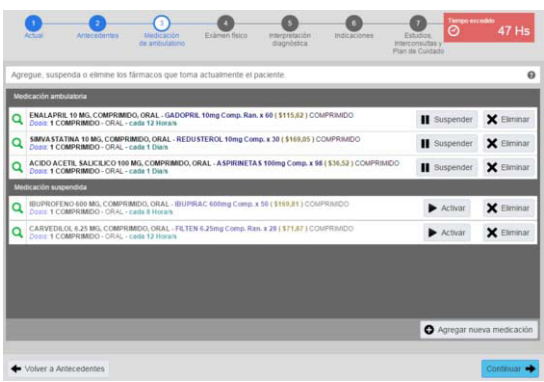

Figure 1- Admission module at EHR: the step to verify what medications the patient is taking, to create the best possible medication history.

Each prescription can be confirmed, paused, or deleted, and other drugs can be added if needed (paused medications can be reconfirmed afterwards, whereas deleted medications cannot). A subsequent step in the admissions module shows two columns to compare/reconcile the BMPH (left) and the admission medications (right), to reconcile differences. Similarly in the discharge module (Figure 2), there is a step to reconcile the prescriptions of the last day of hospitalization and the BPMH, to create the best possible medication discharge list (BPMDL). At this point, medications can be reconfirmed, paused or deleted. (See a brief tutorial at http://www.hospitalitaliano.org.ar/infomed/index.php?contenido=ver_curso.php&id_curso=17931#.VSVZpNyG_1Z)

Figure 2 - Discharge module at EHR: the step to compare medications during hospitalization (left) and ambulatory medications (right).

Results

During the 10 month period of the study, there were 37,471 hospitalizations of 27,375 patients and 205 participant physicians. With respect to patient demographics (See Table 1), the mean age of patients was 45.1 years (SD 28.57; SE 0.17). 57% of the patients were women (15,693). PS covered 41% of the inpatients (11,222); 93% of them had assigned PCPs. There were 1.36 hospitalizations per patient, most of them having just one (82%: 22,373 patients). The mean length of stay was 4.97 days (SD 8.71; SE 0.05). The most common admission and discharge diagnoses were childbirth, parturition (and C-section) and chemotherapy.

y.o.:years old; y: years

With respect to physician demographics, 205 physicians were in charge of both admission and discharge documents; 38% of them were women. The majority of physicians were from Internal Medicine, Orthopedics, Intensive Care, General Surgery and Obstetrics. Two thirds of the physicians were younger than 35 years old and 83% had been in the hospital less than 5 years (See Table 2).

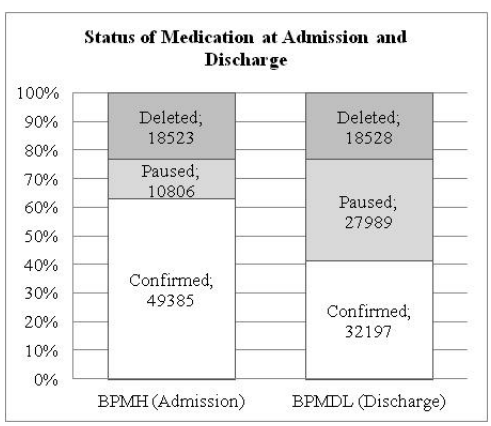

Figure 3 - Changes in medication status at transitions of care (admission and discharge)using the MedRec tool.

In the given period, there were 2.08 reconciled *medications* per hospitalization and 2.88 medications per patient. Concerning medication status, Figure 3 shows how many were confirmed, paused, or deleted at admission and discharge. The medications that were added to the BPMH using the MedRec tool were called "Newly Created" and represented just 7% of the total number of reconciled drugs (6,082 from 78,714). 58% of them were confirmed at admission (3,512), and the remaining 42% were paused or deleted (2,570). At discharge, just 44% of the newly created drugs were reconfirmed.

Discussion

The objective of this paper was to evaluate the use of an EHR-based reconciliation tool at admission and discharge. HIBA has an in-house developed Health Information System that works in both, inpatient and outpatient settings. Even though every HIBA inpatient treatment was documented using the CPOE, only PS affiliates would benefit from the electronic prescription at discharge. Electronic prescription is uncommon for other insurers and providers, who still use paper based systems. Otherwise, the MedRec electronic tool would be useful for the entire HIBA population, creating a BPMH/ BPMDL as accurately as possible.

Among the HIBA inpatient sample, almost 40% were over 60 years old. Unintended medication discrepancies are more frequent in elderly populations [22,23], related to their high number of comorbidities and medication usage, and several health profesionals' involvement [24]. The terminology data are still under further investigation, but preliminary analysis showed a significant rate of Cancer and Chemotherapy as some of the hospital's top diagnoses, in addition to maternal and neonatal health. Oncology patients are also at higher risk for medication omissions [25], and they would benefit from a MedRec program. Patients' regular length of stay was short (74% less than 5 days), according to the acute care profile of our hospital. Satisfactory MedRec could have an impact by reducing unexpected adverse drug events that could delay opportune discharge and also prevent early readmissions [26].

Our electronic MedRec tool was designed as a mandatory step in the admission and discharge process documentation. The data analysis indicated that most of these documents are completed by young and new hospital physicians, typical attributes of physicians-in-training involved in HIBA medical residency programs. Their academic training and professional responsabilities should not exclude proper supervision from experienced staff. It has been published that positive recognition programs enhance resident physician compliance with MedRec, when properly instructed and improvements are recognized publicly [27]. Although pharmacist MedRec interventions seem to be superior than other specialists [28,29], efforts should be made to engage every hospital clinician in the process, as multi-professional teams have shown better outcomes [30].

Considering the changes in medication status at transitions of care, we evidenced that it is more frequent to stop a previous prescription at discharge (pausing or deleting it) than validating it. Shortening the list could be a reasonable decision, taking into account that the most frequent unintended discrepancies would be by excess of unnecesary drugs, as shown in a previous study about medication list accuracy at HIBA [31]. Our research has limitations, some of them being related to the type of study (cross-sectional study); the database analysis (getting just part of the information from the process); and information from a single academic healthcare center, therefore the results cannot be generalized. On the other hand, thanks to this primary investigation, we are conducting new research projects to analyze prescription accuracy, and consequent impact in clinical outcomes like reported adverse drug events.

CPOE or electronic MedRec does not guarantee successful discrepancy resolution [32,33]. Many physicians may not feel prepared to perform such tasks with a compulsory tool, thus introducing new errors. We have been getting some helpdesk

incidents from PCPs asking for patients' missing chronic medication after discharge. Most of the incorrectly deleted medications were done by non-PCP physicians. We plan to conduct a mixed method study (qual-quan) to evaluate this unintended consequence. We consider it important not only to know the rate of such deletions but the ultimate reason of the deletion, to evaluate its extent and impact.

MedRec should be standardised and implemented in daily practice as a routine part of healthcare provision. EHR emerged as a useful booster for many health processes, including MedRec, but it should follow strong institutional policies and programs with regular feedback to check its outcomes.

Conclusion

This study analyzed how an EHR-based mandatory reconciliation tool at admission and discharge was used. The data showed a discontinuation dominance when editing the discharge list. Regarding the creation of the best possible medication history, our experience showed that the use of the MedRec tool would clean overloaded lists, but at the same time medications could be erroneously deleted .

Acknowledgments

This study was done under the Residency Program in Health Informatics at HIBA. We want to give special thanks to Dina Miguel, Gastón López and everyone at the Health Informatics Department who contributed to this paper. A special thanks to Patricia Yao who assisted us in proofreading this text.

Abstract

Improvements in medication management may lead to a reduction of preventable errors. Usability and user experience issues are common and related to achieving benefits of Electronic Medical Records (EMRs). This paper reports on a novel study that combines the lead user method with a safety engineering review to discover an innovative design for the medication management module in EMRs in primary care. Eight lead users were recruited that represented prescribers and clinical pharmacists with expertise in EMR design, evidence-based medicine, medication safety and medication research. Eight separate medication management module designs were prototyped and validated, one with each lead user. A parallel safety review of medicaiton management was completed. The findings were synthesized into a single common set of goals, activities and one interactive, visual prototype. The lead user method with safety review proved to be an effective way to elicit diverse user goals and synthesize them into a common design. The resulting design ideas focus on meeting the goals of quality, efficiency, safety, reducing the cognitive load on the user, and improving communication wih the patient and the care team. Design ideas are being adapted to an existing EMR product, providing areas for further work.

Keywords:

Electronic Medical Records; Electronic Prescription; User Interface Design; Safety; Lead User Method.

Introduction

There are an estimated 380,000 to 450,000 preventable Adverse Drug Events (ADEs) occurring annually in the United States [1]. Similarly, in Canada, there are an estimated 70,000 potentially preventable Adverse Events each year, 24% of which (approximately 16,800) are related to medication errors [2]. Electronic medication management systems are considered one way to help improve these errors.

Despite the potential of eHealth systems, such as Electronic Medical Records (EMRs), evidence of benefit has been inconsistent [3]. Designing better systems requires getting aspects "right" [4], including content, workflow, and user interfaces (UI). Designing effective UI in clinical information systems is challenging [5]. There are several UI elements to consider for clinical decision support, including: consistency, appropriate visualization, and presenting advice at the time of decision making in a way that matches clinical goals [6].

There is ongoing usability research in the area of clinical information systems; however, there appears to be a lack of design research to uncover innovative features to improve the safety and usability of the medication management within tools in systems such as EMRs. The Common User Interface project (CUI at http://www.cui.nhs.uk) was one key exception, although it focused on acute care and is no longer active.

Lead User Method

For this study, we looked for a user-centred method that promoted *abductive reasoning* about how a medication management system in an EMR *might be* designed. Design research can support this kind of abductive reasoning [7]. The lead user method is a user-centred design research method that promotes abductive reasoning by advanced users to develop product innovations [8], [9]. It fit the scope and scale of our study and we had previous experience with the method [10]. This method has been shown to lead to breakthrough products in domains outside [11], [12] and inside healthcare [13]. The goal of this method is to design innovative products [11] by engaging users who are ahead in their field of expertise and to discover their more extreme goals, needs, and how they consider meeting those needs [8], [14]. User selection is intentional and lead users are not meant to be representative: they are meant to be cutting edge in some way. The lead user method is a method that can fit into the software development lifecycle as an early requirements engineering tool and could be complemented by a number of additional approaches.

Study Objective

The objective of this study was to develop a novel method that worked with lead users to design a user interface for a medication management module for primary care EMRs.

Methods

We adapted the lead user method to clinical information systems to create a design of a medication management module for a primary care EMR. A novel contribution was to combine a safety review with the lead user design method.

Lead User Recruitment

Lead users considered for this study were: primary care clinicians using the EMR (e.g. family physicians, pharmacists in primary care) and individuals who had experience in designing EMRs or teaching or researching in the field of medication management/prescribing. Lead users were recruited through our existing network of Canadian collaborators. Potential participants received a recruitment letter and a consent form, and had an opportunity to ask questions before agreeing and signing the consent.

Lead User Design Sessions

Each lead user was invited to attend a series of three individual design sessions (held separately for each user). A research analyst (RA) was assigned to each lead user. The first semi-structured interview explored lead user's ideas related to why and how medications could be better managed through EMRs.

An interview guide was available for the RA to ensure that common workflows were considered (e.g., prescribing a new medication, renewing a medication, discontinuing a medication). Each lead user was encouraged to discuss workflows they considered important. In scope for the sessions was the use of EMRs in primary care for acute and chronic/ongoing medication management. Out of scope were other information systems such as hospital systems and personal health records. Sessions were recorded and transcribed for analysis. Goals, activities and visual design ideas were extracted from the interviews. Each lead user's requirements were translated into an interactive visual prototype using Axure RP Pro 7.0 (one prototype per lead user). The multidisciplinary research team reviewed interview findings as part of the analysis and the lead RA prototyped their user's requirements.

Follow up interviews with each lead user then focused on walking through their prototype to validate and refine their requirements. These sessions were recorded and the goals, activities, and prototype were revised between each session.

Safety Review

Safety is an important quality attribute of EMR systems. We integrated a safety review into our adaptation of the lead user method, combining two complementary hazard analysis methods: an adaptation of Failure Modes and Effects Analysis (FMEA) [15] and Hazop [16]. The methods are complementary since they provide opposite perspectives on hazard analysis. FMEA starts by enumerating accidental situations and successively identifies hazards, failure modes, and contributing events that may lead to these accidents. We used EMR/CPOE-related accident reports in the FDA's adverse event reporting system MAUDE [17] as well as input from lead users as the primary data source for defining an evidence-based set of prescribing-related accidents. Hazop analysis is performed in the opposite way; it starts with a given system design (or set of designs) and uses a systematic technique based on guidewords to identify potential workflow deviations that may lead to unsafe situations. In order to apply Hazop, we needed to define process model abstractions for the visual prototypes created as a result of the lead user design sessions. We used Keystroke Level Modeling (KLM) as the method for attaining this process abstraction [18]. The findings of both hazard analysis techniques were ranked with respect to severity, likelihood and detectability, and mitigations for the top-ranked hazards were incorporated into the final design of the medication management system.

Synthesis

The multidisciplinary research team (consisting of a physician, software engineer, computer science and health information science analysts) reviewed each lead user's design requirements and prototypes. In these synthesis sessions the analyst who worked with the lead user would act as their proxy, providing rationale for the specific design decisions. Using a combination of UI/Ux best practice and safety analysis feedback, preferred approaches were selected for the set of common goals. The synthesized requirements were captured in four ways: a goal model, an information model, an activity model, and an interactive visualization (in Axure RP Pro 7.0).

Ethics approval was received from the University of British Columbia's behavioural research ethics board (H13-01059).

Results

The full study took five months. Eight lead users were recruited for this study (nine were invited, one declined due to scheduling conflicts), none were lost to follow up during the study, and each contributed 3-5 hours of interviews. Collectively, the lead users had considerable relevant experience (Table 1) at regional, jurisdictional, national, and international levels. Each user was interviewed on average 3 times with additional email follow up with some for final validation. For each lead user, the analysis of the interviews included a list of goals and medication activities that should be supported in the EMR as well as a visual prototype validated by the lead user (analysis took two person weeks of effort per lead user).

Table 1 – Lead User Participant Characteristics

Average Age	50.5 years
Gender	4 Male / 4 Female
Family Physicians	6
Pharmacists	2
Average Years in Practice	22.5 years
Average Years using EMR	14.6 years
Involved in EMR Design	6
Involved in EMR / Rx research	6
Teaching or Academic Role	8

Safety Review

The safety review was approximately two person weeks of effort. FMEA-based hazard analysis identified 22 prescribing-related hazards, each of them associated with a list of potential failure modes and contributing factors. For example, the hazard "*no alert on harmful drug interaction*" was associated with "*alerting function expects data encoded in different coding system*" as one (of several) failure modes, and with "*hospital discharge medication encoded in different coding system*" as one (of many) contributing factors. Several assumptions were made to limit the scope of the analysis, e.g., hazards related to failed, lost or delayed communication of information over the network was declared out of scope for the analysis.

The Hazop-based analysis identified additional hazards that emerged from the specific UI design choices made in the visual prototypes. For example, one lead user design incorporated a patient-specific "news feed" that would alert the provider about any change in the patient's health process since her last visit with the provider (e.g., a patient had seen another provider who changed her medications). The source of the feed may be external, such as a health information exchange. The initial design did not differentiate between the state of "no news" and the state of the "news feed" (temporarily) being unavailable (an empty news display was used for both states). This design choice created a hazard associated with a provider confusing the state of "no news" with "no available news". Other hazards identified during Hazop analysis were related to the structure and timing of user processes (e.g., race conditions between the user entering and submitting her prescription and the decision support processing and raising alerts).

Synthesized Design:

Goals

Developing the synthesized design took four person weeks of effort. There were four main goals for an effective medication management system. The system should:

1. **Improve Quality of Medication Management**. This included reducing potential harm caused by medications through software and workflow design solutions.
2. **Improve Efficiency when Managing Medications**. This included supporting common workflows with elegant solutions that are quick for the users.
3. **Reduce Cognitive Load of the User.** This included ensuring that appropriate information is accessible when

making decisions throughout the encounter, and having the EMR data help when making choices.

4. **Improve Communication with the Patient and the Care Team.** This included providing features that help the user communicate about medications and changes clearly with the patient and the rest of the care team, even in EMRs that are not electronically connected.

Activities

Lead users described several activities that needed to be supported by the software. Through the research team's synthesis and review, the following activities were considered key (others were also prototyped).

Document and See Current Medications: users needed the ability to document a complete, single set of *current* medications for the patient. This included medications that were prescribed in the EMR as well as medications/supplements not prescribed or prescribed elsewhere (e.g., over the counter or prescribed by other providers). This included documenting instructions, indications, targets, expected end date, and current prescriber. The current medication list needed to show several pieces of additional information related to each medication, including: current instructions, current prescriber, prescription information, and presence of alerts related to that medication. Further, the list needed to be sorted/grouped by: alphabetical order, indications, prescriber, regular vs. PRN medications, and long-term vs. short-term medications.

Prescribe New Medications: Users wanted to ensure the system enabled them to prescribe new medications quickly and safely. When prescribing, users needed evidence-based guidance including support of medication choice and alerts for contraindications. Tools to support quick prescribing included leveraging recent medications (recent for the user) and user / clinic level medication favourites that would quickly populate all instructions and prescription information.

Represcribe Existing Medication(s): Many medications for chronic diseases are represcribed with their instructions unchanged. The system should support quick review of medications that need represcribing. For example, review: alerts, instructions, who the most recent prescriber is and when the prescription is expected to run out. The workflow should also allow for medications to be represcribed all at once or in batches (e.g. all antihypertensive medications, then all COPD medications), allowing for encounters to flow naturally.

Modify Medication Instructions: Over time, medication instructions may change for a patient. Medications may be titrated up or down. Modifying includes several options including: changing instructions (e.g., dose), stopping, discontinuing (with reason), and restarting a previously expired medication.

Receive and Review Decision Support (DS): Users simultaneously considered decision support to be important and often too intrusive. Lead users had several ideas where DS was needed and could be effective, including: selecting new medications, seeing the medication list, and reviewing or changing medications. There were several types of decision support that were desirable, including: medication selection support, drug alerts (e.g., interactions), and financial decision support (cost).

Lead users considered the issues related to dismissing alerts and how they may impact the patient in the future. An approach that was supported through the safety review was to allow alerts to be acknowledged but still be present/visible to the user (or another user) in the future.

Users also needed to seek information, such as requesting concise and trusted information about a medication (e.g., dose, indications, side effects) and suggesting medications or alternates in case of a contraindication.

Detailed Review of Current Medication(s): Several lead users were interested in a two-step process of review. A core set of information would always be available when seeing the current medication list (see above). A more detailed set of information would be available when the user wanted to review one or more medications. Details included the history of the instructions, specific prescriptions for the medication, and estimations of compliance. Reviewing a medication would provide information such as indicators/targets and would relate dosing history to effect; it would also provide details on alerts.

There were additional activities that were considered but not illustrated such as managing favorites.

Information Model

Figure 1 highlights the synthesized conceptual information model that is "medication centric". It includes core elements related to the medications, prescriptions, and related knowledge bases required to support medication activities. A medication can have multiple *instructions* over time and a medication can have zero to many *prescriptions*; this supports the need to review a medication's history effectively. Prescriptions can be collected in a *prescription order set* to allow for prescribing multiple medications for a patient within an encounter. Knowledge bases provide DS. To support efficiency, reusable medication *favourites* are available.

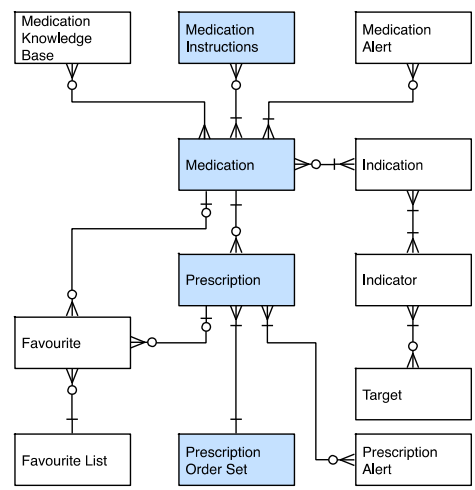

Figure 1 – The conceptual medication information model, based on the design requirements from lead users.

Synthesized Design: Visualization

The synthesized EMR UI prototype developed in this study captured the goals and activities of the lead users. The medication module UI design consists of four main panels: *current medication list*, *prescription panel, prescription order set*, and the *side panel* (Figure 2). The *EMR and patient banner* is included as misidentification is a significant safety hazard.

To enable many of the lead users' requirements, a *Medication Widget* was developed (Figure 3 and Figure 4). The widget has two states: closed and open. Each closed widget shows the medication, its current instructions, alerts (if present), and most recent prescribing information. A set of closed widgets forms the current medication list panel. The closed widget can be clicked to select the medication (Figure 5). The widget can be opened to allow the user to perform several actions on that medication: update instructions, review details (including alerts), review history, or discontinue the medication.

An *Add Medication Panel* is available when a new medication is being added. It provides the ability to add any medication (without needing to prescribe it) and provides decision support such as indications and interaction alerts. When searching for medications (by brand name or active ingredient), only active ingredient would be displayed to reduce cognitive load. Along with the formulary medications, favorite medications/prescriptions would be displayed for the user.

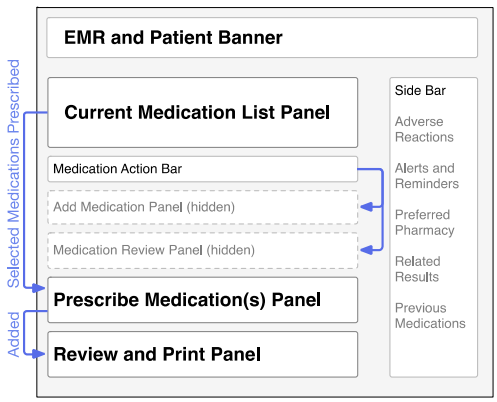

Figure 2 – Medication Management Module consists of the list of current medications, a prescribing panel, and a review and print panel.

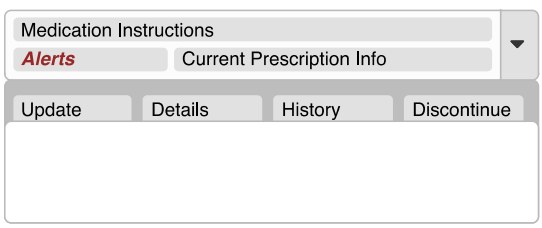

Figure 3 – The Medication Widget framework. Each widget has editing and review functionality embedded within.

Figure 4 – Example medication widet with ramipril as the current medication having one outstanding alert.

Design Comparison

The synthesized design generated through the lead user method was compared to two existing, open electronic medical records: OSCAR (www.oscarmcmaster.org) and openEMR (www.open-emr.org). We compared our design concepts to available online demo sites and user manual documentation for the equivalent core medication management functions. The new design appears to address several gaps that we saw in these products, for example: (1) a medication-centric information module (instead of a prescription module) with more coded content, (2) more robust decision support features such as suggesting alternatives, linking to indications, and having alerts visually available both when prescribing and when reviewing medications, (3) a detailed view of a medication that includes estimated adherence information and dose adjustments. However, the lead user synthesized design is currently more complex, which may prove to be challenging to new or typical users. This complexity needs to be considered and balanced when working with more typical users in busy clinics.

Discussion

This study was established to explore methods to develop innovative design solutions for medication management modules in primary care EMRs. The lead user method was adapted and applied to clinical information systems as further innovations in this area could result in significant improvements in care quality [19]. Our synthesis included the integration of a safety analysis and incorporated concepts from the literature, such as findings from the NHS' CUI project.

The lead user method was an effective way of developing the medication management module design relatively quickly. The lead user method was well received by expert clinicians. The visual validation allowed for refinement and a deeper discussion of each lead user's ideas. The synthesis by an interdisciplinary team reduced the risk of idiosyncratic design ideas from single, vocal users defining requirements in a committee or focus group. The users recommended features that were consistent with recommendations on CDSS design such as: consistency of design, appropriate visual presentation of data, use of coded data, and presenting advice at the time of decision making in a manner that matches to clinical goals [6]. Lead users have become unsolicited champions of the design, with at least half of the participants advocating for the design ideas in other EMRs or arranging opportunities to share the findings.

A challenge with this method was user selection. We found it important for lead users to have exposure to more than one EMR as well as been actively involved in the use of the EMR for research/teaching. This helped users to think outside of their own "EMR box".

Lead users thought of the EMR not just as an electronic version of the paper record, as can sometimes happen [20]. Rather, lead users considered the EMR as an interactive tool that could help with several goals: 1. Improved quality of care, 2. Improved efficiency of common workflows, 3. Reduced cognitive load, and 4. Improved communication. Decision support was an important aspect that was discussed in many areas of the medication management module and various activities. Users consistently agreed that decision support was important and they wanted it with minimal disruption. The strength of alerts was varied, depending on the workflow. Alerts would rarely stop the user from proceeding but display close to where they were active on screen (e.g., right below where they added a medication). Additional decision support such as access to knowledge bases with information on medication indications, side effects, and costs was important.

The synthesis activity allowed for integration of multiple perspectives, including the safety review and the literature. The early safety review allowed the analysis to consider lead user design ideas and potential impacts on safety and to incorporate safety elements into the design.

Limitations and Future Work

As a first phase in a design research project, further empirical evidence is needed to confirm that the design will lead to improvements in medication management. Future work is being considered along two paths: refining the methods and testing and refining the design. Three activities are proposed related to refinement and testing the design: (A) Usability testing of the prototypes with novel users. Usability testing would provide insight into the ease of use and intention to use. It was decided that the lead users would not be preferred for usability testing as (i) they were involved in the design and (ii) they were intentionally not representative of typical users. Comparative testing between multiple designs could be considered that could also show medication management errors that were

more or less likely to occur. (B) Expansion of the UI design to cover additional features. (C) Implementation of the design in an EMR. Feasibility of an implementation has been explored with the OSCAR EMR.

This study presents the results of adapting and applying the lead user method to designing aspects of clinical information systems. In this presented example, it was successful in developing a synthesized design for a medication management module for primary care EMRs. Safety was considered explicitly through the process to reduce risks to common medication errors. The resulting design included features to support quality, improve efficiency, reduce cognitive load, and improve communication. The synthesized design has been shared with OSCAR EMR and they are considering incorporating it into a future release. Future work will focus on incorporating user testing and integration into an EMR product.

High Override Rate for Opioid Drug-allergy Interaction Alerts: Current Trends and Recommendations for Future

Abstract

This study examined trends in drug-allergy interaction (DAI) alert overrides for opioid medications – the most commonly triggered alerts in the computerized provider order entry (CPOE). We conducted an observational analysis of the DAI opioid alerts triggered over the last decade (2004-2013, n=342,338) in two large academic hospitals in Boston (United States). We found an increasing rate of DAI alert overrides culminating in 89.7% in 2013. Allergic reactions included a high proportion (38.2%) of non-immune mediated opioid reactions (e.g. gastrointestinal upset). The DAI alert override rate was high for immune mediated (88.6%) and life threatening reactions (87.8%). Exact allergy-medication matches were overridden less frequently (about 70%) compared to non-exact matches within allergy groups (over 90%). About one-third of the alert override reasons pointed to irrelevant alerts (i.e."Patient has tolerated the medication before") and 44.9% were unknown. Those findings warrant further investigation into providers' reasons for high override rate. User interfaces should evolve to enable less interruptive and more accurate alerts to decrease alert fatigue.

Introduction

During the past several decades, computerized provider order entry (CPOE) systems have become a standard and are now required for each medication order in many countries (e.g. Meaningful Use requirement in the US) [1]. These systems are vital in providing better quality care and reducing medical errors [2]. One of the important features of CPOE systems is to help providers avoid prescribing medications their patients are allergic to. This is done through drug-allergy interaction (DAI) alerts in the electronic health records. However, constant interruptive DAI alerts might overwhelm providers and cause alert fatigue – a common phenomenon where clinicians become desensitized and tend to delay or miss the response to the alarms [3,4]. There is only limited evidence on the issues related to design and implementation of DAI alerts. This study examines the rates and reasons for DAI alert overrides for one of the most common types of alerts – opioid medications.

Background

Previous evidence suggests that DAI alerts involving opioid analgesics – or narcotics – are among the most common types of alerts encountered by health practitioners [5-7]. However, true immune mediated reactions to opioids are rare and most of the opioid related reactions are non-immune mediated sensitivities or opioid induced adverse events [8,9]. True immune mediated reactions to opioids are often IgE mediated or T-cell mediated and include hives, rash, severe hypotension, bronchospasm, angioedema, and anaphylaxis [8,9]. Non-immune mediated or mimic immune reactions to opioids are usually caused by endogenous histamine release from the mast cells and cause urticaria, flushing, sweating, vasodilation, and bronchoconstriction [8,9]. Such reactions to opioids are often idiosyncratic; they may or may not recur when patients take the same opioid medication again. Other non-immune mediated side effects include nausea/vomiting, constipation, sedation, delirium, respiratory depression, and urinary retention [8,9]. In CPOE systems, a significant proportion of opioid DAI alerts are not generated by an exact match between the allergy and prescribed medication (e.g. Codeine→Codeine), but rather represent a possible cross-reactivity association between medications in similar drug families (e.g. Codeine→Oxycodone). For these reasons, opioid DAI alerts are often non-specific and might potentially increase "alert fatigue" among providers.

In the past, studies have shown that DAI alerts are frequently overridden by providers [10]. For example, two previous studies from Brigham and Women's Hospital in Boston have identified an increasing DAI alerts override trend since introduction of CPOE system over two decades ago. The overall override rates increased from about 50% in 1995 [5] to about 80% in 2002 [6]. Also, studies have shown that providers are less likely to override allergic reactions generated by an exact prescribed medication-allergy match [6, 7]. In this paper, we aimed to follow-up on this previous work and provide an update on the trends in opioid DAI alert overrides in the past 10 years. Our goals were to: 1) describe

prevalence rate of opioid DAI alert overrides 2) examine the nature of opioid-related allergic reactions (immune mediated vs. non-immune mediated; potentially life threatening vs. non-life threatening) and 3) examine factors associated with providers' tendency to override opioid DAI alerts (exact drug-allergy match vs. cross reactivity vs. drug class).

Methods

For this observational study we used data from two large academic medical centers (Brigham and Women's Hospital and Massachusetts General Hospital) from Partners Healthcare, an integrated healthcare system in the Boston area. The data generated during 10 years (2004-2013) was extracted from Partners Enterprise-wide Allergy Repository (PEAR), a longitudinal allergy database shared within the Partners provider/hospital network [11].

In PEAR, medications are encoded using a combination of local (Partners Master Drug Dictionary) and proprietary (First Databank, Inc.™) terminologies. For each patient admitted, providers are required to enter allergy information or indicate no known allergies. The recorded information combines both patient and provider reported reactions. Allergic reactions are also entered as structured or unstructured (free text) information for each allergen. Every prescribed medication is automatically checked against possible allergies in PEAR.

Drug-allergy interaction alerts are triggered when a prescribed medication matches stored allergy information in either: 1) an exact manner (definite match between main medication ingredient and allergen, i.e. Codeine→Codeine) or 2) a probable manner (probable match where allergen matches allergy group of one or more of the prescribed medication ingredients, i.e. Codeine→Oxycodone). DAI alerts present the provider with several information components, including: the allergy; the allergen; nature of the allergy-allergen match (definite/probable); and patient's reaction(s), if known. When presented with the drug-allergy interaction alert, provider needs to decide whether to cancel the medication or to override the alert. Several structured dropdown options (i.e. "Patient has tolerated drug previously") are available for the override reason together with a free text option. Providers decisions and alert information are then stored in PEAR for future reference.

Some allergy-reaction combinations are overridden less often than others (i.e. allergies resulting in anaphylaxis vs. nausea). To account for this, our research team has classified allergic reaction information into two categories based on the literature review [8,9] and consultations with allergy specialists: 1) likely immune mediated (i.e. rash or anaphylaxis) or non-immune mediated (i.e. nausea or vomiting) and 2) potentially life threatening (i.e. anaphylaxis or bronchospasm) or non-life threatening (i.e. gastrointestinal upset or nausea).

All data including allergies, allergens, medication groups, and DAI alert override rates/reasons was kept and managed using Microsoft SQL Server Management Studio [12]. For aim 1 of this study, we queried the PEAR database and summarized the frequencies of opioid DAI alerts by year. Aim 2 was achieved by summarizing the frequencies of life threatening and immune-mediated allergic reactions. For aim 3, we first queried PEAR database for medication-allergen match type (definite/probable). We then compared the frequencies of DAI alert overrides for immune-mediated and life threatening reactions by allergy-medication match type. Statistical procedures included t-tests and chi-square tests, when appropriate. The statistical analysis and group comparisons were conducted in STATA v.11 [13]. Lastly, we summarized the frequencies of the DAI alerts override reasons recorded by the providers.

This study was approved by Partners Institutional Review Board (IRB).

Results

Aim 1: Describing the prevalence and rates of opioid DAI alert overrides

Overall, the PEAR database included about one million drug-allergy interaction alerts between 2004-2013. Of these alerts, 37.3% (n=355,179) were generated for the allergens that belong to "Analgesic Narcotic Agonists" drug class (e.g. Codeine, Oxycodone, Morphine, Hydromorphone, Tramadol). This was the most common class of drugs generating drug-allergy interaction alerts in our database. While the general override rate was 83.9% for all medications, opioid DAI alerts were overridden in 88.8% cases. Figure 1 presents the increasing proportion of overrides over the years, from 85.1% in 2003 to 89.7% in 2013. We also identified a constant increase in the overall number of opioid DAI alerts from 10,500 in 2004 to 55,048 in 2013.

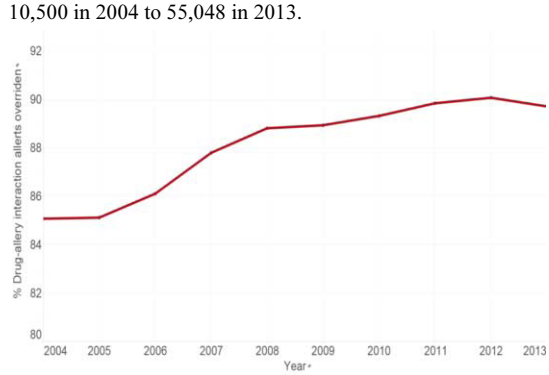

Figure 1 - Percentage of drug–allergy alert overrides for opioids over the last decade

Aim 2: Examining the nature of opioid-related allergic reactions

Table 1 presents the frequencies of the 15 most common opioid allergy reactions (covering 98% of all the reactions). Each reaction is also classified into likely immune mediated and potentially life threatening categories. 40.6% of the reactions were likely immune mediated (38.2% non-immune mediated, and the rest 21.1% unknown or not available) while only 10.4% were potentially life threatening.

Table 1 – Opioid allergy reactions

Reaction	Freq.*	%	Likely immune-mediated	Potentially life threatening
Hives or Rash	75,528	20.8	Yes	No
Gastrointestinal Upset	63,583	17.5	No	No

Itching	32,291	8.9	No	No
Mental Status Change	22,669	6.2	No	No
Vomiting	22,555	6.2	No	No
Nausea	21,820	6.0	No	No
Anaphylaxis	15,953	4.4	Yes	Yes
Shortness of Breath	5,175	1.4	Yes	Yes
Swelling (unspecified location)	4,725	1.3	Yes	No
Headaches	4,342	1.2	No	No
Angioedema	3,269	0.9	Yes	Yes
Hypotension	2,785	0.8	Yes	No
Bronchospasm or Wheezing	2,428	0.7	Yes	Yes
Seizures	1,829	0.5	No	Yes
Unknown/ unavailable	76,861	21.1	n/a	n/a
Total	**363,557**		**147,780**	**37,678**

*The total frequency of allergic reactions is larger than unique DAI alerts triggered since each unique DAI alert could have more than one associated reactions.

Aim 3: Examining factors associated with provider's tendency to override opioid drug-allergy interaction alerts

First, we examined whether there was a difference in override rates for previously reported immune mediated and life threatening reactions versus non-immune mediated and non-life threatening reactions. Although the DAI alerts override rates were statistically different, the clinical difference was only marginal for either immune mediated reactions (immune mediated overrides 88.6% vs. non-immune mediated overrides 89%, p<.001) and for the life threatening reactions (life threatening 87.8% overrides vs. non-life threatening 89% overrides, p<.001).

Further investigation revealed that majority of DAI alerts were triggered by the probable match medications (allergen matches the allergy group of one or more of the prescribed medication ingredients, 87% of DAI alerts) rather than definite match. To account for this, we conducted further comparisons based on allergy-medication match status.

We found that providers were significantly more likely to override probable matches for both immune mediated (90.7%) and non-immune mediated (91.3%) reactions whereas definite matches were overridden less frequently (72.4% immune mediated, 75.8% non-immune mediated). Similar differences (Table 2) were discovered based on life threatening reaction status which were the least overridden combination (69.9% overrides). All comparisons were statistically significant at p<.001.

In 44.9% of DAI alert overrides, we found no override reason entered by the practitioner (Table 3). Among the provided override reasons, 29% indicated previous tolerance or no allergy to the prescribed medication and 7.1% indicated that there was no reasonable alternative (provider will monitor for reaction). The remaining 17.2% of the reasons were presented as other free text with entries such as "OK with patient" or "Pain protocol". Since one-third of the cases were indicated as either previous tolerance or no existing allergy, we compared the rates of immune mediated and life threatening reactions override without those two override groups. Override trends (not shown) were similar to those presented in Table 2.

Table 2 – Drug-allergy interaction overrides by definite and probable allergen-medication matches

Reaction type	Allergy/ Medication match	Medication canceled N(%)	Alert Overridden N(%)	Overall N(%)
Immune mediated reactions to opioids				
Likely NON-immune mediated	Definite	5454 (24.2)	17103 (75.8)	22557 (6.4)
	Probable	11442 (8.7)	120290 (91.3)	131732 (37.1)
Likely immune mediated	Definite	4048 (27.6)	10634 (72.4)	14682 (4.1)
	Probable	10251 (9.3)	100196 (90.7)	110447 (31.1)
Unknown	Definite	2298 (26.1)	6514 (73.9)	8812 (2.5)
	Probable	6349 (9.5)	60600 (90.5)	66949 (18.8)
Life threatening reactions to opioids				
Likely NON-life threatening	Definite	8301 (25)	24945 (75)	33246 (9.4)
	Probable	18335 (8.8)	189961 (91.2)	208296 (58.6)
Likely life threatening	Definite	1194 (30.1)	2775 (69.9)	3969 (1.1)
	Probable	3317 (10)	29802 (90)	33119 (9.3)
Unknown	Definite	2305 (26.1)	6531 (73.9)	8836 (2.5)
	Probable	6390 (9.4)	61323 (90.6)	67713 (19.1)
Total		39842 (11.2)	315337 (88.8)	355179

Table 3 – Drug-allergy interaction alerts override reasons

Override reason	Freq.	%
Patient has tolerated drug previously	91,548	29.0
Patient reports no allergy	5,666	1.8
No reasonable alternative – will monitor for reaction	22,496	7.1
Unknown	141,437	44.9
Other (allows user to enter free text)	54,190	17.2
Overall	331,669	

Discussion

Our findings confirm a concerning trend of continuously increasing drug allergy alert overrides over the past few decades. Since the introduction of DAI alerts as a core feature of CPOE, the override rates increased from about 50% in 1995 [5], to about 80% in 2002 [6], culminating in the current rate of about 90% in 2013 in our study. We also identified an overall four-fold increase in the number of opioid DAI alerts over time. To our best knowledge, no major changes were made to the CPOE system during the study time period. This finding is consistent with the recent studies reporting a constant increase in the opioid drug prescription rates over time in inpatient and outpatient settings. For example, several recent studies have reported that opioid prescriptions increased as high as three-fold in the past two decades in the US [14-17]. It is possible that the increase in the DAI override rates is associated with an increase of opioid prescriptions. Also, opioid DAI alerts are the most common type of alerts, and providers might override more of them due to alert fatigue – a well-known phenomenon where providers become overwhelmed with the constant interruptive alerts and override more of them over time [3,4,10].

Further investigation into the nature of the opioid-related reactions has also reveled several further concerning trends. First, only about 40% of the indicated reactions were likely a result of immune-mediated processes (i.e. IgE mediated or T-cell mediated reactions such as anaphylaxis or rash). Another 40% of the reactions were likely opioid side effects, such as gastrointestinal upset or nausea and the remaining reactions were unknown or unavailable. In our study, both types of reactions were overridden in approximately 89% of the cases. Presenting accurate information has the potential to increase users buy-in to the system [18,19]. However, in our case, an inaccurate mix of allergy and side effects-related reaction information may have increased the rate of DAI alert overrides. In addition, providers might need to pay more attention to capturing reliable allergic reaction information to avoid further inconsistencies. Potentially, clinical decision support tools might help in identifying and presenting the non-immune mediated reactions differently, either at the point of allergic reaction entry by the provider or when the DAI alert is presented [19].

In an attempt to better understand providers' decision making when overriding DAI alerts, we also grouped reactions into potentially life threatening reactions versus non-life threatening reactions. Although only one-tenth of the reactions were potentially life threatening, we were surprised by the high rate of overrides. Here again, the high DAI override rates for life threatening and non-life threatening reactions were almost identical. This again underlines a critical need in decreasing the alert fatigue [4,7] and further exploration of users' experiences.

Another important aspect of our study was to examine the override rates by allergen-prescribed medication match. Similar to other reports [6], only about one-tenth of alerts were triggered by an exact match while the rest were triggered by probable matches of medication-allergy group. Not surprisingly, providers were significantly more likely to override probable matches, especially for non-immune mediated and non-life threatening reactions. Definite match allergy-medication combinations, especially those with life threatening reactions, were overridden the least, in about 70% of the cases. Still, the override rate was notably high and there is a need for further investigation, potentially using qualitative methods to better understand providers' reasons for overriding even the most alarming DAI alerts.

Finally, examining providers' reasons to override DAI alerts, we found that about one-third of the alerts were triggered for medications that patients have either previously tolerated or had no allergy to. Clearly, CPOE user interfaces must evolve to learn or negate medications patients have tolerated or had no allergy to in the past so providers are not inundated with alerts to previously tolerated medications [2]. Of note, we did not identify changes in DAI alert override patterns when we repeated the analysis without those categories. Another concerning trend was the lack of override reasons for about 45% of alerts. This finding raises several liability and ethical questions and warrants careful re-examination of the user interface to improve the capture and storage of DAI alert override reasons. Training of providers on importance of information captured by electronic health records might be one of the keys to this issue [20,21]. Finally, we also conducted some preliminary interviews with the providers to better understand why alerts are frequently overridden. This anecdotal evidence suggests that inpatient providers are reluctant to remove or otherwise change patients' allergies as they believe that this is a primary care provider's responsibility.

Limitations

This study is not without limitations. First, the analysis was limited to two large academic hospitals in Boston. In addition, different CPOE systems have different approaches to DAI alerting and use different medication vocabularies for drug-allergy interaction. Those factors might decrease the generalizability of our findings. Finally, our classification of immune mediated and life threatening opioid reaction is an estimation based on the captured patient reactions rather than a conclusive statement based on allergy tests.

Conclusions

This study examined trends in drug allergy interaction alerts for the most common trigger – opioid medications. Over the past decade, we found an increasing rate of DAI alert overrides culminating in a 90% rate. Allergic reaction information in our database included a high proportion (over 40%) of non-immune opioid reactions (e.g. gastrointestinal upset). The DAI override rate did not seem to differ significantly for immune mediated and life threatening reactions. The only factor contributing to the decrease in overrides was the nature of the DAI alert: definite allergy-medication matches were overridden less frequently compared to probable matches. Finally, about one-third of the alert override reasons pointed to the irrelevant alerts (i.e. "Patient has tolerated the medication before") and a significant proportion of DAI overrides were missing the override reason. Those findings warrant further investigation into providers' reasons for overriding alerts. It is also clear that user interfaces and drug-alerting algorithms should evolve to enable less interruptive and more accurate alerts to decrease alert fatigue.

Aknowledgments

This study is a part of a larger research project titled "Encoding and Processing Patient Allergy Information in EHRs" aimed at creating natural language processing tool for allergy information (R01HS022728-01).

Abstract

Decision support systems (DSSs) are recognized as important tools, capable of processing high volumes of data and increasing productivity. The usability of these tools affects their effectiveness. By evaluating the interactions between registered nurses (RNs) and the DSSs, this study explores how they impact RN decision-making. This study analyzed 24 months (2011-2012) of data collected in Brazil in two units of a large, public, urban hospital in São Paulo that uses a nurse documentation system with an embedded DSS based on NANDA-I. Using mixed effects logistic regression, this study analyzed the agreement between RNs and a DSS when selecting nursing diagnoses. Results suggest that the agreement is mediated by characteristics of the RNs (education and experience) as well as units and year of encounter. Surprisingly, disagreement between RN and DSS when selecting defining characteristics (DC) had positive effects on the odds of agreement on diagnoses. Our results suggest that DSSs support nurses' clinical decision making, but the nurse's clinical judgment is the mediating factor. More research is necessary.

Keywords:

Nursing Information System; NANDA-I; Nursing Diagnoses, Classification System; Behavioral Model.

Introduction

The Institute of Medicine compiled several reports that support the use of technology to improve the quality and the safety of healthcare [1-4]. Computers are able to structure information and communication, becoming an intellectual tool. In this context, decision support systems (DSSs) are recognized as important tools, capable of processing high volumes of data and increasing productivity. Nurse focused DSSs collect, store, process, retrieve, display and transmit information in real time to assist registered nurses (RNs) with their work.

Through the nursing process nurses continuously assess, diagnose, plan, intervene, and evaluate their patients. All the while, nurses document their steps. PROCEnf-USP (Electronic Documentation System of Nursing Process) is a DSS – a product of a project funded by the National Council of Scientific and Technological Development (CNPq), a Brazilian agency of the Ministry of Science and Technology, and by the University of São Paulo (USP). The project has three aims: to develop computer systems, to install them, and to evaluate them. The PROCEnf-USP was designed by a group of faculty, students, and nurses from the School of Nursing, the Informatics Department, and the University Hospital (HU) of the USP, Brazil. The PROCEnf-USP was implemented in the surgical and clinical units at UH of the University of São Paulo in 2006 [5].

The system offers the RN a set of questionnaires to guide the RN documentation when performing patient assessments. The questionnaire has drop down menus with answers. Using these answers, the system computes probabilities for defining characteristics (DC) and presents them to the nurse. The nurse responds by selecting the DCs deemed most important. Once again the system uses the nurse's input and computes a set of nursing diagnoses (Dx) that best fit the clinical scenario. In special instances, the responses at the assessment may trigger Dxs without triggering DCs. The algorithm is based on the International Nursing Diagnoses Classification (NANDA-I), [6] which is being embraced worldwide. The system therefore can influence the way nurses think about priorities and patient care [7].

Nurses prioritize a DC or Dx based on intrinsic nurse characteristics. The intrinsic characteristics of the nurse deemed as relevant contributors to the effectiveness and efficiency of an individual in the workplace are human capital characteristics, such as level of education and years of experience [3]. These assumptions predict that nurses who are more educated and with more years of experience make more accurate nursing diagnoses.

Using the Donabedian's [8] quality framework, quality is analyzed through a relationship between structures, processes, and outcomes. Kelley, Brandon, and Docherty [7] apply this framework to the study of the effect of electronic nursing documentation on the quality of patient outcomes (Figure 1). Patient health outcomes are thought to be derived from high quality processes (what is done by the nurse to the patient) and high quality structures (human capital, setting, and equipment used when caring for patients).

With that in mind, this study aims to test the usability of the PROCEnf-USP in clinical practice by evaluating the agreement between the RN and the DSS when selecting Dx. The overarching goal is to better understand how the system is used by the RNs to promote better RN decision-making, and consequently improve patient outcomes.

According to this model, the interaction between the RN and the DSS is a key process (Figure 1). Structural aspects affecting this interaction are the characteristics of the nurse and the environment where she practices. The model purports that although the NANDA-I DSS system may be highly accurate, it is only capable of impacting patient health outcomes through interventions mediated by the nurse [7]. When applying the model to the PROCEnf-USP, it suggests that the DSS calculates the most complete list of DC and Dx;

therefore presenting information that may not have been obvious to the nurse. The nurse then selects the DC and Dx deemed most important and continues on with the other parts of the nursing process.

Figure 1 – Donabedian according Kelley et al [8,9].

Materials and Methods

This study is a secondary data analysis of existing observational nurse documentation data collected at a large, public, urban hospital in São Paulo, Brazil between January 1, 2011 and December 31, 2012. The unit of analysis is the admission encounter (N=337, 056).

Using all 24 months, this study analyzed the effects of several RN characteristics on the agreement between the RN and the DSS when selecting a nursing diagnosis, given the assessment data documented by the RN. A generalized linear mixed effects model for binomial family (mixed effects logistic regression) was conducted to assess the odds of agreement given the variables in the model [10,11] (Table 1).

The outcome (dependent) variable was represented by a dichotomous variable created by combining the four possible options. Agreement = yes, when the diagnosis was calculated by the DSS and selected by the nurse OR when the diagnosis was not calculated by the DSS and not selected by the nurse. Disagreement = no, when the diagnosis was calculated by the DSS but not selected by the nurse OR when the diagnosis was not calculated by the DSS but it was selected by the RN.

There were 18 nurses who documented using PROCEnf-USP between 2011 and 2012. RN variables included in the model were: age, level of education, years working at the HU, experience with research, and hours of continuing education in the past year. In addition, type of clinic (medical or surgical) and patient assessment data were included in the model.

Patient data were represented in terms of defining characteristics (DC). Selection of key DCs is the gold standard for nursing diagnosis selection accuracy [12]. Dummy variables representing four combinations of agreement between the DSS and the nurse in the selection of key DCs were created. They represented (a) when the DC was calculated by the DSS and selected by the nurse (62.71%), (b) when the DC was calculated by the DSS but not selected by the nurse (12.68%), (c) when the DC was not calculated by DSS but it was selected by the nurse (23.05%), and (d) when the DC was not calculated by the DSS and was not selected by the nurse (1.57%).

Results

Results from the analysis of our model by year of encounter 2011 (N=166,061) and 2012 (N=170,995), as well as the analysis of both years combined suggest that agreement between the DSS and the nurses regarding the selection of a nursing diagnosis was statistically significant affected by the year of the encounter, the number of hours of continuing education a nurse received, the unit in which the nurse worked, and the nurse's decision-making regarding the selection of DC (Table 2). Agreement occurred in 73.48% (N=247,656) of the time.

The analysis of all 24 month combined is presented in Table 2. The odds of agreement between the DSS and RN when selecting a priority Dx decreased by 7.2% (IC 95%; 0.927-0.929) between 2011 and 2012. The odds increased by 1.3% (IC 95%; 1.001-1.026) for each hour of continuing education the nurse received in the past 12 months, and by 12.8% (IC 95%; 1.071-1.188) if the RN was working at surgical unit compared with working at medical unit.

The odds of agreement between the DSS and the RN when selecting a Dx was also affected by the agreement between the RN and the PROCEnf-USP when selecting DCs. Compared with agreement characterized as 'DC calculated by DSS and selected by the RN,' 'DC calculated by the DSS but not selected by the RN' increased the odds of agreement in the selection of the Dx 37.4 times (IC 95%; 34.56-40.58), and 'DC not calculated by the DSS but selected by the RN' increased the agreement by a third or 36.8 % (IC 95%; 1.33-1.40).

In contrast, compared with agreement characterized as 'DC calculated by DSS and selected by the RN', 'DC not calculated by the DSS and not selected by the RN' reduced the odds of agreement when selecting a priority nursing diagnosis by 99.4% (IC 95%; 0.005-0.008).

Level of education (BSN vs. MS/PhD), participation in research (Yes/No), years of experience at the HU, and age were not significant, and therefore did not affect the odds of agreement between the RN and the DSS when selecting Dx (Table 2).

Discussion

The most important finding of this study is that the agreement between the decision support system (DSS) and the registered nurse (RN) when selecting a nursing diagnosis (Dx) is dependent on the agreement between RN and DSS when selecting defining characteristics (DC), but not in the way it was anticipated. We expected that the agreement in the selection of Dx was dependent on the "literal" agreement between the DSS and RN regarding the selection of defining characteristics (DC). However, we found that varying degrees of agreement regarding DC may provide agreement between the RN and DSS when selecting a Dx.

As described in the methods, patient data were represented in the model through DC. There are four possible combinations of agreement between the RN and DSS on the selection of DC. One combination can be characterized as being the true agreement (i.e. when the DSS calculates a DC and the RN selects it). Two combinations are in fact disagreements with a 50:50 split between the DSS and the RN and one combination ,a false agreement, neither calculates nor selects a DC.

These variations in agreement occur when the RN completes the nursing assessment phase of the encounter, but does not complete the documentation thoroughly. Since the documentation is the basis for the calculation of DCs, the system is bound by the information inputted. Therefore, when selecting or ignoring a DC, nurses are editing the data from the assessment phase.

For instance, in 23.05% of the admission cases between 2011 and 2012, the RN selected a DC that was not calculated by the PROCEnf-USP, but ultimately agreed with the system when selecting a Dx. In fact, in these instances there was an increase of 36.8% in agreement between DSS and the RN in the selection of Dx. This supports the idea that the RN is the mediator for nursing diagnostic decision-making. The RN may skip the step of entering the data, bypassing the NANDA-I algorithm, and going straight to the diagnosis.

Conversely, in 12.68% of the admission encounters between 2011 and 2012, the RNs did not select a DC calculated by PROCEnf-USP, but ultimately agreed with the system in the selection of a Dx. In fact, in these instances the odds of agreement increased by a large margin, 37 times. By ignoring a DC calculated by the DSS but agreeing with the DSS on the priority diagnosis, the nurse is suggesting that the DC calculated by the DSS is less important that it appears. It is possible that the RN is providing contextual information that was not captured in the documentation.

In 1.57% of the admission encounters between 2011 and 2012, the RN did not select and the DSS did not calculate a DC. In those instances there was a decrease in agreement by 99.4%. The algorithm is designed to allow the DSS to bypass the DC and directly suggest a Dx given dichotomous assessment questions. It is possible that in these instances, the DSS did not calculate a DC, but suggested a Dx. Since the DSS did not calculate the DC, the RN was less like to select it on their own, and consequently less likely to agree with the Dx calculated.

When the nurse adds information or ignores information, the RN's decisions are influenced by something other than the DC. The model suggests that RNs' human capital characteristics, such as experience working at that unit and hours of continuing education may have had an impact. Our results support that. For each additional hour of continuous education a nurse received in the past 12 month, there was an increase of 1.3% in the odds of agreement between the RN and DSS when selecting a nursing diagnosis. At University Hospital, nurses received a mean of 36.11 hours per year of continued education. Although some of the topics included informatics, nursing taxonomy, and nursing documentation, most topics were not specific for DSS usage. They provided or reinforced clinical knowledge, which is essential for clinical reasoning development [13].

The odds of agreement was 12.8% higher in the surgical unit than in the medical unit. Although this finding appears to be positive, it is of concern. Patient turnover is higher in the surgical unit than it is in the medical ward; the average length of stay is shorter, but patient profiles are very similar. Therefore RNs are required to work faster during the assessment. They have less time to be in contact with their patients, but are experiencing similar clinical conditions. It is possible that RNs in the surgical units are thinking that they know a priori what their patients' problems are. The RNs at the surgical unit may be collecting patterns of patient data, inputting them in the DSS, and then agreeing with the system. In 2012 the odds of agreement between the RN and the DSS decreased by 7.2% when compared to 2011. This may be a result of inexperience, given that in 2012 the medical unit had four new RNs who transferred from other units of HU [14].

Conclusion

The agreement between the RN and the DSS when selecting defining characteristics (DC) significantly affects the odds of agreement between the RN and the DSS when selecting nursing diagnoses (Dx), but not as anticipated. The system offers the structure for nurses to collect data and analyze information by offering opportunities for nurses to accept or reject DC and Dx. These interactions between the RN and DSS are mediated by the RN characteristics; such as years of experience and continuing education. These characteristics are proxies for clinical reasoning and clinical judgment. Systems such as PROCEnf-USP are especially helpful to students, new nurses, or expert nurses in a new environment. Future studies should compare the documentation of the novice RNs and students to those of more experienced RNs. These results along with future studies in this field will contribute to the refinement of the Dx classification based on real clinical environment evidences.

Patient Safety in Critical Care Unit: Development of a Nursing Quality Indicator System

Camila S.P. Lima[a], Sayonara F.F. Barbosa[a]

[a] *Federal University of Santa Catarina (UFSC), Brazil.*

Abstract

This is a methodological study and technological production that aims to describe the development of a computerized system of nursing care quality indicators for the Intensive Care Unit. The study population consisted of a systems analyst and fifteen critical care nurses. For the development of the system we adopted some of the best practices of the Unified Process methodology using the Unified Modeling Language and the programming language Java Enterprise Edition 7. The system consists of an access menu with the following functions: Home (presents general information), New Record (records the indicator), Record (record search), Census (add information and indicators of the patient), Report (generates report of the indicators) and Annex (accesses the Braden Scale). This information system allows for measurement of the quality of nursing care and to evaluate patient safety in intensive care unit by monitoring quality indicators in nursing.

Keywords:
Nursing Informatics; Quality Indicators; Intensive Care Unit.

Introduction

Applications of information technology in nursing aim for knowledge systematization to quantify management and nursing care [1]. In the area of patient safety, a Health Information System can be developed in order to reduce the occurrence of adverse events by improving the quality of care practice using quality indicators, which are screening tools for the purpose of identifying potential areas concerning clinical care quality. Quality indicators also reflect the quality of care in hospitals and should bring to light what is usually invisible in nursing, rather than what is visible only when absent [2,3]. Therefore, it is essential to control indicators to improve clinical care and to achieve the desired results. Among the various health care scenarios, the Intensive Care Unit (ICU) stands out as an environment where the focus on patient safety should be strongly present [4]. Here, aspects such as complexity of care, the severity of the patient's disease, large amount of drugs and invasive devices, and the multiple procedures performed, make the ICU environment quite vulnerable to adverse events. It raises the question: how to develop a system to register and analyze quality indicators specific for critical care nursing? It is believed that the use of computerized tools can contribute to obtaining desirable results related to health practices, providing patient safety and decreasing the occurrence of adverse events. This study aims to describe the development of a computerized Quality Indicators Nursing System (SIQenf) for an Adult Intensive Care Unit.

Methods

This is a methodological study and technological production designed for the ICU of a university hospital in southern Brazil. It had the participation of a systems analyst and fifteen nurses in intensive care. The inclusion criteria of the study participants were, a) to be a critical care nurse to validate quality indicators and their related factors and also to use the computerized system; b) Systems Analyst - graduate in Computer Science or Information Systems. The period of data collection (system development period) was from February to April 2014. Data were entered into the system by the nurses that accepted to participate in the study. They were registered and received a username and password, maintaining the anonymity of the participants. For the development of the system, some of the best practices of the Unified Process methodology were used [5]. This process is divided into four phases: inception, elaboration, construction and transition. The inception phase identified the requirements that were described in terms of use cases, and presented which features and functions are desirable for each class of users [6, 7]. Use cases can be represented by Use Case Diagrams (Figure 1).

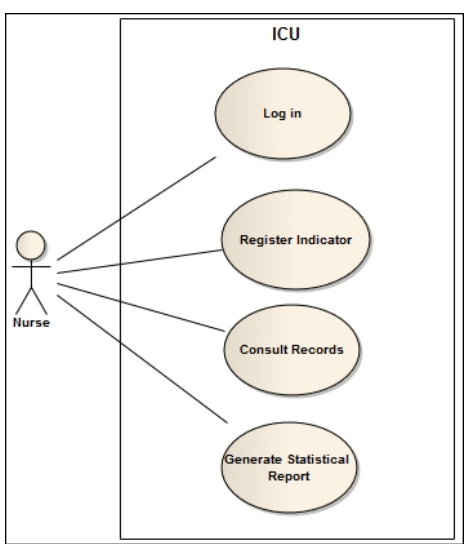

Figure 1- SIQenf use case diagram

The content validation of quality indicators in nursing was performed at this phase and also its related factors (causes) with the ICU nurses who participated in the study. Eight indicators were selected: 1) Fall Incidence; 2)Incidence of non-planned tracheal extubation; 3)Loss of Oro / Nasogastroenteral tube; 4) Incidence of Pressure Ulcer; 5) Medication error; 6) Near miss related to Drug Administration; 7) Phlebitis Incidence and; 8) Lost of Central

Venous Catheter. After the definition of the desired indicators, the participants also identified 73 related factors (causes) of the indicators. These indicators were selected because they are used in various health organizations and because research shows the incidence rates of them in intensive care areas [8-15].

In the elaboration phase, the system was modeled using the Unified Modeling Language (UML). In the construction phase the software components that will make each use case operational for the end users were developed. And in the last phase of transition, a training was carried out with all the nurses of the study, enabling them to use the computerized system. For the development of the system the object-oriented programming language Java Enterprise Edition 7 object (Java EE 7) was used. An Apache Tomcat server was used for the Java application and we also used the Java Server Faces framework (JSF) for the development of the web interface. As a Database Management System (DBMS), a relational open source MySQL version 5.6 was chosen. The study was approved by the Ethics Committee of the University where the study was conducted.

Results

The system was named SIQenf (Nursing Quality Indicator System) and was developed for use in an intensive care unit. The SIQenf aims to support the healthcare practice, allowing the measurement of quality of patient care through the use of quality indicators, and to assist in management and research.

System Functional Characteristics

Login screen

Each nurse that participated in the study received an username and password. The system is accessed through the Internet address: giate.ufsc.br/SIQenf.

Home Screen

The System Home screen consists of a menu at the top of the screen that has the following functions: Home, New Record, Record, Census Report, Annex and Exit.

New Entry screen

The SIQenf allows nurses to record the quality in nursing indicators (Figure 2) and its related factors (causes), selected from among eight indicators: (1) Fall Incidence; (2) Incidence of unplanned extubation of endotracheal cannula; (3) Incidence of unplanned Oro/Nasogastroenteral tube removal; (4) Incidence of Ulcer Pressure; (5) Medication error; (6) Near miss Drug Administration; (7) Incidence of Phlebitis and; (8) Unplanned retrieval of Venous Catheter Central.

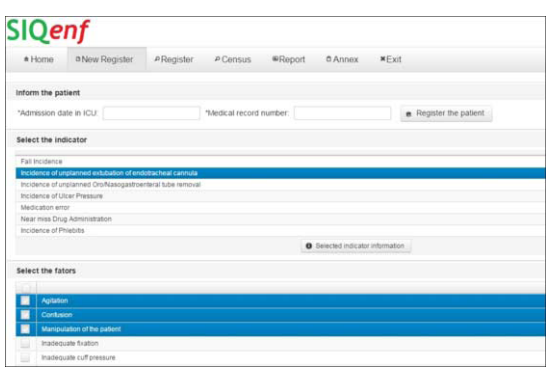

Figure 2 – New registration screen

By accessing this screen, nurses can view the indicators recorded on the current date. The "Filter Time" function reports the desired period and search the recorded indicators.

Census screen

To calculate the indicator it is necessary to insert a new census, i.e., the daily number of hospitalized patients, the number of intubated patients, the number of patients with oro/nasogastroenteral tubes, the number of patients with a risk for ulcer pressure, the number of patients with peripheral venous access and the number of patients with central venous catheters.

Report Screen

On this screen it is possible to generate the general report indicators (Figure 3), which is available in Portable Document Format (PDF), where the value of all indicators is calculated using their respective formulas, and provides the index (%) and graph of each indicator in the selected period. On this screen it is also possible to select individual report indicators, and this report will show the definition of the indicator, its formula, and its value in the period.

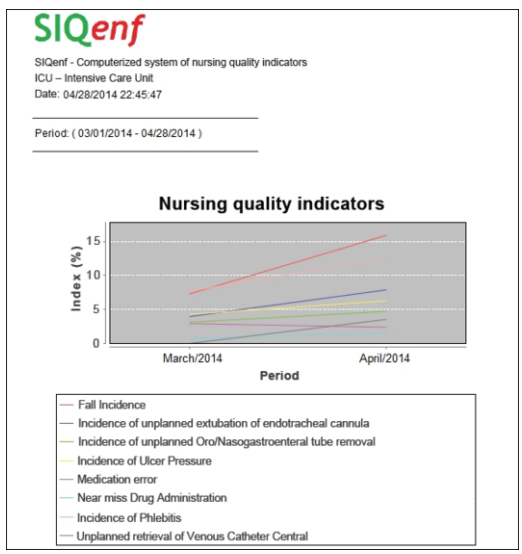

Figure 3 – General Indicators Report

Annex Screen

In this screen it is possible to download the Braden Scale, which must be used daily in the ICU to assess the risk of pressure ulcer development. This scale has a maximum score of 23 and a minimum of 6 points. It evaluates the following aspects: sensory perception, moisture, physical activity, mobility, nutrition, and friction and shear [16]. In the system a Braden score $\leq$ 16 was adopted for risk of development of ulcer pressure.

Discussion

SIQenf was developed in order to facilitate the measurement of quality and evaluation of patient safety in intensive care, since the indicators allow us to measure the level of health actions.

The idea of developing a computerized system of indicators rather than a manual system emerged in order to facilitate the management of nursing care, since the computer facilitates the integration of data, information and knowledge [17]. It

represents a resource to facilitate nursing registration, making it faster and more accurate, providing nursing and other professionals updated and reliable information, and has the potential to transform the quality of care and establish links between nursing care and results for the patients [18-19]. There are a significant number of studies, predominantly international, seeking information technology solutions to improve patient safety and to bring this issue to the area of intensive care. Research shows there are a high number of errors and adverse events in the ICU, and emphasizes the importance of assessing nursing care in this scenario [20-22].

Studies have assessed the quality of care and patient safety in the ICU through nursing quality indicators, where the incidence of medication errors, loss of nasogastroenteral probe, loss of central venous catheter and incidence of pressure ulcers were highlighted, however these surveys were developed using manual systems for the analysis of indicators [23-25]. In Brazil, the number of studies using computerized systems for detecting adverse events and evaluation indicators is still low. As an example, one study described the steps of building a computerized system for managing nursing care indicators of the Hospital São Paulo, using the following indicators: incidence of unplanned extubation, hypothermia, skin lesions, loss of urinary catheter, loss of central venous catheters, peripheral venous catheters loss, loss of drain tube, loss of the gastrointestinal tract tube, patient falls and pressure ulcers [26].

It can be observed that most information systems in the patient safety area focus on reporting events and to improve the safety of the patient, it should go beyond the registration report and use, and therefore identify data security risks, develop interventions to mitigate these risks, and evaluate whether interventions have reduced or prevented the damage [27].

The use of SIQenf can make it possible to detect adverse events, to record and analyze the quality indicators, as well as the major factors that are involved and that contributed to their occurrence. Thus, in the future preventive measures may be applied to minimize or even reduce the incidence of these indicators in the intensive care unit, through training, continuing education and safe interventions based on scientific evidence.

Conclusion

The use of information technology by nurses has been an increasingly constant practice, in clinical environments, management, teaching, or research. This integration of information technology and nursing facilitates the management of health information and contributes to the quality of patient care. On this basis, this paper describes the development of a computerized system of Nursing Quality Indicators (SIQenf) for the ICU, which supports the nursing care practice, which can measure the quality of care and evaluate patient safety through the detection of adverse events and monitoring quality indicators in nursing. It is believed, however, that SIQenf is more than a tool for reporting events, as it can contribute to the promotion of quality and strengthening patient safety in the ICU. It records and calculates the indicators and their related factors (causes), making it possible to understand the main problems related to patient safety in intensive care and make interventions to decrease these problems, as well as help in the search for solutions and excellence in nursing care. In addition, it is also possible through the reports to identify the main incident indicators according to the period and to compare them with other ICU indicators. For future work, this system will undergo an evaluation period of ergonomic criteria and usability, and will subsequently be implemented in the ICU for which it was developed.

Pre-Implementation Study of a Nursing e-Chart: How Nurses Use Their Time

Maria B. Schachner[a], Francisco J. Recondo[b], Janine A. Sommer[b], Zulma A. González[b], Gabriela M. García[b], Daniel R. Luna[b], Sonia E. Benítez[b]

[a] *Nurse Department of Hospital Italiano de Buenos Aires*
[b] *Department of Health Informatics de Buenos Aires*

Abstract

In clinical practice, nurses perform different activities that exceed direct care of patients, and influence workload and time administration among different tasks. When implementing changes in an electronic nursing record, it is important to measure how it affects the time committed to documentation. The objective of this study was to determine the time dedicated to different activities, including those related to electronic documentation prior to implementing a redesigned nurse chart in an Electronic Health Record at the Hospital Italiano de Buenos Aires. An observational work sampling study was performed. Nursing activities observed were categorized as direct care, indirect care, support, non-patient related, and personal activities. During the study, 74 nurses were observed and 2,418 observations were made in the Intensive Care Unit (32.22%), the Intermediate Care Unit (29.57%), and the General Care Unit (38.21%). Nurses' activities included 37.40% of direct care, 41.18% of indirect care, 0.43% support tasks, 11.14% non-related to patient tasks, and 9.77% personal activities. The results allow for the estimation of the impact of a nursing e-chart on nurses' activities, workflow and patient care.

Keywords:

Work sampling study; Time and motion study; Non-direct care; Indirect care; Nursing workload; EHR use; EHR documentation.

Introduction

The shortage of nurses is a growing problem, and it is estimated that in the next few years the problem will intensify [1]. The existence of nursing activities and factors that are not related with direct patient care is known. Several authors have pointed out that the time devoted to these activities impact the nurses' workload [2–4]. In addition, according to Myny et al. [5], there are still doubts regarding which of these indirect patient care activities are perceived by nurses as part of their work responsibilities. Information technology could be leveraged to solve this problem through multiple implementations that take into account specific nurses' needs. There is no consensus in the literature on how the implementation of an Electronic Health Record (EHR) system may affect the efficient use of time. Several studies show a reduction in nursing documentation time [2,4], while others show that the time gained due to new functionalities in the EHR is lost. According to nurses, informed implementation of the new EHR system reduces communication with physicians, generating mistrust on certain prescriptions, which requires constant re-confirmation, leading to an increase in associated documentation time [6]. Consequently, this results in a lack of nursing staff, endangering work efficiency and generating a rise in hospital costs [7]. Given the impact on time standards of nursing care and human resources management, data regarding nursing time dedicated to different activities is crucial [8]. This information is necessary to evaluate changes in nursing practice after the implementation of a new system, and is decisive in evaluating its efficacy [9]. In order to measure both work and time, different techniques exist to generate standards, "time and motion studies", and "work sampling". The selection of these techniques will depend on the precision and nature of the object in study. These types of studies have been done to describe and evaluate the impact of health care professional activities, including physicians [10], pharmacists [11,12], and nursing professionals [13]. In the context of an implementation of a redesigned electronic nursing record at Hospital Italiano de Buenos Aires (HIBA), the objective of this article is to determine the time needed for nurses to do specific activities, including those related to electronic documentation prior to implementation.

Materials and Methods

Setting

HIBA is an academic tertiary level hospital founded in 1853. It belongs to a nonprofit healthcare network including 25 ambulatory clinics and 150 outpatient offices in Buenos Aires, Argentina. The infrastructure includes 750 beds (200 for critical care), 800 home care beds, and 41 operating rooms. There are 2,800 physicians, 2,800 non-physician healthcare professionals, and 1,900 individuals in administrative services and management. During 2013-2014 there were approximately 45,000 discharges, 45,000 surgical procedures (50% of which were ambulatory), and 3 million visits. Since 1998, HIBA has gradually developed and implemented an "in house" Health Information System (HIS) that handles medical and administrative information from point of capture to analysis. The HIS includes a single, modular, problem-oriented, and patient-centered electronic health record (EHR). The EHR, named ITALICA, allows for the recording of patient care at different levels (outpatient, inpatient, emergency, and home care). ITALICA also enables complementary studies, drug prescriptions, and results display that includes the storage and transmission pictures system (PACS - Picture archiving and communication system). In recent years, the nurse chart evolved from paper to the computerized system. The first phase was digitized paper

documents, but in 2010 the first version of the electronic nursing record was embedded in the EHR, consisting of sections of structured data entry, medication administration, fluid balance, vital signs and a free-text area where nurses record narrative observations. Two years later, the system was updated to a version organized by sections according to nursing process, including planning of nursing interventions (but not nursing diagnosis). Currently, the electronic nurse chart is structured in four sections independent of each other: Assessment, Planning, Implementation, and Evaluation. Different sections allow nurses to record patient care following the logic of nursing processes, or skip to any section without completing the others.

For the pilot, we chose three representative sectors: the Adult Intensive Care Unit (ICU), the Adult Intermediate Care Unit (IMCU), and the Adult General Care Unit (GCU). The ICU has 38 beds allocated in three areas, according to the severity and therapeutic requirement of the patient. The nurse:patient ratio is 1:2, and there are 108 nurses allocated to the different shifts. The IMCU has 28 beds, the nurse:patient ratio is 1:3, and the total number of nurses is 58. The GCU has 44 beds; it is a medical-surgical unit, with a nurse:patient ratio of 1:8, and 32 nurses are distributed across the different shifts.

Design

This study was an observational descriptive work sampling. Data collection was made through observations, and work samples were made following the steps proposed in the literature [7,14]. The task consisted of observing a work sample of nurses, and describing the activities performed as well as determining the time cost of those activities.

After the approval of the project, the task categories and the specifics activities were determined. After a literature review [9,15–17], the categories were agreed on with the Chief of Nursing Department (CND). The categories chosen are direct care, indirect care, support activities, non-patient related activities, and personal activities.

***Direct care*:** The activities near a patient's bed, including admission, anamnesis (medical history), comfort, emotional support, and education, among others.

***Indirect care*:** Documenting on paper or EHR, information exchange on handoffs, pharmaceutical preparations, and supplies for procedures typify this category.

Support activities: Interdepartmental activities, scheduled training, and coaching other nurses are examples of this kind of activity.

***Non-patient related activities (NPRA)*:** Activities associated with equipment search, arranging the unit, performing claims to suppliers, use of computers for non-patient related tasks, changing the patient to another bed within the same unit, and the "waiting time" to perform other tasks.

Personal activities: These activities include breakfast/lunch breaks, social interaction, and non-patient related conversations.

Three trained observers collected the data using a worksheet. The CND estimated the percentages of time spent on each category. The use of the EHR (or EHR documentation) was set to 15% [16]. The time duration analysis included mean, standard deviation (SD), minimum (Min), and maximum (Max).

Results

From November 17 to December 5, 2014, 2,418 observations were made. The ICU had 32.22% observations, the IMCU had 29.57%, and the GCU 38.21%. Seventy-four nurses were observed, 82% of whom were women, with mean age 37.56 years old (SD 9.46), and the mean seniority was 10.37 years (SD 8.95). Overall, the nurses' activities included 37.40% of direct care, 41.18% of indirect care, 0.43% support tasks, 11.14% non-patient related tasks, and 9.77% personal activities. The following tables show mean, standard deviation, minimum and maximum values for percentages from different observations, differentiated per sector and categories.

Table 1 shows the ICU data, where the direct care activities represent 34.55%, and EHR activities are 23.79% of the total.

Table 1 - Intensive care unit activities

%	Direct care	Indirect care	Support activities	NPRA	Personal activities	EHR use
Mean	34.55	44.51	0.00	13.14	7.80	23.79
SD	1.49	2.63	0.00	2.25	1.67	3.65
Min	32.69	41.94	0.00	9.93	5.77	19.88
Max	36.77	48.94	0.00	16.03	9.62	29.08
Estimated	35.00	30.00	20.00	5.00	10.00	15.00

The next table (Table 2) shows the IMCU data, where the direct care activities increase to 38%, and EHR activities are 18.26%.

Table 2- Intermediate care unit activities

%	Direct care	Indirect care	Support activities	NPRA	Personal activities	EHR use
Mean	38.61	36.79	0.14	10.69	13.77	18.26
SD	5.22	5.09	0.32	3.65	4.25	2.93
Min	34.44	30.82	0.00	6.34	8.89	15.23
Max	47.41	44.37	0.71	14.57	20.55	21.48
Estimated	40.00	30.00	15.00	10.00	5.00	15.00

The last table (Table 3) presents GCU unit data. Here, direct care activities are 39.05%, and EHR activities are 19.97%.

Table 3- General care unit activities

%	Direct care	Indirect care	Support activities	NPRA	Personal activities	EHR use
Mean	39.05	42.25	1.14	9.59	7.74	19.97
SD	7.51	2.68	1.06	3.32	3.32	2.17
Min	27.32	37.64	0.00	4.59	5.10	17.06
Max	46.63	44.33	2.06	12.89	13.40	23.12
Estimated	30.00	30.00	10.00	20.00	10.00	15.00

The following figures show the variations along the period of study. Figure 1 corresponds to the ICU. EHR documentation was the activity with the most fluctuation. At the beginning, 19.88% of the activities where related to the EHR, while at the end, these activities increased to 29.08%:

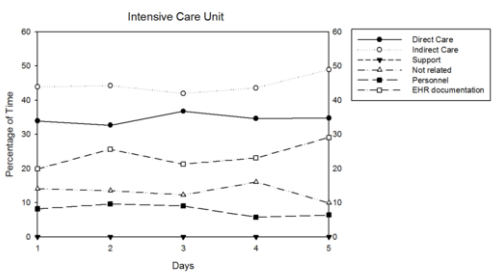

Figure 1- Observations at ICU during the study

In the IMCU (see Figure 2), all activities had large variations along the evaluation period, but none of them had big differences comparing the beginning and the end of the study.

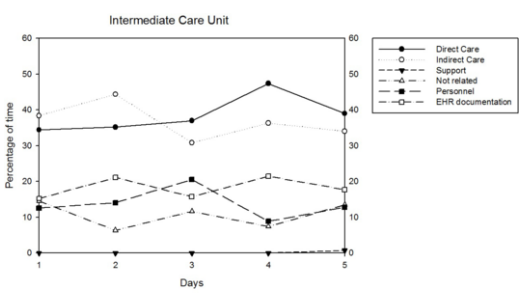

Figure 2- Observations at IMCU during the study

In the GCU, the direct care activities were found to be 27.32% at the beginning, and ended at 46.63%. Other categories did not have important disparities (See Figure 3).

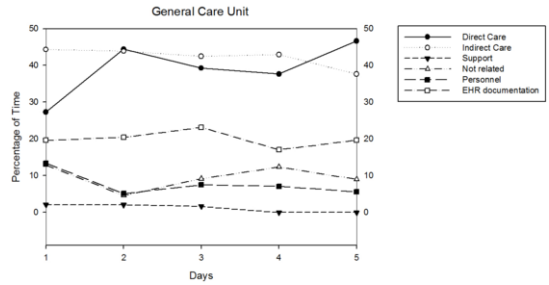

Figure 3 - Observations at GCU during the study

Discussion

In this pilot study, we evaluated how nurses use their time in the pre-implementation phase of redesigning a nursing e-chart. As part of the pre-implementation, we inquired about the nurses' staff expectations regarding implementation, and one of the main issues was the time it would take to complete the nurse record, which motivated the present work. Based on the results of this study, the IMCU direct care and non-patient related tasks matched with the estimated percentage. However, there is an enormous difference in support and personal activities. In the GCU, there was difference in all the categories. In the ICU, the most significant differences were in indirect care and support.

The support task category had zero or few activities in all units. Because this is the first study on this subject, this category will be re-evaluated in a future study.

Except for in the IMCU (that had an almost equal proportion of the direct and indirect care tasks), there was a greater proportion of time spent in the indirect care activities than the direct ones, with less time spent in the personal activities.

Regarding daily activities, the IMCU was the only unit that showed the greatest variations over the course of the study. This may relate to the different patients' complexity of care, the nurse:patient ratio, and/or the infrastructure of the facility compared to the other units. On the other hand, at the end of the study in the ICU, there was a tendency to use the EHR more extensively, and to perform more direct care activities in the GCU. The work sampling method may reduce the Hawthorne effect, but in this first evaluation we cannot determine if this tendency is the product of this effect or a particular characteristic of both units.

Regarding EHR documentation, the percentage was greater than expected in all of the units. ICU showed the greatest percentage (23.79%). According to the literature, the nurse staff expends 15.79% (95% CI 14.25, 17.33) of their time in all documentation tasks, including paper documentation (10.55%) and EHR use (5.24%) [16]. Other authors mention 17.7% [9], 10.1% [17], and even 35.3% time commited to documentation. While there is certain agreement regarding the time modification when transitioning from paper to electronic documentation, it is unclear when there is an update or redesign to an existing electronic record system. For this reason, when the impact to the workflow during EHR implementation is recorded, some studies consider the time associated to registration and direct care as primary and secondary indicators [18].

We included "personal activities" as an individual category separate from the others (or included but in a different category like non-value-adding work [13]). The total time comprising this category contributes to the better understanding of how nurses use their time.

The findings of this study give us useful preliminary information regarding how nurses use time in completing assigned tasks. However, there are some limitations. The WS technique is one of the most frequently used due to its usefulness and cost effectiveness [19], and findings can be compared statistically. However, there are variations in the use of the technique [13]. Additionally, nursing task definitions do not always match in these studies. In spite of this, WS is a useful technique when there are constraints on time and resources, making the evaluation feasible.

We researched adult units during morning and afternoon shifts. To evaluate the night shift, it would be necessary to adapt the list of activities, due to the fact that there are different types of tasks performed during the night shift. Even though the observations took place during three weeks, the observed time only corresponds to five days. However, we obtained the required minimum of observations. To be able to determine if the implementation of the new EHR version will or will not affect the time, it is necessary to complete the evaluation in the post-implementation phase, planned six months after the implementation. It will be necessary to increase the number of units involved, and ideally should be done over a much longer period.

The data regarding the time spent by the nurses in their different tasks enables the evaluation of changes in the nursing practice after the implementation of a new system [9]. While this information is important, it only reflects one part of the phenomenon, since implementation may not only change the time used for doing a task but also the workflow and, consequently, the continuity of care. Further research will help to better understand this situation and to perform improvements during the process.

Acknowledgments

The authors would like to thank the students Leonel Cameselle, Agustina Bertoia, and Leonardo Juarez for tasks related to field observations, data entry, and translation of the manuscript. We extend special acknowledgements to the Chief of Nursing Department, Lic. Elsa Villalba, and the nursing personnel of HIBA.

This research was done under the Health Informatics Residence Program.

Abstract

For many complex diseases, finding the best patient-specific treatment decision is difficult for physicians due to limited mental capacity. Clinical decision support systems based on Bayesian networks (BN) can provide a probabilistic graphical model integrating all necessary aspects relevant for decision making. Such models are often manually created by clinical experts. The modeling process consists of graphical modeling conducted by collecting of information entities, and probabilistic modeling achieved through defining the relations of information entities to their direct causes. Such expert-based probabilistic modelling with BNs is very time intensive and requires knowledge about the underlying modeling method. We introduce in this paper an intuitive web-based system for helping medical experts generate decision models based on BNs. Using the tool, no special knowledge about the underlying model or BN is necessary. We tested the tool with an example of modeling treatment decisions of Rhinosinusitis and studied its usability.

Keywords:
Clinical decision support system; Bayesian network; conditional probability tables; probabilistic modelling; expert system; treatment decision; web tool; rhinosinusitis.

Introduction

For some patient-specific treatment decisions (e.g., in oncology) more patient information needs to be considered at once than a single physician is able. For this reason, time intensive meetings of experts from different medical domains (e.g., surgery, radiology and radiotherapy) are conducted to understand and discuss the entire patient situation and possible therapy options and outcomes. However, each of the experts participating in these meetings considers the patient-specific situation from an individual viewpoint or background, making a discussion and finding a unanimous decision difficult.

Intelligent clinical decision support systems (CDSSs) [1] based on probabilistic graphical models, and more specifically, a Bayesian network (BN) [2], could support physicians by modeling complex interdisciplinary treatment decisions and simulating integrated decision making. A BN's graphical model contains nodes representing information entities (IE) with a set of events that can occur (e.g. Boolean values). In the domain of medicine, IEs describe for example results regarding medical examinations, medical imaging, patient's compliance, genetic factors, or describe patient characteristics (e.g. age, gender, tobacco and alcohol consumption). Nodes are linked by directed edges. More specifically, a parental node is connected to a child node by edges representing their direct causality.

The probabilistic model is dependent on the modeled graph structure and represents the strength of the causality between an IE and its direct linked causes (parental nodes) by a conditional probability table (CPT). In a CPT, for each event of an IE probabilities are assigned based on all permutations of its parental events. Consequently, the amount of necessary probabilities for a CPT grows exponentially with the number of parental nodes and their events. A main challenge when modeling the graphical structure of BNs is to find the right balance between the granularity of IEs with their events and the complexity of the model in order to avoid large CPTs. Based on our previous work [3], CDSS for increasingly complex treatment decisions requires more detailed BN models.

The graphical model of a BN can be created by applying machine learning algorithms to a set of data collected from guidelines and other sources that define relations between IEs. The information already provide the probabilities [4-6]. Our previous study revealed a significant disadvantage of this method for complex diseases, evidences for many IEs are usually based on easier accessible and cheaper patient information (e.g. age, gender, tobacco- and alcohol consumption) [3]. Thus, proven relations as they are available in guidelines and statistics do not represent the desired natural direct dependencies in the graphical model.

In contrast to machine learning, our approach creates the model structure by considering the natural direct dependencies without limits given by statistics. The conditional probabilities are assigned in a subsequent step. In that way, the graphical model forms the basis for collecting probabilities. This kind of model-based medical evidence [7] is expensive to achieve at the moment, and manual modeling by medical experts is subjective and very time-consuming.

To overcome this limitation, we developed a web-based tool that allows experts to assign probabilities to nodes and respective events in a graphical model describing treatment decisions. In this paper, we introduce the system. It was tested on a the graphical BN model representing treatment decisions related to acute- and chronical rhinosinusits (ARS and CRS). The paper is structured as follows: In the *Methods* section, we describe the web tool to collect the CPTs for the probabilistic model. We evaluated the tool by having physicians assign probabilities to events in a treatment decision model. In the section *Evaluation and Results,* we present a comparative

assessment of the expert's probability values by using an intraclass correlation, and by analysing metadata recorded during the assignment process. Further, we present the results from a usability study. In the *Discussion* section, we describe advantages and disadvantages of the application, reasonable issues for the disparities in the expert's assessments and necessary extensions. The *Conclusion* summarizes the results and provides an outlook on future expert-based modeling in the medical domain.

Methods

Web-based Tool for Assigning Probabilities

Previous work from L.C. van der Gaag et al. [8] showed that experts can assign probabilities to IE in a given probabilistic network by formulating natural language questions and allowing the assessments to be provided on a scale. When prompted, domain experts were able to provide probabilities at a rate of over 150 probabilities per hour. Our approach is based upon that work, but goes beyond by using a computer system to digitalize the process of eliciting probabilities from domain experts through a web-based tool.

Our CPT-tool runs as a server application on the Node.js architecture and uses MongoDB as a persistence layer. The application requires a user authentication to prevent misuse of the system by unauthorized parties, and also to record user specific metadata that is used for the evaluation of the system. As a web application, the tool can be used from any browser and is thus system independent.

The CPT-tool takes as input a probabilistic network in XML format that contains all nodes of the model with its events and edges from parental nodes. We are building these networks using the open source software UnBBayes [9], but any other tool for generating BN models would be applicable. The CPT-tool automatically extracts the nodes, their events, and edges from the model to *(1)* generate an overview table and two types of questionnaires, *(2)* generate CPT specific questionnaires of permutations of parent events and *(3)* node specific selection page of probability combinations. The output of the application is again an XML file stored in the same XML format as the input, but with the probabilities set by the user.

User Interactions with the System

In the following, we describe the interactions between medical experts and the system when assigning probabilities to a graphical BN model. After logging into an account, a user can upload a probability network with events to which probabilities need to be assigned.

(1) Once the network has been analyzed by the system, the pertaining nodes are displayed in an overview table to the user, see figure 1. Each row contains the number of pages the domain expert has to complete (i.e. the number of permutations of the given node) and the number of variables each node contains. The domain expert is able to freely choose which node to start the elicitation process, by clicking the corresponding button next to the node. The required probabilities can be set at any time and from anywhere, which doesn't force the domain expert to a fixed schedule that might otherwise cause an inconvenience.

(2) The first questionnaire is similar to the elicitation sheet suggested by van der Gaag [8]: The selected IE is presented as a text fragment, but is divided into two parts. One part presents the preconditions of the current iteration, while the other part presents the events of the current node to be assessed. For example, figure 2 asks the user to assess the probability of antibiotics being used, given the state of the parent events on the left hand side. Since the events of the antibiotics node are either true or false, the user is only required to set the probability for the question: *How likely is it that antibiotics is: true.* The tool specifies the percentage bar in seven percent steps (1%, 15%, 25%, 50%, 75%, 85%, and 99%) with a text description ("(almost) impossible", "improbable", "uncertain", "fifty-fifty", "expected", "probable", and "(almost) certain") assigned to each of the percentages. However, there is still the possibility to set the exact percentage in 1% increments.

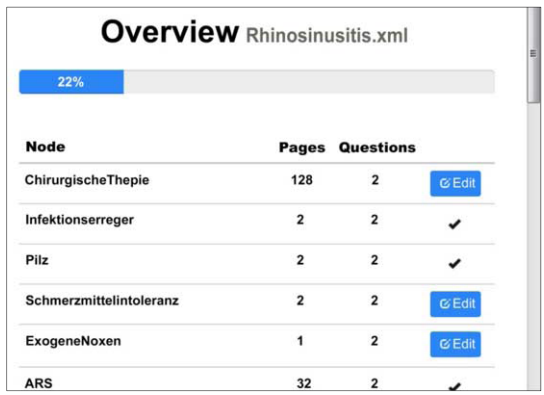

Figure 1–Overview table from CPT-tool

In case of determining the probabilities of a node with more than two events (e.g. Tumour-state), the expert is asked to set the probabilities with a total of 100%. At the end of the page, a multiple choice selection to evaluate the confidence level of the assessments is presented. The options are: very confident, confident, unconfident and very unconfident. If the assessment was unconfidently made, an additional input field is presented to describe the uncertainty of the evaluation. After submitting the probabilities, the next permutation of the node's parent events will be presented. But before, the system interpolates all probabilities to 100% in the background based on the combination of parent events, by dividing each of these probabilities by their quotient. Their quotient is the sum of the probabilities, divided by 100.

For example: The probabilities for the events $\{n_1, n_2, n_3\}$ of the node n are set with 35%, 30%, 60%. Then, the system divides each of the probability by 125%, because of (35 + 30 + 60) / 100 = 125%. 28% + 24% + 48% = 100%.

At the top of the page, the user is presented with a progress bar guiding her through the node iterations. After assessing all probabilities of a node, the user is returned to the node overview page where the recent node will be marked as completed.

(3) If a chosen node n has at least two parent nodes, before step (2), an additional questionnaire is presented to find significant combinations of parental events, see figure 3. On this page, the probability of n dependents on a non-empty and incomplete set of parent events E are to be asseessed, so that the probability of n is set for all CPT items that contain the combination of E. Significant combination of parental events are identified using the following hypothesis:

The probabilities for a node *n* are the same, if an event or a combination of events *E* of *n*'s parental nodes occurred independent on all combinations of events of all other unconsidered parental nodes of *n*. ■

The percentage for the node dependent on the selected combination is assessed by the user in the same way as in the other questionnaire (step 1). After confirming a combination with a percentage, the combination is visualized by a blue dot with a number. Same numbers indicate one combination and the number itself the order of setting the combinations.

Figure 2– Example of the questionnaire from CPT-tool

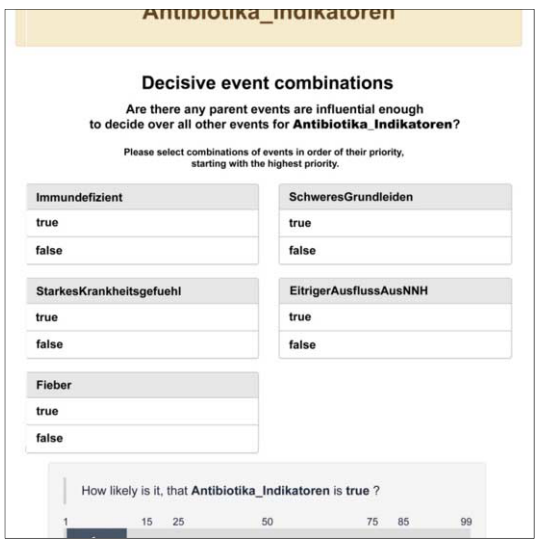

Figure 3– Questionnaire for significant combinations of parent events

Finally, after completing the assessment of all nodes, the user can export the network encompassing the elicited probabilities for each node.

Evaluation Methodology For evaluating the CPT-tool, we performed a user study with clinical experts, which also included a usibility study. Evaluation methods and results are described in the following.

Study Design: CPT-tool Used by Medical Experts

For a study of the presented CPT tool, we used a graphical model for the treatment decision of acute- and chronic rhinosinusits (ARS, CRS) comprising 75 nodes and 100 dependencies. The model was handcrafted, first by non-medical-experts based only on guidelines. For graphical representation and later inference tests, the model was implemented using UnBBayes. Three physicians were asked to correct and validate the graphical model and later, to set the CPTs by using the presented web tool. One physician was a resident physician in his second year and experienced in Bayesian theory. The other two were ENT-surgeons with 7 to 10 years of experience of ARS and CRS, with around 1000-1200 treatments a year, from this around 520 to 780 of which are surgical treatments and the remaining are conservative therapies.

The CPT-tool computed for the rhinosinusitis model contained 1526 questions, i.e., the number of probabilities that needed to be assigned. For assigning the probabilities, accounts for all three physicians were created. The experts were free to choose when and where they would use the CPT-tool to answer the questions. The only requirements were to finish a node once it was started, to keep a general overview of the node in mind, and to finish the whole assignment in two weeks. The second questionnaire for significant combinations was not part of this first study, but was assessed at a later time by resident physician.

During the assignment process, meta-data was collected to help with the evaluation of the users' decision making process. These include the previously mentioned self-evaluation of the users' choices, the amount of time it took for a user to set a probability and complete a node, and the order in which the nodes were completed. The purpose of this evaluation was to study the time required for probability assignment, to study the user satisfaction with the CPT-tool and to find out to what extent the experts agree in probability setting.

Results

Usability Study: Design and Objectives

After the first study, and based on the experiences, a usability study with 20 participants of different gender and ages between 25 and 44 years was done. Focus of the usability study was to identify potential sources of error that may lead to wrong assessments caused by the application's construction, design and usability. Therefore, a special, smaller model was created with a more intuitive example about a common topic, the accident rate of traffic, with IEs such as *road surface, the type of road, weather and season conditions*. For the tests, different usability methods were combined to get qualitative and quantitative results out of the study, such as screen capturing, voice recording, eye tracking, questionnaires and interviews. During this study, the participants were asked to think out loud and to answer questions about their actions. The participants were asked to use the CPT-tool independently by their own intuition but with the possibility to ask the usability experts if necessary.

Evaluation Results

The assignment process of the rhinosinusitis probability network took each expert an average of 7 to 12 seconds per elicitation step. At just over 1500 probabilities to assess, the experts were able to complete their task at a rate of 300 to 500 probabilities per hour, with a minimum of 2 seconds for the fastest and 26 seconds for the slowest answer. This means that a total time of 3.5 to 5 hours was necessary to complete the elicitation process for this particular model. With the aid of selecting decisive event combinations, the resident physician was able to eliminate 47.97% (n = 732) of all probabilities using less than 50 assessments.

From the metadata, we could recognize that the experts started with the nodes that had the least number of questions, before working through the remaining nodes in chronological order. Comparing the results of our experts, we found that only 148 out of the 1500 probabilities had a deviation of 50% or more. However, 501 probabilities had a deviation of over 15%. To better evaluate the assessments of the experts, we employed intraclass correlation as a form of reliability testing. The intraclass correlation coefficient kappa describes how closely the elicited values resembled each other in six categories: no agreement, slight, fair, moderate, substantial, and almost perfect agreement [10]. Figure 4 shows the kappa, on a scale of -1 to 1, for each node that has at least one parental node. Nodes without parents are ignored based on their opinionated characteristic. We did not specify in the assignment rules whether probabilities to such nodes have to be set on the basis of the specific epidemiology. The graph depicts an overall positive result, with an average kappa of 0.16, indicating "moderate agreement". Twelve of the thirty nodes depicted in the graph were categorized "substantial agreement". The few nodes found during the intraclass correlation reliability test that fall into the "fair agreement" category will be discussed and reevaluated in an upcoming post-elicitation meeting with the experts.

The two experienced experts in our study did not make use of the applications feature to report uncertainties during the elicitation process. Instead, only the resident provided feedback on several of his decisions, most frequently criticizing the epidemiology of the nodes. At this stage, it was not clear if these deviations in probabilities and the almost positive assessments of confidence originate from the differing medical expertise or is caused by the usability of the system. For this reason, we performed a usability study.

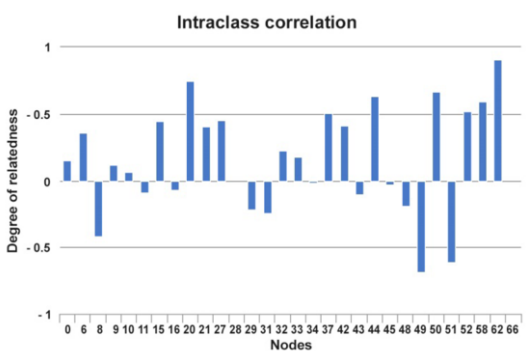

Figure 4– kappa for each node with at least one parental node from the rhinosinusitis model

In the usability study, we recognized 28 negative aspects determined by the system that we classified in three levels of severity: (1) critical – system crash or misleading to wrong probabilities (6 of 28). (2) user-unfriendly – demotivating or loss of attention (6 of 28), and (3) nice-to-have – is not affecting the rating (16 of 28). Table 1 shows the problems and the number of affected testers from the severity level 1 and 2. The additional step of presetting key combinations that was integrated only in the usability study was one of the main misleading problems. Problems with the severity level 2 lead to a longer answering time. For the most participants the study has shown first signals of demotivation after 15 to 30 minutes; after around 30 to 45 minutes participants started to loose attention. The third level is not listed as it contains subjective feelings. Only a few testers were affected by the same aspects and they did not influence the usability of the tool.

Table 1– Table of negative aspects determined by the system

Problems	# affected testers out of 20
Level of severity 1:	
Understanding of pre-setting key combinations of causes unclear	12
Group of direct causes not recognized	7
Duration of the questionnaire for one node too long	7
Only the first probability bar taken serious	5
Relation between all bars unclear	4
How to interpret the input field for uncertainty unclear	4
Some web browsers allow to stop pop-ups which prohibits functions of the tool	3
Level of severity 2:	
Comment feature hinders the assessment process	4
The node terms or subject unclear – missing instructions	3
Duration of "pages" and "questions" unclear	1
Information on lost data when closing the application	1
Program entraps to clicking through the questionnaire	1
Not enough application feedback, "unable to tell what's happening in the background"	1

Discussion

In the following , the results of both studies are discussed with examples for a better usability of the CPT-tool, and also compared with previous literature. To finish the first study with the rhinosinusits model, a follow up meeting with the experts will be needed for personal interviews and to evaluate and discuss any problems or difficulties that occurred during the elicitation process. Additionally, nodes that have led to differing assessments will be discussed to compile a convergent model for further evaluations.

The usability study with 20 participants gave highly reliable result. Early researches of Nielson and Landauer [11] showed, that five users will find about 85% of all existing usability problems and "when collecting usability metrics, testing 20 users typically offers a reasonably tight confidence interval" [12]. Based on the results from both studies, all problems with a severity level 1 should be corrected and also some of level 2 with higher numbers of affected testers. Especially, the additional step of presetting key combinations is a powerful and necessary approach for treatment decision models to minimize the large amount of probabilities. By addressing the issues revealed during the usability study, the CPT-tool can be improved to build an intuitive tool that allows domain experts to help in collecting probabilities without any need of knowledge about the underlying network or BNs. This could lead to a collection of large amount of CPTs in a short amount of time by using the crowdsourcing principle, so that later a justifiable average of probabilities can be composed.

Another significant problem is that the duration of setting the CPT for a node without interruptions is too long and leads to impatient, inattentive, fast and incorrect assessment. This problem can be solved in many ways, for example by using the average time of expert based answering, multiplied with the number of a node's questions the expert will have a better feeling for the upcoming effort. Also, the interruption during the probability setting of a node could be allowed by saving the current editing state, but with the resumption of the node its presetting history should be accessible and studied by the expert to guarantee an overview on the graph. Eliminating the problems, we expect a very intuitive tool. Another study of the upgraded application will follow.

Our CPT-tool has several advantages compared to the method from van der Gaag [8], in particular with respect to flexibility, answering rate, and precision. The separation of current and dependent events allows the user to see the preconditions all in one place, and also enables the questionnaire and underlying network to take on any form and size. With a time consumption of approximately 11 seconds per answer, the average answer rate is substantially higher. A digital solution also allows to present an exact percentage. Although it is known from van der Gaag's work that the precision of 1% increments is not necessary for the CPTs, it was one of our expert's requests to be able to distinguish between similar answers. An important and promising solution for large models is the questionnaire of significant combinations. At this stage, the usability study shows that this questionnaire is not intuitive or obvious, but it can significantly decrease the amount of questions. In a BN example with laryngeal cancer [13] some nodes in the model contain a CPT with more than ten thousands of probabilities, but can be minimized to only a small number of 20 to 30 nodes by presetting key combinations.

At the moment, the CPT-tool uses as input an XML-format given by UnBBayes's export-file that is very extensive and software specific. In the next version of the CPT-tool, this will be changed to a simpler XML-format, so that also other software export could be parsed and used in the web-tool. Additionally, an upgrade for instantiable models as multi-entity Bayesian network is planned.

Conclusion

In this paper, we introduced a web-based tool for assigning probabilities to BN models of clinical treatment decisions. The tool was evaluated with respect to usability and in a user study. The assessments we have received from the domain experts are promising even though we collected problems of three level of severity. At least level 1 problems need to be eliminated to minimize the number of wrong expert based assessments caused by the usability of the presented web-tool. The usability study not only increased the understanding of usability issues but also improved the development of an intuitive web-tool. This is a major step in encouraging medical experts to use probabilistic modeling. Based on this work, another web-tool for creating graphical models based on natural language questions is planned. These kinds of tools will allow crowdsourcing the development of CDSSs.

Acknowledgments

This research has been done within the research group "Digital Patient and Process Modeling" funded by the German Ministry of Research and Education.

We would like to thank L. Koch's usability group of the University of Merseburg for a professional and volunteered evaluation of our tool. We also like to thank Prof. Strauss's AQUA clinic team of medical experts and the International Reference and Development Center for Surgical Technology (IRDC), and also the ENT department of the University Hospital of Leipzig.

Abstract

When wrongly used, guideline-based clinical decision support systems (CDSSs) may generate inappropriate propositions that do not match the recommendations provided by clinical practice guidelines (CPGs). The user may decide to comply with or react to the CDSS, and her decision may finally comply or not with CPGs. OncoDoc2 is a guideline-based CDSS for breast cancer management. We collected 394 decisions made by multidisciplinary meeting physicians in three hospitals where the CDSS was evaluated. We observed a global CPG compliance of 86.8% and a global CDSS compliance of 75.4%. Non-CPG compliance was observed in case of a negative reactance to the CDSS, when users did not follow a correct CDSS proposition (8.6% of decisions). Because of errors in patient data entry, OncoDoc2 delivered non-recommended propositions in 21.3% of decisions, leading to compliances with CDSS and CPGs of respectively 21.4% and 65.5%, whereas both compliances exceeded 90% when CDSS advices included CPG recommendations. Automation bias, when users followed an incorrect CDSS proposition explained the remaining non-compliance with CPGs (4.6% of decisions). Securing the use of CDSSs is of major importance to warranty patient safety and benefit of their potential to improve care.

Introduction

Variations in medical practices have been observed for decades around the world. If some level of variation related to differences in population need, health status or patient preferences, is expected, "unwarranted variation" raises questions about quality and appropriateness of care [1]. Following evidence-based medicine principles, clinical practice guidelines (CPGs) have been developed to eliminate these "unwarranted variations". Recommended by health professional societies or national health agencies, CPGs are information resources describing the recommended therapeutic management for different clinical situations encountered in given pathologies. They are thus intended to improve the quality of clinical care, reduce inappropriate variations, produce optimal patient outcomes, and promote cost-effective practices.

Many studies have shown that the sole dissemination of narrative CPGs had nearly no impact on physician behavior. On the opposite, numerous reviews [2] suggest that clinical decision support systems (CDSSs) have the potential to promote CPGs use. However, many studies showed positive effects of CDSSs, whereas others found only a limited impact of these systems upon physicians' behavior. One of the difficulty comes from the wide, non-totally agreed upon, meaning of CDSSs. This denomination covers indeed systems ranging from the simple provision of brief prompts and calculation services, through the provision of the therapeutic support for the management of complex patients with multimorbidity. CDSSs may also vary according to user interaction modalities, operating either as automated reminder systems generating alerts, or as on-demand systems. A recent study [3] reported for instance that presenting decision support within electronic charting or order entry system was associated with failure compared with other ways of delivering advice. In addition, requiring practitioners to provide reasons when overriding propositions and providing advice concurrently to patients and practitioners were more likely to be effective.

Cancer management is subject to practice variations and to varied levels of compliance with oncology CPGs [4].

Multidisciplinary meetings (MDMs), or tumour boards, are generally associated with improvements of guideline compliance rates [5]. However, the efficiency of MDMs has been recently questioned [6] and CDSSs used in MDMs are considered to improve the compliance of MDM decisions with CPGs [7].

OncoDoc2 is a guideline-based decision support system applied to the management of non-metastatic breast cancer patients to be used by MDM physicians [8]. Routinely used for three years in breast cancer MDMs of the Tenon hospital (Paris, France), it showed very good results in terms of compliance [9]. More recently, we conducted a prospective cluster randomized controlled trial to evidence the impact of the system on the compliance of MDM decisions with CPGs. When studying the sole intervention arm of the trial, where MDM physicians used the system for all breast cancer patients, we observed that, in half of the cases, the system was not correctly used. In theses cases, patients were described with "errors", and the compliance rate of MDM decisions was significantly decreased. We concluded that it was better not to use the system than to use it improperly [10].

Indeed, health information technology is expected to improve the quality of care. Tools such as electronic healthcare records (EHRs), CDSSs, computerized provider order entry systems (CPOEs), are believed to make the delivery of healthcare safer, more effective and more efficient. However, with the widespread implementation of HIT, studies that suggest HIT introduces unpredicted and unintended adverse consequences (UACs) potentially harmful for patients have been published. Campbell et al. [11] have identified 9 types of UACs, among which the Type 7 category (new kinds of errors) covers the concept of "e-iatrogenesis" defined by Weiner et al. [12] as "patient harm caused at least in part by the application of health information technology". These errors, known as technology-induced errors, are the result of a mismatch between the functioning of HIT tools and the real-life demands of healthcare work. Sittig and Singh [13] reported that UACs of HIT occur when HIT is unavailable for use, malfunctioning during use, or used the wrong way. Usability engineering methods are thus increasingly being used to ensure improved system usability and the safety of HIT applications [14].

When studying the non-compliance of physician decisions with *state-of-the-art CPGs* while using a guideline-based CDSS, e-iatrogenesis is not always involved. Physicians may not comply with the system propositions and not decide according to the best evidence for the patient. But they may also *comply* with the system propositions and not decide according to the best evidence for the patient. Two main scenarios should be considered. In the first one, the CDSS is correctly used and propositions are "correct" but physicians do not follow them. This corresponds to the mechanism of "reactance" borrowed from cognitive engineering, and introduced by Vashitz et al. [15]. Psychological reactance is an unpleasant motivational state, in which people react to situations, they feel their autonomy is threatened. This is the negative side of reactance, in which physicians want to reaffirm their freedom of choice and consciously or unconsciously either ignore the CDSS propositions or choose on purpose a different course of action. In this case, the quality of the resulting decision has deteriorated as compared to the system propositions. This negative side is balanced by the positive reactance, in which physicians do not follow the system propositions but built on them to refine and thus improve their decision according to the specific condition of the patient or to take into account the very last published evidence not yet integrated in the CDSS knowledge base. In the second scenario, we are in the case of the automation bias (AB) [16], i.e. the tendency to over-trust HIT leading a physician to make an incorrect decision in order to follow the advice provided by a CDSS [17]. Automation bias may be demonstrated by "negative consultation", a term used to denote when a correct decision is changed to an incorrect one on the basis of an incorrect advice. In a systematic review [18], negative consultations range from 6 to 11%.

The aim of this work is to analyze the intervention arm of the randomized controlled trial where OncoDoc2 had to be used for all breast cancer patients discussed during MDMs. In previous works with the same context, we studied the accuracy of actual data entry, and how the way OncoDoc2 was used had an impact on the quality of MDM decisions assessed by their compliance with CPGs [10]. In this paper, we study the attitude of MDM physicians towards the advice of OncoDoc2 in order to assess the part of reactance and automation bias when they finally make their decisions. This paper does neither discuss the methods nor present the results of the trial, which will be presented in a different paper.

Materials and Methods

The guideline-based CDSS OncoDoc2

OncoDoc2 [8] is a computerized guideline-based CDSS. It provides patient-specific recommendations for breast cancer patients according to CancerEst (local) CPGs. The system can be automatically run on patient data extracted from EHRs. It can also be used according to the document-based paradigm of decision-making where the knowledge base is interactively browsed by the user. In this case, using OncoDoc2 consists of answering, by a simple click on the right value, a sequence of closed-ended questions displayed in the interface to finally access the guideline-based advice of the system made of a set of recommended care plans. The user-controlled navigation through the knowledge base, noted N, instantiates criteria according to patient-specific data, and selects the theoretical clinical profile of the knowledge base that best fits the actual patient. Figure 1 shows a screenshot of OncoDoc2 displaying a navigation, characterized by the "Recapitulative", and the corresponding advices ("CancerEst Recommended Treatment Plans"). OncoDoc2 has been routinely used at the Tenon hospital (Paris, France) with a compliance rate of 91.7% [9].

Data collection

We have analyzed the data produced by the weekly organized MDMs of the three hospitals of the intervention arm of the randomized controlled trial. In each of the three hospitals, MDM physicians had to use OncoDoc2 for all breast cancer patients. For each decision, we automatically collected the navigation performed by MDM physicians N^{MDM}, the advices provided by OncoDoc2 $\{R\}^{CDSS}$, and the MDM decision d. Additionally each week, clinical research assistants (CRAs) collected the list of patient cases discussed in MDMs the previous week. For each of them, they ran OncoDoc2 and performed their own navigation on the basis of the information found in patient medical records, without knowing what were the navigations of MDM physicians for the same patients.

The two types of compliance

We considered that for each patient, the CRA-performed navigation was the "gold standard" named "reference navigation", denoted N^{Ref}, and that the advices of OncoDoc2 attached to the reference navigation represented the set of reference guideline-based recommendations that applied to the

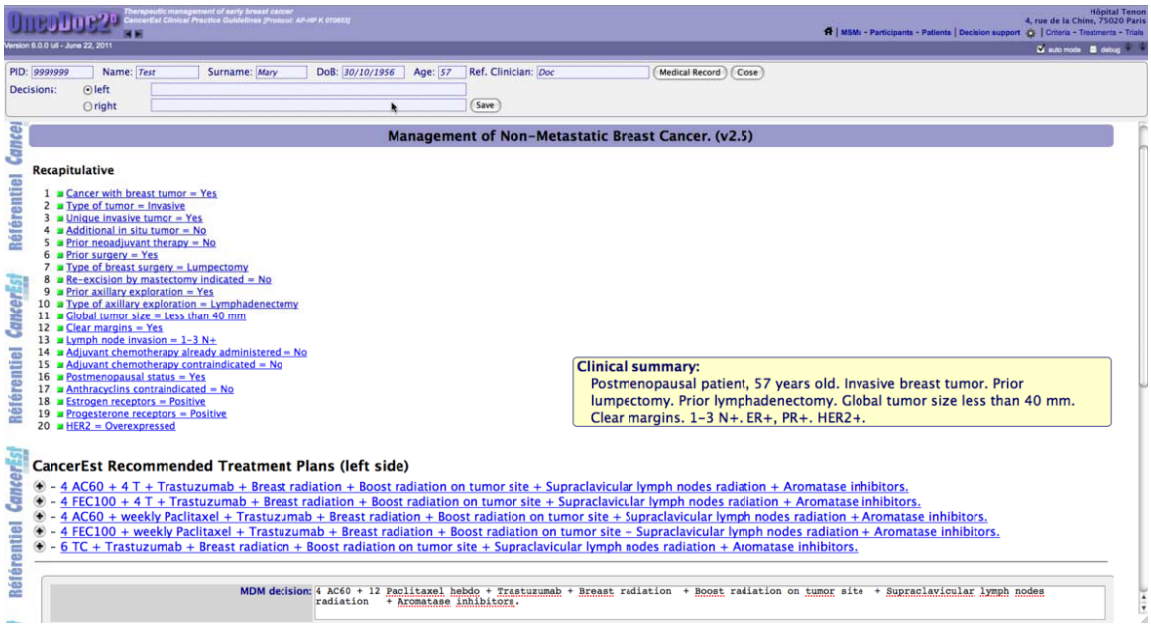

Figure 1 – A screenshot of OncoDoc2 providing advices as treatment plans for a given patient profile

patient, noted $\{R\}^{Ref}$. We stated that a MDM decision d complies with CPGs when $d \in \{R\}^{Ref}$, noted CPGs+.

When MDM physicians used OncoDoc2, and obtained the system advices $\{R\}^{CDSS}$, they could either follow one of the CDSS advices, or react and decide a different care plan. We state that a MDM decision d complies with OncoDoc2 when $d \in \{R\}^{CDSS}$, noted CDSS+.

Quality of the CDSS advice

As previously mentioned, misuses or errors when using CDSSs could lead to the delivery of non-CPG-compliant advices by the CDSS. In the context of OncoDoc2, errors in data input during the user-controlled navigation lead to situations in which $N^{MDM} \neq N^{Ref}$. Usually, in these situations, the set of advices provided by OncoDoc2, $\{R\}^{CDSS}$, does not correspond to the set of reference guideline-based recommendations $\{R\}^{Ref}$. However, it may happen that erroneous data entries lead to appropriate reference recommendations. When considering MDM decisions made with OncoDoc2, we distinguish three different situations:

- Advice+: $\{R\}^{CDSS} = \{R\}^{Ref}$. The CDSS proposes exactly the set of recommended care plans. This is systematically the case when the navigation N^{MDM} is correct, i.e. $N^{MDM} = N^{Ref}$, but can also be true when N^{MDM} is erroneous.
- Advice+/-: $\{R\}^{CDSS} \cap \{R\}^{Ref} \neq \emptyset$. The CDSS proposes at least one of the recommended care plans. N^{MDM} navigations are also necessarily erroneous.
- Advice-: $\{R\}^{CDSS} \cap \{R\}^{Ref} = \emptyset$. The CDSS proposes none of the recommended care plans. N^{MDM} navigations are necessarily erroneous.

Physicians' attitudes towards the CDSS advice

Considering the two types of compliance, CPGs+ and CDSS+, four different CDSS-supported decision-making attitudes, have to be considered. Notations are summarized in Table 1:

Table 1 – Summary of notations and categories of physicians' attitudes in CDSS-supported decision-making

CPGs+	Decision complies with CPGs
CPGs-	Decision does not comply with CPGs
CDSS+	Decision complies with CDSS
CDSS-	Decision does not comply with CDSS
Advice+	All CDSS propositions comply with CPGs
Advice+/-	At least one CDSS proposition complies with CPGs
Advice-	None of CDSS propositions comply with CPGs
Comp+	User follows CDSS and decision is CPG-compliant
React+	User does not follow CDSS and decision is CPG-compliant
Comp-	User follows CDSS and decision is not CPG-compliant
React-	User does not follow CDSS and decision is not CPG-compliant

- Comp+: CDSS+ $\wedge$ CPGs+. The user follows the CDSS advices and her decision adheres to CPGs, which corresponds to a positive compliance with the CDSS.
- React+: CDSS- $\wedge$ CPGs+. The user does not follow the advices of the CDSS, but her decision complies with CPGs. She reacts to the system to improve the final decision which corresponds to a positive reactance.
- Comp-: CDSS+ $\wedge$ CPGs-. The user follows the advices of the CDSS although they do not comply with CPGs. She does not have a critic attitude towards the system propositions and decides as proposed by the CDSS, which corresponds to a

negative compliance with the CDSS, also named automation bias.

- React-: CDSS- ∧ CPGs-. The user does not follow the advices of the CDSS and she does not decide according to CPGs. She reacts to the CDSS propositions to adopt a decision which does not comply with CPGs, which corresponds to a negative reactance.

Consolidation of the CDSS use and physicians' attitudes

We analysed the relationships between the type of advice delivered by OncoDoc2 and the type of physicians' attitudes depending on their compliance with CPGs and compliance with the CDSS. Figure 2 illustrates the possible configurations.

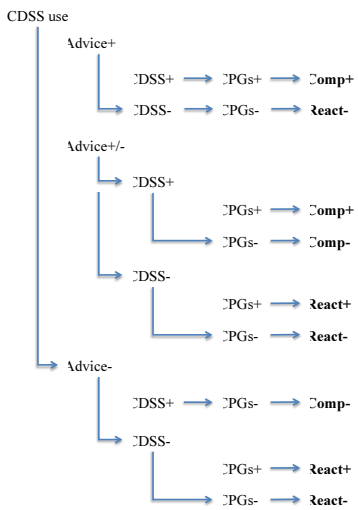

Figure 2 – Formalization of physicians' attitudes towards the CDSS depending on the type of the advice

Results

Data was collected for the intervention arm of the trial, including three hospitals, between June 2009 and April 2010. A total of 394 MDM decisions were made with the support of OncoDoc2 and considered for the analysis. The overall CDSS compliance rate was measured at 75.4%, showing a reactance rate of 24.6%. The overall CPG compliance rate was 86.8%.

As reported in [10], OncoDoc2 was incorrectly used in 52% of the cases. However, on the basis of the comparison with the recommendations of reference navigations, we observed that 68.8% of MDM decisions were made in Advice+ situations where all OncoDoc2's propositions were correct recommendations, and that 21.3% of MDM decisions were made in Advice- situations where all advices provided by OncoDoc2 were incorrect. Compliance with CPGs was significantly different according to the advice category (χ^2, $p < 10^{-9}$) and was measured at 65.5% for Advice-, whereas it was 92.3% for Advice+, and 94.9% for Advice+/-. In the same way, the CDSS compliance rate was significantly different according to the advice category (χ^2, $p < 10^{-37}$), and measured at 92.3%, 74.4%, and 21.4% for Advice+, Advice+/-, and Advice- respectively. Table 2 summarizes the distribution for the three advice categories and the associated CDSS and CPG compliances.

Table 2 – Distribution of advice categories and their corresponding CDSS and CPG compliances

Categories	n	(%)	CDSS+	CPGs+
Advice+	271	(68.8%)	92.3%	92.3%
Advice+/-	39	(9.9%)	74.4%	94.9%
Advice-	84	(21.3%)	21.4%	65.5%
Total	394	(100.0%)	75.4%	86.8%

The distribution of MDM physicians' attitudes towards OncoDoc2 is reported in Table 3. In 70.8% of the cases, the compliance with the CDSS advice was positive (Comp+), yielding CPG-compliant decisions. Reactance to the system advice represents nearly one quarter of all decisions (24.6%). Reactance is positive in about 2/3 of reacted decisions, leading to CPG-compliant decisions. Finally, the automation bias, or negative compliance with the system, is estimated at 4.6% of all MDM physician decisions. It must be noted that automation bias was observed only in the Advice- category.

Table 3 – Distribution of the four categories of MDM physicians' attitudes towards OncoDoc2 for decision-making

User attitudes	n	(%)
Comp+	279	(70.8%)
React+	63	(16.0%)
React-	34	(8.6%)
Comp-	18	(4,6%)
Total	394	(100%)

Discussion

OncoDoc2 was associated with a global CPG compliance of 86.8% and with a CDSS compliance of 75.4%. The expected effect of the CDSS, i.e. the positive compliance Comp+, when the 2 compliances simultaneously occur, was 70.8%.

More specifically, when CDSS advices include guideline-based recommendations (Advice+ and Advice+/-), CPG-compliance exceeds 92%. This suggests that the correct reminder of CPGs by a CDSS may foster their adoption. We observed that Advice- situations occurred in 21.3%. Such situations necessarily occur when the patient characterization in the system (N^{MDM} navigation) is not accurate. This proportion of situations where no guideline-based recommendation is provided by OncoDoc2 is important, but less than the 52% of erroneous navigations observed in [10]. In these cases, physician decisions to follow the erroneous OncoDoc2 advices in 21.4% of the cases, and compliance with CPGs falls to 65.5%. This illustrates the unintended consequences of CDSSs and serves as a reminder that the accuracy of collected data, as well as CDSS usability are fundamental issues to address. Further analysis should investigate the determinants of Advice- situations.

The risk of Advice- situations is to favor the automation bias, and the compliance with CDSS, in the detriment of the compliance with CPGs. With our dataset, and according to the proposed formalization of users' attitudes, automation bias was measured at 4.6% of the CDSS-supported decisions. This

is lower than the 6 to 11% rates reported by the review conducted by Goddard et al. [18].

In 16.0% of the cases, MDM physicians positively reacted (React+) to the system. This demonstrates that they critically considered inappropriate CDSS advices and that in these cases, physicians' knowledge of CPGs is strongly established. On the opposite, negative reactance (React-) occurred when CDSS advices were not adopted and the decision was not CPG-compliant. This suggests that either CPGs are not known, or are not trusted, or are not appropriate to the patient. Indeed, in some particular clinical situations, deviating from CPGs can be either necessary since recommendations may not apply. This highlights the limits of CPG-based care and the room for clinical expertise, as promoted by evidence-based medicine.

This study presents some limitations. First, the reference navigation were built from the data found in patient records and considered as the gold standard, but might not be the best characterization of the patient. Errors in the patient record could lead to erroneous reference navigation. Thus an erroneous reference navigation is compared to an accurate MDM navigation. Some data input by MDM physicians considered as erroneous compared to the reference could in fact come from their clinical interpretation. For instance, they may consider that a patient could not undergo a chemotherapy, while nothing in the patient record suggests it. In addition, when the reference navigation is correct, physicians may have good clinical reasons not to comply with the CDSS advices for the benefit of the patient. This occurs for instance in the case of particular patient characteristics like BRCA1 mutation, patient preferences, or evolutions of the state of the art, where the propositions of the CDSS are not the best up-to-date recommendations for the patient. Automation bias may also be hidden behind Comp+ situations, where users follow the CDSS advices, and comply to CPGs while it would be better for a particular patient to deviate from CPGs. The same could be observed in React- situations. For instance, in the case of a surgery by mastectomy and axillary dissection is recommended, CDSS advice is tumorectomy, and decision is mastectomy, then, the decision neither complies with the CDSS nor with CPGs and is classified as React-. However, if the surgical treatment is split into two different surgical steps, mammary and axillary surgeries, we observe that there is a positive reactance (React+), from the advised tumorectomy to the recommended mastectomy for the mammary surgery, and a negative compliance (Comp-), since no axillary treatment is advised or decided albeit recommended. As a conclusion, the effect of the CDSS on the decision-making process is more complex than our proposed formalization, especially for complex multiple-step decisions. But these effects are hardly quantifiable since not detectable.

Conclusion

This study demonstrates that, when wrongly used, a guideline-based CDSS could deliver non guideline-based advices that hinder compliance of decisions with CPGs and favors user attitudes like negative reactance and automation bias. Hopefully, the advantages of HIT could outweigh the disadvantages. In our study, global compliance with CPGs was improved in the intervention arm, when OncoDoc2 was used [10]. The challenge is now to foster CPG compliance while warrantying patient safety through correct use of CDSSs. Potential solutions include improving CDSS user interface, ensuring data quality, and training physician to both CDSS and CPGs while adopting a critical appraisal on CDSS output.

Acknowledgments

Authors thank all the MSM members of the centers that participated in the study, the DSI/AP-HP that developed the OncoDoc2 system, and URCEST for their logistic support.

Abstract

Hospitalized patients in the U.S. do not always receive optimal care. In light of this, Computerized Decision Support (CDS) has been recommended to for the improvement of patient care. A number of methodologies, standards, and frameworks have been developed to facilitate the development and interoperability of computerized clinical guidelines and CDS logic. In addition, Health Information Exchange using Service-Oriented Architecture holds some promise to help realize that goal. We have used a framework at Intermountain Healthcare that employs familiar programming languages and technology to develop over 40 CDS applications during the past 13 years, which clinicians are dependent on each day. This paper describes the framework, technology, and CDS application development methods, while providing three distinct examples of applications that illustrate the need and use of the framework for patient care improvement. The main limitation of this framework is its dependence on point-to-point interfaces to access patient data. We look forward to the use of validated and accessible Service-Oriented Architecture to facilitate patient data access across diverse databases.

Keywords:

Computerized Decision Support; CDS; framework; Service-Oriented Architecture; SOA.

Introduction

Hospitalized patients expect to receive the best possible care. However, of 25 clinical conditions examined, patients in the U.S. only received the recommended processes for basic care an average of 54.9% of the time [1]. Use of information technology has been recommended to help improve patient care [2, 3]. Computerized Decision Support (CDS) has been defined as "any computer program designed to help health professionals make clinical decisions" [4]. Airline pilots cannot look out the cockpit window and determine their exact altitude, air speed and flight direction. On-board computer programs provide that information. Likewise, if pilots try to land without the landing gear down and locked, or numerous other potential problems are detected during flight, the on-board computers generate alerts notifying the pilots of the situation and danger. In a similar manner, CDS has been used to provide real-time information, reminders and alerts to healthcare providers over the past 40 years, and has been shown to improve patient care [5, 6]. For more than 20 years, a number of methodologies, standards, intelligent systems, syntaxes and frameworks have been developed to facilitate the development and interoperability of computerized clinical guidelines and CDS logic. Protégé, GLIF, Arden Syntax, Prodigy, SEBASTIAN, GELLO and SAGE have been successful in demonstrating the reconstruction of previous CDS logic and the use of standards and ontologies to facilitate CDS and computerized guideline interoperability [7-14]. Health Information Exchange (HIE), using a Service-Oriented Architecture (SOA), provides some additional capacity to realize the goal of data independence [15-18]. Recently, the Substitutable Medical Applications, Reusable Technologies (SMART) project has recommended the development of substitutable applications built around core electronic medical records (EMR) [19]. To date, using the Fast Healthcare Interoperability Resources (FHIR) data format standards for web-based application programming interfaces (API), SMART looks like the best candidate for API development [19]. However, HIE efforts are not ready to be used and historically, committee acceptance has been difficult to obtain [20]. For over 13 years, we have used a framework at Intermountain Healthcare that uses familiar programming languages and technology to develop over 40 CDS applications, which clinicians depend on each day. This paper describes the framework, technology and CDS application development methods and provides three different examples of applications that illustrate the need for, and how we use the framework to improve patient care.

Materials and Methods

Background

Intermountain Healthcare (IH) spans the U.S. states of Utah and Idaho, and is comprised of 22 hospitals and 197 clinics, in addition to urgent care centers, physician offices and home health.. A key feature of our independently developed hospital information system (HELP) is the integrated EMR that contains most clinical information. The coded data in the EMR facilitates the development and use of CDS applications to analyze patient data and constantly monitor patient care. Natural Language Processing (NLP) is also used to analyze non-coded dictated reports.

In 1995, development on the HELP^2 system was started and ambulatory data in addition to hospital data began to be entered into the EMR. HELP^2 was expected to replace HELP before 2005. Moreover, during the past 20 years, IH has partnered with four different EMR vendors to develop a new information system, which would replace HELP and HELP^2. The HELP system and two vendor partners' EMRs were built on a hierarchical data dictionary while HELP^2 and the other two vendor partners' EMRs were built on relational databases and different data dictionary coding. Thus, for over 15 years,

the needs of IH clinicians for new and updated CDS applications continued to grow while we were not sure which EMR or data dictionary would eventually be used at IH nor which clinical guideline, medical logic development or HIE would become the standard.

Framework Description

Currently, the EMR at IH contains data from HELP and HELP^2 (Figure 1). Eventually, all the data in the EMR will only be provided by Cerner, the current partner, as HELP and HELP^2 are replaced at all IH hospitals and clinics. Each night, all clinical and business data in the EMR are archived in the enterprise data warehouse (EDW). After the EDW has been updated, Extract, Transform and Load (ETL) jobs are activated by the time driver and use SQL to extract and populate numerous Oracle tables on the staging server. The staging server is maintained 24/7 and backed up each night. The staging server provides faster data access as opposed to collecting that data from the large, slower and non-24/7 EDW. The data on the staging server are stored in data marts oriented by specific clinical needs of decision support applications. The "time driver" (Table 1) is also used to activate over 40 Java based CDS applications that run from once a month to every 5 seconds. The enterprise encounter table contains the master list of all inpatient and outpatient encounters along with some demographic data. The first thing most of the CDS applications do is look in the enterprise encounter file for patients that match specific requirements specified in the logic. The logic in each of the CDS applications also has a specific list of needed patient data elements within specific time windows. An application may require a variety of different patient data elements that could have been stored in any inpatient or outpatient facility from a number of years back in time or just during the current encounter. Historical data from other facilities is retrieved from the tables on the staging server, data for monthly reports are retrieved from the EDW, and current encounter data are retrieved from the EMR. A "data driver" monitors the EMR and is activated by data entry to the system. The data driver then runs specific medical logic modules based on the data being stored. If the medical logic module detects an action that needs to be made, an alert is stored in the Alert File on the IH network. Additionally, there exist data types not stored in the EMR. Electrocardiograms, echocardiograms, pulmonary function tests and data from the IH Health Plans are stored in different databases but also on the IH network.

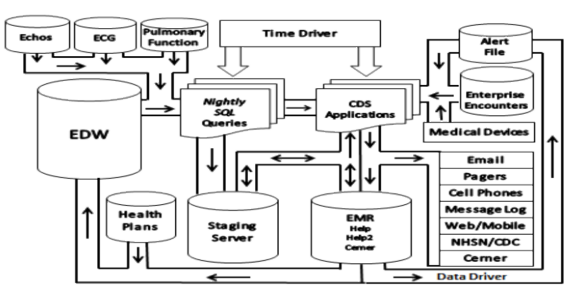

Figure 1 - Framework used for clinical decision support applications at Intermountain Healthcare. NHSN-National Healthcare Safety Network, CDC-Center for Diseases Control and Prevention.

Medical Devices Interface

Some CDS applications also need access to data from medical devices on the framework such as ventilators, infusion pumps, bedside and portable monitors, etc. Collection of data from medical devices and stored in tables on the staging server or the EMR is straightforward if the device has an interface that allows data to be transmitted to an external device. That interface can be analog or digital. If it is analog, the data must be converted from an analog signal to a digital interpretation of the signal. Many common analog-to-digital (A/D) converters are available to perform that function. If the data comes from the medical device in digital format, it may be in a number of different formats, e.g., binary or ASCII. Binary data are generally decoded to form some kind of human understandable format so that they can be stored as coded data. If the data are in ASCII, it may follow several standard protocols, e.g. HL7, XML, or it may be in a manufacturer's proprietary format, which may also need to be decoded to extract the desired components from the data. Hardware interfaces on the manufacturer's devices range from 2 wires for an analog output, to RS232 interfaces for simple serial data transmission and wired Ethernet connections, or a wireless interface including 802.11 (WiFi) or 802.15.4 (Zigbee).

Through the use of this framework, the logic in the CDS applications has access to all data within the IH network and not just a single hospital's EMR. Some data stored in the staging server are not needed until a patient is re-admitted or scheduled for a clinic or home health visit the next day. Actions from the CDS applications can be stored in the EMR or include alerts that can be sent to email addresses, pagers/cell phones, the Message Log within the HELP^2 EMR, Web and mobile devices, the National Healthcare Safety Network at the Centers for Diseases Control and Prevention, or through an API or service to a vendor. Data in the EMR from HELP^2 is accessed through Oracle SQL queries imbedded in Java code while HELP data are extracted using a client/server system of components developed in-house.

CDS Application Development

The CDS applications we have developed on the framework range from fairly simple alerts such as sending primary care physicians daily alerts in the HELP^2 "Message Log" stating that ECG results are finalized to a complex web-based version of the Antibiotic Assistant program [21]. We have found Java to work well and provide us with all the methods we need for simple to complex CDS logic (Table 1). We use Eclipse as the integrated development environment (IDE) for the CDS application development (Eclipse Foundation, Inc., Ottawa, Ontario, Canada). In addition to being free and open source, it provides all the development and testing tools we need; source code editor, intelligent code completion, build automation, documentation generator and especially debugging tools. For complex applications, we need a symbolic debugger that provides the ability to step through code, set break points, break when variables are changed, modify variables and rerun the program from specific lines of code. SQL embedded within the Java code is used to extract the needed data elements from relational databases through Java database connectivity. Java classes also handle the HELP data extraction interface or point-to-point interfaces for the electrocardiogram, echocardiogram and pulmonary function databases and medical devices.

We use JBoss middleware to write to queues and buffer data sent to the EMR. While we use in-house developed services to display alerts to our HELP^2 Message Log, we use common methods to provide most alerts and reports to the users. Simple mail transfer protocol (SMTP) is used to send alerts to

pagers and cell phones and lengthy text reports are sent via email. Reports are encoded using XML to send monthly antibiotic use data to the Center for Diseases Control and Prevention. JavaScript is also used to display CDS derived output on the web.

Table 1 – List of CDS tasks and common methods used within the framework.

CDS Task	Common Method
Core programming language	Java
Integrated development environment: source code editor, intelligent code completion, build automation, documentation generator, symbolic debugger	Eclipse
Time driver	Windows Scheduler
Relational data access	SQL embedded within Java and Java Database Connectivity
Non-relational data access	Point-to-point developed Java classes
Messages within the HELP[2] EMR	In-house developed Java classes
Pager, cell phone and email alerts	Simple Mail Transfer Protocol
Medical device access and data storage	RS232 interfaces, analog-to-digital converters, HL7, XML, wifi, JBoss
Antimicrobial use reports to Center for Diseases and Control	XML
Web-based report generation	JavaScript and HTML within Java

Application Examples

Ventilator disconnection: In 2004, we developed a system to monitor critical ventilator events by using the framework [22]. We collect data from mechanical ventilators every 5 seconds and look for evidence of a disconnection. Whenever an event is identified, the system takes control of every computer in the patient's intensive care unit and generates an enhanced audio and visual alert indicating there is a critical ventilator event and identifies the room number. Once the alert is acknowledged or the event is corrected, all the computers are restored back to the pre-alert status and/or application state. That CDS application was first installed in the Shock/trauma intensive care unit (ICU) at LDS Hospital. Today, the ventilator disconnection alerts are installed in 13 ICUs at 6 different IH hospitals. The audio and video alerts are so distinct and annoying that all medical personnel quickly respond to get the alerts turned off. Data from the past 10 years show that the present critical ventilator alarm times are below durations that are likely to be dangerous. In addition, now that data is collected on all ventilator disconnections, our respiratory therapy departments have been able to identify risk factors such as where ventilators are placed in relation to heat and air conditioning vents which can cause water accumulation in the tubing and restrict airflow. This CDS example illustrates the need for data access with the encounter data, medical devices, EMR, the time driver and use of an IDE for complex code development.

Venous thromboembolism (VTE) high-risk alerts: Routine use of evidence-based guidelines for VTE prophylaxis is uncommon due to the difficulty in integrating them into routine patient care**.** We developed a CDS tool which captures sufficient data to use a risk prediction model to identify patients at high risk for VTE [23]. This CDS application illustrates the need for encounter, historical and current patient data from throughout the enterprise. Patients are screened each day of hospital admission at all 22 IH hospitals and their risk of VTE is determined. Pharmacists are sent an email message listing each high-risk patient and which risk factors they have. Patients at high-risk are then checked to see if they are on appropriate VTE chemoprophylaxis including the drug, dosage, route and interval. If not, 65 hospitalists get a page if their patient is identified. Patient age, new surgery, bed-rest, cancer, height and weight information are collected from the EMR. Previous cancer, previous VTE, previous surgery within 90 days, hypercoagulability and hormone replacement and oral contraception use are collected each night from the EDW and stored in the staging server. The time driver activates the application at 7am each day. We found this computerized tool to identify patients at high risk for VTE with a sensitivity of 98% and positive predictive value of 99%. As of January 2014, high and low risk alerts are sent for every patient to the nurse-charting program in the HELP EMR to meet the new Center for Medicare and Medicaid Service mandate in the U.S.

Antibiotic Assistant: The most complex CDS application we have developed is the antibiotic assistant [21]. Most of the data are accessed from the EMR except for previous microbiology, laboratory, radiology and pathology data from other hospitals during the previous 6 weeks. The application displays all the information physicians need to be aware of before they order antimicrobial agents or are checking the infection status of their patients. The most complex part is the suggestion of which antimicrobial(s) along with the dosage, route, interval and duration to use. The application was originally developed using Tandem Application Language and a symbolic debugger on HELP. With the eventual sunsetting of HELP, we were able to duplicate the application using Java and JavaScript so it can run on HELP[2] or any other system that can render web-based applications such as most vendor EMRs. Based on the complexity of the logic and number of interdependent Java classes in this application, it is used to illustrate the need for a symbolic debugger. It would not have been possible to develop, maintain or add new features to this CDS application without the functionality provided by a symbolic debugger - an ability provided by both Java and Eclipse.

Discussion

The CDS framework and application development methods described in this paper have served us well for the past 13 years, and have allowed us to meet the diverse information needs of many different types of clinicians and medical domains. The majority of CDS applications that we have developed are a) time-driven, b) run in the background, and c) send alerts or email reports at programed intervals in time designated by clinician workflow and patient care. These applications are well aligned with the four predictors of improved clinical practice: 1) automatic provision of decision support as part of clinician workflow, 2) provision of recommendations rather than just assessments, 3) provision of decision support at the time and location of decision making, and 4) computer based decision support [6].

At present, there is no widely accepted, standard approach for representing CDS intervention types and their structural components including alerts and reminders, order sets, infobuttons, documentation templates/forms, and relevant data presentation [24]. Many gaps and challenges remain, including the complexity of many standards, limited availability of accessible knowledge resources, and lack of tooling and other resources to enable the adoption of existing standards [25]. Moreover, many question the "outsourcing" of CDS to potentially imperfect external agencies [26].

While system-agnostic CDS development tools hold great potential to facilitate CDS implementation, little has been described regarding their benefits and challenges (26). A benefit of using Java and SQL is that they are common programming languages taught within most computer science departments. Thus, no other special knowledge or training is required to learn how to use a new CDS development tool and syntax by the programmers. Our experience is that most clinicians are extremely busy providing and looking for ways to improve patient care and don't have the time for or an interest in learning how to program CDS applications. Also, use of Java classes and libraries provide an easy way to share and reuse the same developed and tested logic from one application to another. While not quite true, the Java write once, run anywhere java virtual machine does facilitate the transfer of CDS applications to many different platforms. We do not imply that this framework ought to replace others, nor do we predict that it will outperform any of the other CDS development methods available. Rather, we contribute this framework as a viable option for other systems, given its high functionality in application development and reduction of testing time at IH.
Use of this framework has taught us that the ability of CDS to improve patient care depends on reliable access to the needed patient data. Often, those data need to be derived in real time from the EMR or medical devices, and not the EDW. We are fortunate to have access to most patient data using this framework we have built at IH. Other institutions can use these same programming and development methods we describe to create new CDS applications using the data to which they have access.

The main constraint of our framework is its limiting accessibility to EHR patient data, by way of medical device and database point-to-point interface. Accessing patient data across multiple EHRs has been a desired but largely unattained aim of clinical informatics, especially in commercial EHR systems (24). A potential opportunity for enabling CDS across multiple EHRs is to leverage vendor-supported SOA development and APIs. A recent report by JASON, an independent group of scientists who advise the U.S. federal government on technology issues, states that to achieve the goal of improving health outcomes, Stage 3 Meaningful Use requirements should be defined such that they enable the creation of an entrepreneurial space across the entire health data enterprise and suggest that EHR software vendors should be required to develop and publish APIs for EMRs for third-party software developers (http://healthit.gov/sites/default/files/ptp-13700hhs_white.pdf).

SMART's approach is to use FHIR, a HL7 draft standard describing data formats and elements and an API, to help drive down healthcare costs, support standards, accommodate differences in workflow, and especially foster competition in the market to help promote "innovation" in healthcare [19]. To date, we have used services provided by Cerner to access data for two of the clinical applications that run on our framework. Cerner's upper management has publically stated they support the need for vendors to provide SOA and especially use SMART on FHIR. If so, when a SOA is finalized and in use, we would be able to replace the current point-to-point database specific services and continue to be innovative without the need to make any changes to our current framework, technology or CDS logic.

Conclusion

We have used the described framework, which has employed familiar programming languages and technology in the development over 40 clinician dependent CDS applications during the past 13 years. The main limitation of this framework is the dependence on point-to-point interfaces to access patient data. We look forward to when we can use validated and accessible SOA to facilitate patient data access across diverse databases.

Abstract

Decision support systems, as means of disseminating clinical practice guidelines, are powerful software that may lead to an improvement of medical practices. However, they are not always efficient and may suffer from limitations among which are lack of flexibility and weaknesses in the integration of several clinical practice guidelines (CPGs) for the management of patients with multiple chronic disorders. We propose a framework based on an ontological modeling of CPG contents as rules. The ontology provides the required flexibility to adapt patient data and enable the provision of appropriate recommendations expressed at various levels of abstraction. To solve decisional conflicts that occur when combining multiple sources of recommendations, we proposed a method based on the subsumption graph of the patient profiles corresponding to the rules. A prototype CDSS implementing this approach has been developed. Results are given on a clinical case to illustrate the assets of ontological reasoning in increasing the number of issued recommendations and thereby the reliability of decision support.

Practice guidelines as topic; Knowledge bases; Ontology; Clinical decision support systems; Medication therapy management.

Introduction

Delivering optimal quality of care for all is one of the major challenges of modern medicine. Unwarranted variations of medical practices should be reduced [1], and improvement of care based on solid evidence should be promoted. Health agencies and medical professional societies develop clinical practice guidelines (CPGs), which are textual documents that synthesize the state of the art on the management of medical disorders. CPGs are expected to provide decision support for certain clinical situations, being one instrument of the promotion of evidence-based medicine. So far, their implementation remains insufficient. The challenge consists in a clear understanding of the reasons that prevent the use of CPGs [2], and the development of interventions to increase their implementation [3].

Clinical decision support systems (CDSSs) are considered as an efficient vector of CPG implementation. CDSSs rely on formalized knowledge bases and are usually integrated to electronic patient records to assist the clinician in her everyday practice. The integration of CPGs in CDSSs requires a preliminary formalization step of CPG contents [4]. CPG knowledge may be represented as a set of decision rules where each rule consists in the description of a given patient profile and its associated recommendation. Therefore, CPGs are modeled as clinical patient profiles for which recommendations are provided. Guideline-based CDSSs yield patient-specific recommendations by pairing the description of the actual patient with related CPG patient profiles. Despite their promise, several studies reported discrepancies between CDSS expectations and their effectiveness in promoting best practices, illustrating the existence of obstacles to their widespread use in routine [5, 6].

CPGs generally focus on a specific medical disorder, eg. Hypertension, Asthma, Obesity, etc. But, actual patients often present multiple pathologies and the management of multi-morbidity can be a real challenge for the clinician [7]. Indeed, this requires identifying CPGs related to the patient state, to gather every relevant recommendation, and to combine them accordingly [8]. Competing CPGs and their potential decisional conflicts are identified as a reason of non-adherence with CPGs [2]. Future CDSSs should account for the integration of multiple CPGs [9].

Clinical descriptions of theoretical patient situations are often not detailed in the same way depending on CPGs. Indeed, CPGs are usually written in free text by different consortia, sometimes in different languages. Therefore, the same concept might be described using different terms, and with stylistic variations. A standardized description is then required for representing CPG knowledge. Depending on CPGs, some patient characteristics may be described at different levels of abstraction, which requires the tacit knowledge that link them. For instance, kidney disease is mentionned as a co-morbidity in diabetes CPGs, whereas more specific precisions in terms of renal failure are considered in hypertension CPGs. This lack of normalization makes the identification of appropriate patient states complex. It may lead to an incomplete or bad characterization of the patient and consequently to the production of conflicting recommendations, incorrect recommendations, or even no recommendation. Indeed, it happens that guideline-based CDSSs are not able to match patient data with the premisses of recommendations, which can result in a problematic silence when the system does not provide any recommendation to the user. This may cause a loss of confidence and usually ends up with an abandonment of such systems.

While developping biomedical applications, ontologies (domain conceptualizations for representing CPG knowledge) can efficiently be used as a stable framework [10]. Our

assumption is that they could provide solutions to the seamless consideration of multiple CPGs within CDSSs.

We have developed a method based on ontologies to give CDSSs the flexibility needed to deal with patients with multiple pathologies. The aim of this paper is to describe the framework we developed where ontological reasoning is used to enrich the patient description at different levels of abstraction and thereby increase the number of appropriate recommendations. The approach allows to solve decisional conflicts exploiting the subsumption of CPG-based patient profiles in order to provide the most relevant recommendations. We have implemented a prototype CDSS applied to CPGs on hypertension (HT) and type 2 diabetes (T2D). We used an example to illustrate the impact, on the quality of the recommendations provided, of taking into account the ontological reasoning.

Methods

Our goal is to address the management of multiple CPGs, expressed at various levels of abstraction, within a functional CDSS. The approach relies on the use of ontological representation and reasoning. The first step deals with the construction of the knowledge base from multiple CPGs. The second focuses on the exploitation of the knowledge base and the processing of patient data to deliver patient-specific recommendations. The proposed framework aims at increasing the number of patient-specific recommendations while managing potential conflicts.

Hypertension and type 2 diabetes CPGs

Considering the management of cardiovascular risk in general practice, we first chose to consider HT and T2D. We used contemporary CPGs authored in 2014 by Vidal, a French company that markets a drug database and original medical content whose quality has been certified by the medical profession. CPGs include graphical clinical pathways that illustrate the process of care. Each step of the trees are then detailed by synthetic textual sections. CPGs also deal with particular cases (eg. HT and Pregnancy) and provide indications and contraindications of recommended drug classes.

Construction of the knowledge base

In a previous study [11], we performed a formalization of HT and T2D CPGs by manually extracting and conceptualizing the decision rules. As illustrated in Figure 1, decision rules are built on the IF-THEN model with the conditional combination of patient criteria in the IF-part and the recommended actions in the THEN-part. The IF-part corresponds to a patient profile described in CPGs. We obtained two rule bases: one for the HT CPGs and one for the T2D CPGs.

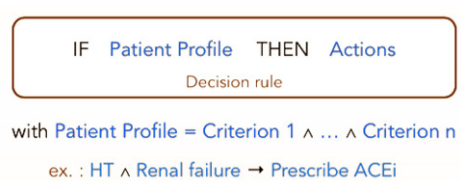

Figure 1 - Formalisation of decision rules

Decision criteria and actions were encoded in a single custom ontology. This ontology was inspired from the existing OntoIUrgences developed for the management of emergencies [12]. Concepts relevant to cardiovascular risk management were extracted from this emergency ontology, and supplemented by CPG-specific concepts required by our decision rules. We encoded the ontology in OWL. Concepts are related by subsumption, equivalence, and disjunction links so that every inference is valid. Figure 2 illustrates an extract of the custom ontology under the "Pathology" concept.

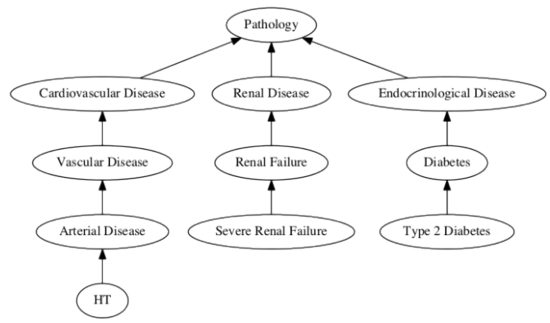

Figure 2 - Extract of the Pathology subgraph of the custom ontology

Generation of the graph of patient profiles

The patient profiles described in the IF-part of the rules are conjunctions of concepts from the ontology. Patient profiles correspond to new defined concepts and are consequently linked within the subsumption hierarchy of the ontology, some being more specific than the others. Following the ontological framework, there are two kinds of specificity: (i) the conceptual specificity which comes from the subsumption of atomic concepts (eg. "HT" is more specific than "Arterial Disease") and (ii) the logical specificity derived from defined concepts (eg. "HT ∧ Diabetes" is more specific than "HT"). The classification of patient profile/rules is performed automatically by an ontological reasoner. This yields a subsumption graph of patient profiles where the root is the least specified profile and the leaves are the most detailed ones. Figure 3 illustrates an extract of the profile subsumption graph for patient profiles of both HT and T2D rule bases.

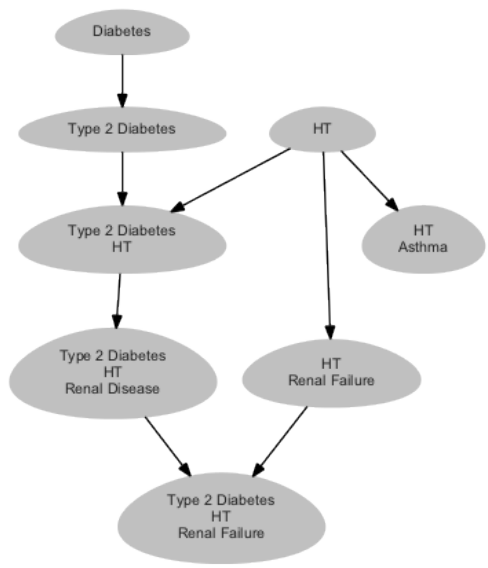

Figure 3 - Extract of the subsumption graph of profiles from HT and Type 2 Diabetes CPGs

Matching of decision rules

When an actual patient's clinical case is considered, patient data is first translated to match the concepts of the ontology. The actual patient description is then a conjunction of ontological criteria. The initial description of the patient is then enriched through the ontology. For instance, a patient described by "HT ∧ Diabetes" will be characterized by "HT ∧ Arterial Disease ∧ Vascular Disease ∧ Cardiovascular Disease ∧ Endocrinological Disease ∧ Pathology". In this framework, finding which decision rules apply for the patient consists in identifying all the CPG-based patient profiles that subsume the actual patient profile.

Management of potential conflicts

By using the subsumption of patient profiles, more rules than those that solely match patient data are, logically, considered for execution, whatever their level of abstraction, and whatever their originating CPG in case multiple rule bases from different CPGs have been merged. Potential conflicts may then be revealed and should be managed. We used the ontological representation of rule actions to detect such conflicts. When comparing every pair of matching profiles, we identified three possible cases:

1. No action conflict. Recommended actions are complementary and can be suggested without causing any decisional conflict. For instance, "Prescribe Anti-HT treatment" and "Monitor hypoglycemia" are two recommended actions of different nature and can thus be suggested together to the user.
2. Action conflict and profile subsumption. Recommended actions are conflicting and subsumption exists between the profiles from which actions have been extracted. The priority is given to the recommendation attached to the most specific profile. For instance, betablockers are recommended for patients suffering from HT, but contraindicated for patients suffering from HT and Asthma. Thus, the contraindication of betablockers overrides their recommendation in the case of a patient matching the "HT ∧ Asthma" profile.
3. Action conflict but no profile subsumption. In this case, recommended actions are conflicting but the originating profiles cannot be compared since there is no sumsumption link between them. Without additional encoded knowledge to solve this conflict, we cannot solve it automatically, and we chose to let the clinician decide what recommendation (if any) is the most relevant for his patient. For instance, for hypertensive patients, thiazide diuretics are recommended for diabetic patients but contraindicated for patient with renal failure. In the case of a patient characterized by "HT ∧ Diabetes ∧ Renal Failure", the system is unable to discriminate between the recommendations.

Analysis of the role of ontological reasoning

To assess the benefits of the ontological reasoning when merging several CPGs, we compared the results provided by the CDSS with the results of the same system when the ontological reasoning was disabled. To illustrate this, we used a simulated patient case profile which has to be a realistic situation of a patient suffering from multiple pathologies among which at least HT or Diabetes. Then, we executed the system and compared the characterization of the patient including inferred findings, triggered decision rules, and the recommendations of drug prescription.

Results

The custom CPG ontology built for HT and T2D CPGs is made of 500 concepts and includes 96 disjunction declarations. It is divided into two main parts: concepts related to the patient or decision variables (i.e. characteristics, pathologies, clinical signs) and those related to the clinical management or actions (i.e. treatment, goals, medical actions).

The rule bases contain 180 different rules for HT CPGs, and 94 different rules for T2D CPGs. These two rule bases share two common profiles ("Diabetes" and "HT ∧ T2D") which yields 272 different patient profiles for the unified rule base.

A CDSS has been developed to provide recommendations issued from HT and T2D CPGs. We used the JENA API for ontological reasoning, and rule inferences based on the set of patient data. A graphical user interface enables interaction with the user and the display of the recommended drug classes for each pathology as well as other recommended information (diet, prevention). Figure 4 displays a screenshot of the CDSS interface.

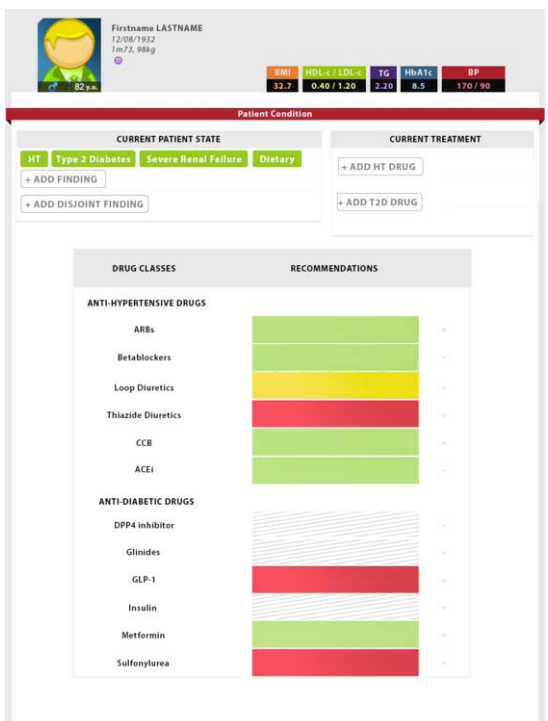

Figure 4 - Screenshot of the CDSS user interface

To illustrate how the system operates, we used the clinical case of a 83 year old male patient under dietary, with HT, T2D, and suffering from severe renal failure. His arterial pressure is 170/90 mmHg and his HbA1c rate is 8.5%. We run the system on this example patient with and without the ontological reasoning. Table 1 synthesizes the results obtained.

Without ontological reasoning, the system missed a contraindication to thiazide diuretics for people suffering from renal failure and recommended this class of antihypertensive drugs. When the ontological reasoning was enabled, the system detected a conflict about thiazide diuretics which are recommended for T2D patients, but are contraindicated for patient suffering from renal failure. Likewise, without ontological reasoning, the system missed the indication of

loop diuretics for patients with renal failure. Other actions that differ between the two execution modes of the system are not related to drug prescription and concern the other aspects of the management (risk factors, medical appointments, monitoring). It must be noted that the recommended drug prescription for the management of T2D is the same regardless of the activation of ontological reasoning.

Table 1 - Comparison of the CDSS execution with and without ontological reasoning on the example patient

Object	Without ontology	With ontological reasoning
Patient Concepts (input/inferred)	3/0 (HT, T2D, Severe Renal Failure)	3/11 (HT, T2D, Severe Renal Failure, *Arterial Disease, Vascular Disease, Cardiovascular Disease, Diabetes, Endocrinological Disease, Renal Failure, Renal Disease, Pathology*)
Incompatible Concepts	0	33
Incompatible profiles	0	136
Triggered profiles	15	22
Recommended actions	42	51
Contraindicated Anti-HT classes	—	Thiazide diuretics
Recommended Anti-HT classes	ARB, ACEi, Betablockers, Calcium-channel blockers, *Thiazide diuretics*	ARB, ACEi, Betablockers, Calcium-channel blockers, *Loop diuretics*
Recommended Anti-Diabetic classes	Metformin	Metformin
Contraindicated Anti-Diabetic classes	GLP-1, Sulfonylurea	GLP-1, Sulfonylurea

On the CDSS interface (see Figure 4), the drug prescription dashboard synthesizes the recommendations about drug prescription for the two pathologies. Drug classes are written on the left of the dashboard and the associated recommendations are indicated using color codes: red when the drug class is contraindicated, green when it is recommended, yellow when it is possible, and grey when no indication is given for this drug class in CPGs.

Discussion

In this paper we presented our work concerning the integration of ontological reasoning to handle multiple CPGs represented as decisional rules. The method has been implemented as a functional CDSS. We have illustrated the functionning of the system on an example clinical case. We compared the results obtained with and without ontological reasoning.

The number of concepts implicitely added by ontological reasoning is closely related to the construction of the ontology; it depends on the number of levels of specificity chosen during the modeling step. This choice has to be made by taking into account the levels of specificity of the decision rules. Indeed, a high number of additional concepts only has a meaning if it allows the triggering of more rules.

The CDSS with ontological reasoning provides, as expected, more recommendations than the classical approach. These additional recommendations were issued because rules of higher level of abstraction have been triggered. Decision rules used in the CDSS were indeed extracted from the text of CPGs and thus, inherited from text imperfections and inconsistency. Including ontological reasoning allowed to depart from the syntactical constraints of the text and to reduce such imperfections. By giving some flexibility in the characterization of a patient, we increased the number of triggered profiles including those that would not have been triggered by classical systems. The resulting recommendations are not only more numerous but also, thanks to our conflicts solving method, more adapted to the current patient case.

The lack of flexibility is pointed out as one of the reasons that clinicians don't keep using CDSSs. Ontologies bring the possibility to enrich the levels of abstraction in the management of patient profiles, and also to create, from static guidelines, dynamic pathways following the needs, the availability of the data and the usefulness of the recommendations. Other research works have incorporated ontologies for decision support as well as for other type of biomedical applications [13,14].

Besides content issues which are fundamental, but also apply to CPGs themselves, the usability of CDSSs and the clarity of the user interface are recognized as key factors for their adoption by health professionals. The real challenge lies in dealing with a lot of information and choosing which CDSSs to suggest to the clinician. We thus have to find a synthetic way to display the relevant provided recommendations and to highlight the most interesting ones. These aspects have to be further evaluated.

Conclusion

We propose a method based on semantic web techniques such as ontological reasoning to bring more flexibility to CDSSs and also offer the ability to deal with patients suffering from multiple pathologies by including several modeled CPGs. The method has been implemented as a prototype CDSS. In future works, we will enrich the current system with additional CPGs on the management of cardiovascular diseases (*e.g.* dyslipidemia). Then, we plan to assess the system both on the usability dimension and on the quality of the recommendations provided with a panel of general practictioners.

Abstract

In recent years we have witnessed the increasing adoption of clinical practice guidelines (CPGs) as decision support tools that guide medical treatment. As CPGs gain popularity, it has become evident that physicians frequently deviate from CPG recommendations, both erroneously and due to sound medical rationale. In this study we developed a methodology to computationally identify these deviation cases and understand their movitation. This was achieved using an integrated approach consisting of natural language processing, data modeling, and comparison methods to characterize deviations from CPG recommendations for 1431 adult soft tissue sarcoma patients. The results show that 48.9% of patient treatment programs deviate from CPG recommendations, with the largest deviation type being overtreatment, followed by differences in drug treatments. Interestingly, we identified over a dozen potential reasons for these deviations, with those directly related to the patients' cancer status being most abundant. These findings can be used to modify CPGs, increase adherence to CPG recommendations, reduce treatment cost, and potentially impact sarcoma care. Our approach can be applied to additional diseases that are subject to high deviation levels from CPGs.

Introduction

The modern medical landscape is characterized by a plethora of different treatment options for almost indistinguishable clinical statuses. While the development of new treatment modalities is beneficial, it also poses challenges associated with the growing body of evidence regarding the outcomes of different treatments.

As a consequence of the complexity of treatment possibilities and the presence of widespread variation in medical practice, it has become clear that a large fraction of patients do not in fact receive the best possible care [1,2]. Deviations from optimal care are abundant in diseases where treatment efficacy varies as a result of subtle changes in the clinical scenario as well as in cases where clear scientific evidence is not present, as is often seen in cancer [3,4]. Therefore, an important question in medicine is what leads clinicians to prescribe treatments that do not adhere to best practice.

One approach to monitor deviations from standard medical practice is by assessing adherence to CPGs. CPGs are collective sets of treatment recommendations that attempt to capture the best medical practices for different pathologies [5]. CPGs are promoted as a means to decrease inappropriate practice variation and reduce medical errors [6]. It is generally thought that clinician adherence to CPG recommendations is the primary means to achieve this goal. High levels of adherence to CPGs may indicate optimal care, whereas low adherence rates may suggest sub-optimal treatment. In reality, however, deviation from CPGs often reflects the fact that CPGs cannot be exhaustive; it is not feasible to cover the entire combinatorial space of patient parameters. Deviations from CPG recommendations may thus be beneficial, and it is expected that clinicians will use their personal judgement to contextualize individual patient decisions. In light of the above, previous work identified several barriers to adherence including physician familiarity with the CPGs, physician attitudes towards the CPGs, environmental factors, CPG implementation factors and patient-related factors such as preference [7,8].

Monitoring compliance to CPGs in the clinical setting can be labor intensive. Therefore, in this study we strived to automate the characterization of adherence to CPGs using natural language processing, data modeling and comparison algorithms. Our vision was to computationally parse electronic health records (EHRs) containing both structured and unstructured data to quantify adherence levels, categorize the types of deviations from CPG recommendations, and finally identify the potential rationale for these deviations.

We demonstrate our approach using EHRs of patients diagnosed with adult soft-tissue sarcoma (STS). STS is a group of connective-tissue based cancers that account for roughly 1% of new cancer diagnoses with historical five year survival rates of slightly greater than 50% [9]. These cancers have diverse anatomical origins and can derive from multiple somatic cell types. The variety of histologies results in the presence of multiple drug options and the different anatomical locations offer multiple surgical possibilities. As STSs are rare cancers with numerous treatment options, it is not surprising that prescriptions for patients frequently deviate from CPGs, making STS an ideal use case to evaluate our methodology [10,11,12].

Methods

Description of concepts

The CPGs used in this study were developed by the Lombardy Oncology Network, a data sharing network that contains over

fifty care premises in Northern Italy. Patient data used in this work were gathered at the Fondazione IRCCS Istituto Nazionale dei Tumori (INT), a network member and thought leader, from November 2006 to November 2012.

The CPGs contained hundreds of clinical cancer presentations (conceptually similar to diagnosis) with matching recommended treatments. There are multiple recommended treatments for each clinical presentation. A single CPG recommendation was defined as the unique coupling of clinical presentation, recommended treatment, and start/end date. The study involved 1484 separate CPG recommendations.

Individual clinical presentations were modeled as a data structure of the following clinical fields: tumor anatomic location, tumor depth (deep/superficial), tumor grade, tumor size, disease status, tumor histological type (liposarcoma, etc.) and surgical status (tumor resectable/not resectable). A clinical presentation included all or a subset of the fields. This modeling approach is standard for CPGs, and is similar to that used by the National Comprehensive Cancer Network [13]. An example of an STS clinical presentation in the Lombardy CPGs is: "Patient with adult soft tissue sarcoma located in the limb or torso with a deep, high grade, ≥5cm, localized tumor".

Treatment programs (TPs) were defined as sequences of medical procedures (treatment elements), for example "Wide surgical excision with adjuvant/neo-adjuvant radiotherapy". A treatment element contained items such as drug administration, surgery, radiotherapy, and transplantation. The Lombardy CPGs contained recommended TPs for each clinical presentation.

Once a physician selected a particular clinical presentation from the CPGs, the matching TPs were presented via the local EHR system. Physicians were able to prescribe a TP that was discordant with CPG recommendations (Figure 1). In doing so, they entered their alternative TP in free-text form. The EHR system recorded this decision as well as additional relevant notes provided by the physicians.

Data regarding the treatment was also entered into the EHR system by caregivers during TP execution. We applied standard NLP methods on this data to deduce the actual TP that a patient underwent. The extracted TP was compared to the CPG recommended TPs to assess adherence. The actual TP was considered to deviate if it was discordant to CPG recommendations, regardless of whether the prescription was according to the recommended TPs or not (Figure 1).

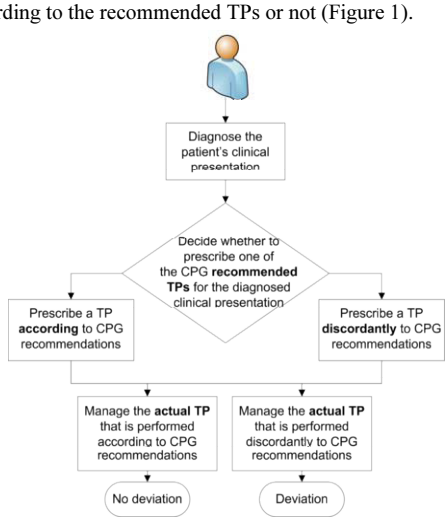

Figure 1 - CPG assisted decision making.

Application of NLP techniques

We applied NLP techniques on the EHR free text data to computationally retrieve the required information for this study. After Italian to English machine translation, we used the Unstructured Information Management Architecture (UIMA) framework to process unstructured information [14]. Our UIMA pipeline included tokenization, parts of speech (POS) tagging, normalization using standard terminologies in UMLS [15], entity and relationship extraction, semantic analysis, negation and disambiguation reasoning. Resulting structured annotations included drugs, diseases, procedures, symptoms, body regions and tumor characteristics. Relationship extractions were used to infer aspects such as the number of chemotherapy cycles, tumor size, tumor grade, and reasons for specific treatment prescription.

The IBM Advanced Care Insights platform (ACI) was used to run the UIMA framework. Within ACI, IBM Content Analytics Studio (ICA Studio) was used to build a Processing Engine Archive file (PEAR), which is a standard UIMA packaging format that can be deployed within any UIMA-compatible framework.

The basic building blocks of ICA Studio are dictionaries and rules. There are three types of rules: break rules that are used for tokenization, character rules that are used for pattern recognition of specific types of information such as dates, names and units, and parsing rules that are used to analyze tokens, other UIMA annotations, and their relationships.

ACI's built-in medical dictionaries contain RxNorm, SNOMED CT, ICD-9, ICD-10, LOINC, and HL7. We supplemented ACI with dictionaries containing chemotherapy drugs, local clinical studies, tumor parameters, and treatment reasons. Finally, ACI also contains entitiy mappings such as SNOMED CT to ICD-9 and ICD-9 to ICD-10.

Treatment program comparison

The results of the text analytics are structured annotations on the text. The annotations first need to be transformed to a pre-defined data model to enable advanced analyses. We therefore designed an actual TP model that defines the treatment which was given to patients (not shown here). The model was designed to enable comparison with the recommended TPs.

To categorize deviations, we identified the most similar recommended TP in the CPGs. The most similar recommended TP was found by assessing the degree of similarity between recommended and actual TPs. The differences between an actual deviating TP and its most similar recommended TP were classified into different categories.

The comparison approach used in this study had three stages. First, we analyzed the abundance of treatment elements to find extra or missing elements. We next used permutation comparison to detected changes in treatment element sequence. The final step was a comparison of the content of every treatment element itself; the specific properties of treatment element were compared. The third step enabled the detection of different chemotherapy drugs, different numbers of chemotherapy cycles, and different surgery types.

Extracting reasons for deviation

We used the same NLP techniques described above to extract reasons for deviation from CPGs. This was done by identifying relationships between extracted annotations using semantic parsing rules. For example, one can consider the following machine-translated sentence: "In light of extension of illness, the patient's age and preliminary activity of molecule in this particular histotype, starting chemotherapy

with gemcitabine". By detecting that the conjunction "in light of" connects the two parts of the sentence, we deduced that the first part of the sentence describes reasons for the given treatment, whereas the second part ("starting chemotherapy …") describes the treatment itself.

Manual validation

We performed manual validation of our computational results on a subset of randomly selected TPs (see results). Four human validators were exposed to the entire EHR records and CPGs. Different subsets of the validation dataset were allocated to each reviewer and results were compiled.

Results

Study setting, patient selection, and data cleansing

Our patient data contained adult STS patients treated at the Fondazione IRCCS Istituto Nazionale dei Tumori between November 2006 and November 2012. We acquired 5598 electronic patient discharge letters representing 2699 STS treatment programs on a total of 2151 different patients. 948 TPs with missing data were excluded consisting of: TPs that were follow-ups, where the actual TP was unknown, did not have at least one CPG recommendation due to CPG incompleteness, or were clinical studies not mentioned in the CPGs. This resulted in 1751 TPs consisting of 1431 patients for analysis (Table 1).

Table 1– Summary of TPs included in the study

Feature	Value
Number of TPs	1751
Male	957
Female	794
Duration	Nov 2006 – Nov 2012
Age range	18 – 100 (median 57)
Unique patients	1431

Quantifying factors that impact deviation frequency

Our computational approach identified deviations in 48.9% of the actual TPs, meaning that most given treatments were found to not fully comply with the CPG recommended TPs.

We next assessed non-clinical parameter correlation with deviation frequency. Strikingly, 35% of the TPs prescribed according to CPG recommendations in reality deviated from the CPG recommendations (Figure 2A). TPs that were prescribed discordantly to CPG recommendations did in fact deviate in 80% cases. Gender and age (cutoff set at median age) were not associated with deviation frequency.

Upon analysis of clinical parameters (Figure 2B), we observed that all disease and tumor parameters were associated with deviation frequencies, except for tumor location. This analysis portrays an expected trend in which poorer prognostic status (large, high grade, and deep tumors) is linked to substantially higher deviation levels. Indeed, the highest deviation frequency was found in metastatic disease (78%).

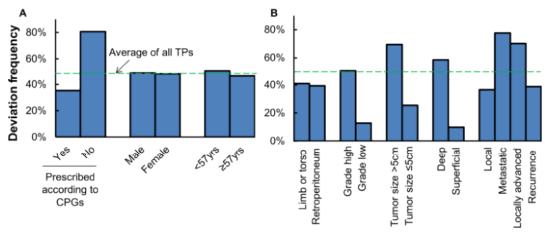

Figure 2 - Features associated with deviation frequency. (A) Demographic/adherence features (B) Clinical parameters. Not all features were specified in each TP. N=: limb/torso (1037), retroperitoneum (304), high gr (661), low gr (512), >5cm (371), ≤5cm (110), deep (445), superficial (331), local (1206), metastatic (359), locally adv. (57), recurrence (183).

Measuring prevalence of different deviation types

TP deviations can be classified using non-mutually exclusive categories. Tabel 2 presents the abundance of deviations that have added or removed treatment elements, exhibited differences in chemotherapy drugs, differences in number of chemotherapy cycles, and differences in surgery type.

The most abundant source of deviation was overtreatment, consisting of 39.7% of all cases in contrast to 12.7% for missing treatments. Notably, metastatic presentations had no excluded elements despite an overall average of 12.7% for all TPs. Also prominent was the observation that there was only a

Table 2 - Frequency of deviation types. Chemotherapy/surgery percentages shown with respect to TPs that included those elements.

Parameters	Added/Removed elements					Chemotherapy differences			Surgery differences	
	N (Dev TPs)	Added element	Missing element	Added and missing	Different order of elements	N (Dev TPs with chemo)	Different drug	Different cycles	N (Dev TPs with surgery)	Different surgery type
Prescribed according to CPGs	431	25.5%	17.6%	0.5%	13.9%	277	34.7%	36.8%	335	32.8%
Prescribed discordantly	426	54%	7.7%	1.6%	7%	301	44.2%	19.6%	239	16.3%
High grade	336	12.8%	24.1%	1.5%	17.6%	220	32.3%	35.5%	278	40.6%
Low grade	66	34.8%	10.6%	4.5%	7.6%	29	3.4%	0%	51	58.8%
>5cm size	258	13.6%	22.5%	0.8%	14%	138	27.5%	41.3%	225	50.2%
≤5cm size	28	46.4%	7.1%	3.6%	7.1%	19	5.3%	15.8%	23	39.1%
Deep	261	13%	23%	1.1%	13%	141	27%	39%	224	52.7%
Superficial	33	42.4%	18.2%	6.1%	15.2%	21	14.3%	14.3%	23	43.5%
Local	441	17.5%	20.6%	1.8%	17%	283	29%	31.4%	355	41.7%
Metastatic	279	57.3%	0%	0%	3.2%	232	10.3%	7.8%	113	0.9%
Loc. advan.	40	27.5%	37.5%	2.5%	12.5%	40	50%	12.5%	19	0%
Recurrence	143	41.3%	9.8%	2.1%	5.6%	98	48%	15.3%	84	16.7%
All TPs	857	39.7%	12.7%	1.1%	10.5%	578	39.6%	27.9%	574	26%

10.3% deviation rate of type 'different chemotherapy drug' for metastatic cases with administered chemotherapy. In general, disease parameters were more strongly associated with chemotherapy differences than surgical differences, with an exception being local/metastatic clinical presentations.

Identification of potential reasons for deviation

NLP parsing identified 1191 potential reasons for deviation among the 857 TPs that we labeled as deviations (average 1.4 per TP). 67.3% of the deviating TPs had one to four reasons and 29.7% had no identified reasons (Figure 3A).

Potential reasons for deviation were classified into five categories: cancer status, other clinical, current treatment related, previous treatment related, and patient preference related. Reasons for deviation that were based on cancer status represented the majority (59%) of all deviations (Figure 3B).

Deviation reasons were further classified into lower-level categories (Figure 3C). The cancer status category consisted of different tumor and disease progression parameters. Other clinically related reasons included demographics, oncological and non-oncological comorbidities, acute symptoms and overall clinical condition. The previous treatment related reasons include amount of previous treatment, poor previous response, previously severe side effects, and presence of residual margins after surgery. The patient preferences category included patient treatment requests or refusals. Lastly, current treatment related reasons consisted of anticipated treatment efficacy, impact on quality of life, and newly available clinical evidence. Deviations due to environmental constraints including lack of personnel or resources were rare and thus not presented.

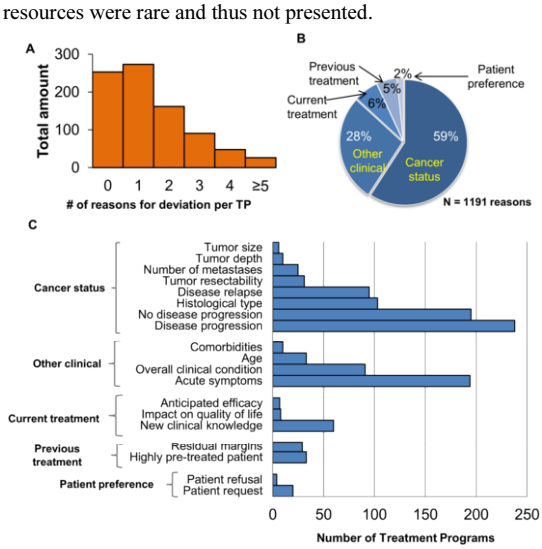

Figure 3 – Potential reasons for deviation. (A) Number of reasons of deviation per TP (N=857 deviating TPs). (B) Different categories of deviations. (C) Deviation subtype analysis (subtypes with n≥4 deviating TPs are shown).

The largest fraction of deviations appear to result from disease progression or a lack thereof, together with presence of acute symptoms. Interestingly, new medical knowledge was only a small fraction of potential deviation causes.

Manual validation

We performed manual validation on a dataset of 222 TPs that were randomly selected from the entire dataset. The validation dataset contained 136 TPs prescribed according to CPG recommendations and 86 discordant TPs.

We first searched for exact matches between NLP-retreived actual TPs to manually retreived TPs. Given this approach, minor or large differences between manually detected and NLP-retrieved actual TPs had the same effect on scoring. The recall for all TPs, TPs prescribed according to CPGs, and discordantly prescribed TPs was 0.71, 0.73, and 0.67, respectively. Chemotherapy cycles were not evaluated for comparison. The TP comparison framework detected differences between actual and CPG recommended TPs. As expected, manual validation showed that the comparison had rather high recall (0.88).

We also assessed deviation labeling. Deviation labeling relies on the accuracy of actual TP extraction and the TP comparison. We compared the quality of our deviation labeling algorithm to a default algorithm that labels TPs prescribed accordingly to CPG recommendations as 'no deviation' and discordantly prescribed TPs as 'deviation' (Table 3). The results show better performance in cases that were prescribed discordantly to the CPGs, while good recall was achieved in the remaining cases.

Finally, a random subset of 60 deviating TPs were selected from the validation dataset for manual analysis of detected reasons for deviation. Validation of detected reasons had the following recall: 0.67, precision: 0.78, and F1 score: 0.72.

Table 3 - Deviation labeling validation (algorithm vs default)

	Entire dataset (n=222)		**TP prescribed according to CPGs (n=136)**		**TP prescribed discordantly to CPGs (n=86)**	
	Alg	Def	Alg	Def	Alg	Def
Recall	0.87	0.62	0.80	NA	0.91	1
Prec.	0.65	0.66	0.47	NA	0.81	0.66
F1 val	0.74	0.64	0.60	NA	0.86	0.79

Discussion

In this work we developed computational techniques to characterize deviations from CPGs in adult STS across thousands of patient records. We identified deviations, classified them by types, and proposed reasons that may reflect the physicians rationale in deviation cases. Beyond the value of understanding clinical deviations, this analysis makes multiple findings that may be useful to sarcoma researchers and the decision support community.

One interesting finding was that approximately half (48.9%) of all TPs deviated from the CPGs. Noting the error present in NLP-based analysis, this value is comparable to a study published in 2012 that reported 54% adherence levels [10] and is higher than a study published eight years prior that had 32% [11]. While being a small sample size, this may suggest that compliance to CPGs is increasing for sarcoma over time.

In contrast to the above, we found that the current deviation level is roughly twice that of a recently published study showing 24% deviation frequency, a study whose data have included many of the same patients as in this work [12]. This discrepancy is due to the fact that deviations in the former study were defined as discordantly prescribed TPs, whereas in this study we analyzed whether the actual given TP deviated. This helps explain the observation that 19% of TPs originally prescribed discordantly to CPG recommendations were not in fact deviations. Conversely, we also found that 35% of all TPs prescribed according to the CPGs were actually deviations.

The observation that adherence to, or deviation from CPGs does not strongly predict if the administered TP adheres to the CPG, may have several causes. For instance, physicians may incautiously select a CPG recommendation with a genuine intent to write the actual prescription in free-text. Alternatively, CPG recommendations may not be clear and their selection may not be sufficiently simple. EHR quality may also play a role if detailed treatment documentation is challenging.

Deviation type analysis identified a large tendency to overtreat patients, representing 39.7% of deviation cases. Overtreatment (reviewed in reference [16]) was 3.1-fold more prevalent than missing treatments. The actual number is likely even higher since we manually observed upon inspection of EHR data that documents are missing for some patients. This issue was addressed by analyzing the treatment program fields, as these tend to summarize the complete course of prior treatment.

Overtreatment was especially evident for metastatic patients (Table 2), whom in general where prone to higher deviation levels (Figure 2). This is interesting when considering that metastatic patients had a relatively small amount of drug related deviations due to the large variety of different chemotherapy options at this disease stage. Deeper investigation of overtreatment cases can potentially assist in reducing treatment cost and improving quality of life.

Mining for deviation reasons can help inform physicians of their medical behavior during the decision making process. This knowledge can motivate specific questions that may impact care, for example why does tumor histological type potentially account for 8.5% of all deviations (Figure 3C).

Several factors that impacted our results warrant mention. First, as with most NLP based studies, our study was also subject to inaccuracies resulting from variability in the free-text representation of medical data. Second, our EHR-based dataset was composed of patient discharge letters, with an average of 2.6 documents per patient. As mentioned, a fraction of patients had missing discharge letters that we were not able to access. We partially addressed this issue by analyzing the treatment program fields. Finally, the study was performed assuming correctness of clinical presentations, although misdiagnosis is expected to be present in oncology care.

Our work focused on developing an integrated framework for understanding physician medical decisions in relation to CPG recommendations. In the future it may be possible to extend this analysis with outcome data, which could subsequently be integrated into EHRs to assist in decision making.

Conclusion

In this study we developed a methodology for a deeper understanding of adherence to CPG recommendations and implemented it in an adult STS use case. The resulting insights from this approach can be used to improve CPGs, to understand the decision making process of physicians, to identify cases where deviations may be beneficial, and to increase adherence to CPGs when deemed appropriate.

Acknowledgments

We thank members of the IBM Biomedical Informatics group and the sarcoma and head & neck departments at the INT for helpful discussions throughout the course of the project.

Abstract

Exposure to a large volume of alerts generated by medical Alert Generating Systems (AGS) such as drug-drug interaction softwares or clinical decision support systems overwhelms users and causes alert fatigue in them. Some of alert fatigue effects are ignoring crucial alerts and longer response times. A common approach to avoid alert fatigue is to devise mechanisms in AGS to stop them from generating alerts that are deemed irrelevant. In this paper, we present a novel framework called INITIATE: an INtellIgent adapTIve AlerT Environment to avoid alert fatigue by managing alerts generated by one or more AGS. We have identified and categories the lifecycle of different alerts and have developed alert management logic as per the alerts' lifecycle. Our framework incorporates an ontology that represents the alert management strategy and an alert management engine that executes this strategy. Our alert management framework offers the following features: (1) Adaptability based on users' feedback; (2) Personalization and aggregation of messages; and (3) Connection to Electronic Medical Records by implementing a HL7 Clinical Document Architecture parser.

Keywords:

Alert Fatigue; Alert Management Engine; Alert Management Strategy; Semantic Web; HL7-CDA.

Introduction

In recent years, medical Alert Generating Systems (AGS), such as vital signs monitoring devices, drug-drug interaction systems, and clinical decision support systems, have become prevalent in health-care environments. Extensive exposure to a large volume of alerts, especially irrelevant alerts, overwhelms users of these systems and causes alert fatigue. Alert fatigue leads to ignoring vital alerts, longer response times, anxiety in healthcare professionals and incorrect decisions [1]. Due to these undesirable effects, several attempts have been made to address the issue of alert fatigue. Existing approaches can be classified under two general categories: (a) *Suppressing alerts*: the rules generating alerts in AGS are modified so that irrelevant alerts are generated less frequently. For instance, in drug-drug interaction systems, if route of administration is considered in the head of rule, several alerts pertaining to nonexistent interactions will be avoided. In this approach, since the alert management strategy is implemented in the AGS, it cannot be reused in other AGS. Moreover, this approach is not readily applicable to situations where several AGS are operating concurrently; and (b) *Managing alerts*: in this approach, an alert management strategy is defined for each type of alert. An alert management engine monitors the generated alerts by the AGS and manages their lifecycles based on their management strategy. Hence, alert fatigue is prevented by less frequent and smarter generation of alerts as they can only be raised when they are in critical stages of their lifecycle and certain conditions are met. Since alert management is performed externally, this alert management strategy can scaled across multiple concurrent AGS.

In this paper, we present a novel alert management framework featuring an *Alert Management Strategy Language (AMSL)* represented as a Web Ontology Language (OWL) ontology; and, coupled with an *Alert Management Engine (AME)* that executes the alert management strategy based on patient information accessible from a *Health Level 7* (HL7) compliant Electronic Medical Records (EMR) using the *Clinical Document Architecture* (HL7-CDA [2]). We have identified and categorized the lifecycle of different alerts and have developed alert management logic as per the alerts' lifecycle. Our framework implements a set of unique features to address alerts fatigue, such as a smart alert counter that filters out irrelevant alerts based on their time stamps, alert notification adaptability based on users' feedback, aggregation of alerts to a unified alert, responding to the alert delivery medium and possibility of connecting to commercial EMR systems. We leverage semantic web technologies to represent the alerts and to manage them.

Related Work

Approaches to avoid alert fatigue can be categorized into three categories. In the first approach, the underlying rules generating the alerts are modified to limit the generation of irrelevant/repetitive alerts or to delay the notification of the alerts until a point that the alert becomes critical. For instance, in vital signs monitoring devices, generation of an alert regarding high heart rate can be delayed until a certain amount of time has passed since the heart rate has been more than a predefined threshold [3]. In another example, *Rule1* that represents theophylline–cimetidine interaction in a drug-drug interaction system is modified in terms of *Modified_Rule1* so that route of administration is taken into consideration to make the rule fire less frequently and more accurately [4]:

Rule1: If (theophylline and cimetidine)→ Alert (Name: theophylline –cimetidine, Message: "….")

Modified_Rule1: If (theophylline and (**oral** cimetidine)→ Alert (Name: theophylline –cimetidine, Message: "…")

The approach to modify alert generation rules to address alert fatigue has the following limitations: (1) the alert generation logic is encoded within the rules, and hence, modifications to the rules is local to the AGS and it cannot be reused by other AGS; and (2) if several sources of alerts exist, each AGS rule set needs to be modified which may eventually lead to inconsistencies across the multiple alert generation rules.

The second approach to address alert fatigue is to allow the AGS to generate the alerts, but subsequently filter the irrelevant alerts using an auxiliary alert management engine. To filter irrelevant alerts, domain experts' knowledge regarding relevancy of alerts is captured in terms of a classifier. In this approach, AGS users tag the alerts, as either relevant or irrelevant, in a normal no alert fatigue prevention setting. These tags are, then, used by machine learning algorithms to train a classifier to determine if an alert should be suppressed or presented to the user [5]. Disadvantage of this approach is the need for a large vole of training data that cover the entire breath of the alerts in different clinical scenarios, and the fact that the decision logic of such classifiers cannot be interpreted by healthcare professionals.

The third approach to avoid alert fatigue is to capture domain experts' knowledge in terms of an alert management language and represent the lifecycle of an alert—i.e. describing when and how often an alert should be shown to the user. Klimov et al. [6] have defined a comprehensive language to define alert lifecycles.

In our work, we pursue the third approach as it allows an explicit description of alerts and their lifecycles, which can be used to develop generic AGS. In comparison to Klimov et al. [6], our approach is different in the following ways: we define the concept of a *counter* that filters the alerts based on their currency—i.e. either the alerts are deemed too old to be relevant or are regarded as too soon to the previous alert in order for it to be meaningful. We also enhanced our framework by adding a set of desirable features such as adaptability based on user feedback, aggregation of messages, consistent alert management framework across several AGS operating concurrently, and connecting to EMR to be able to use patient information in alert lifecycle definition.

INITIATE: an INtellIgent adapTIve AlerT Environment

Our alert management framework shown in Figure 1 comprises the following components:

(1) An OWL ontology that represent our Alert Management Strategy Language (AMSL).

(2) Alert Management Engine (AME) that exposes RESTful web services for AGS to submit their generated alerts. This engine manages alerts based on the alert management knowledge encapsulated in an instantiation of the AMSL. To interpret the expressions that make use of lab test result and medication conditions, this engine contains an HL7-CDA parser that evaluates validity of expressions such as *allopurinol on hold* and *Synthroid dosage > 100mg*, which are representable in AMSL.

(3) CouchDB that is a NoSQL (JSON document based) database storing the following items:

a. HL7-CDA documents each representing a patient medical record.

b. Instantiation of the AMSL ontology stored as a RDF/JSON document that represents the lifecycle of alerts generated by the connected AGS.

c. Alert Status: each alert status represents how many times and when a specific alert has been generated for a patient. We will see an example of this later in the paper.

We used a document-based database to avoid normalizing our ontology and HL7-CDA documents into a relational table in order to store the documents as a whole.

Alert Management Strategy Language

In this section, we discuss AMSL, which is formalized using an OWL ontology. Instead of describing the ontology structure, we discuss the grammar of AMSL in the grammar discussed in this section, where [] represents an optional element, * represent an element that can be repeated from *0* to *n* number of times, and terminals are put between double quotes. An alert management strategy is represented by a sextuple:

Alert → ([AGSName], AlertName, [LifeCycle], [AlertConfig], PatientID*, UserID*).

UserID and *PatientID* show the list of users and patients that use this strategy for this alert. *AlertConfig* and *LifeCycle* are discussed in the rest of this section. *AGSName* names the AGS that is the source of the generated alert.

LifeCycle

LifeCycle represents the lifecycle of alerts and is defined as follows:

- LifeCycle → ([CfounterConfig], [SeverityConfig], [ActivationExpression], [InactivationExpression]).

CounterConfig of a *LifeCycle* defines a counter that represents the number of times an alert has been generated for a patient.

- CounterConfig → ([ResetDuration], [DurationBeforeIncrease]).

Alerts that are too old are deemed to be irrelevant, and hence should not be considered in the counter of that alert. The logic is as follows: if the time when the alert was last generated is more than *ResetDuration*, the counter for that alert is set to zero. Likewise, alerts that are generated too close to the previous one may be irrelevant as well. To account for this situation, if the duration between the last time the counter was incremented and the generation of the current alert is less than *DurationBeforeIncrease*, the counter will not be increased. As we will describe later, this counter is used in the calculation of severity and evaluation of activation and inactivation conditions.

- SeverityConfig→ ([MinSeverity], [MaxSeverity], [NumOfSteps]).

Severity of an alert during its lifecycle may change based on its counter number. Severity changes from *MinSeverity* to *MaxSeverity* in *NumOfSteps* steps as the counter increases. For instance, if the severity configuration is (0,1,10), severity of alert will linearly increase from 0 to 1 in 10 steps.

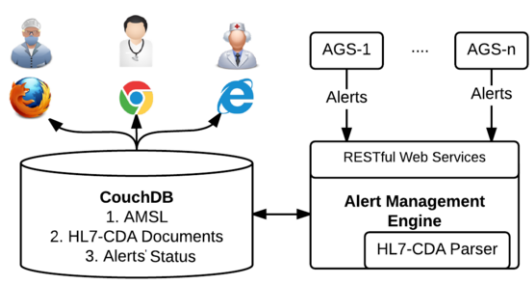

Figure 1 – Our Alert Management Framework

To avoid alert fatigue, an alert generated for a patient can be suppressed until the alert (or the patient) meets certain criteria. Until these criteria have not been met, the alert will not be activated (i.e. notified to the user). As an example, when a patient enters a high value for the blood pressure it will lead to generation of an alert. However, one high blood pressure value does not warrant immediate attention, as it may be a misreading or inaccurate measurement, hence such an alert can be suppressed, and only high blood pressure alerts that are generated within a specific time span may need medical attention. Another mechanism to avoid alert fatigue is to inactivate alerts that are not relevant anymore. An alert may be deemed irrelevant because its purpose has been accomplished. For instance, an active alert "Warfarin is recommended" can automatically become inactivated (i.e. hidden from user) when the patient is prescribed Warfarin. AME uses *ActivationExpression* and *InactivationExpression* in order to activate or inactivate an alert. An expression is defined as follows.

- Expression → Condition | (Expression | Condition, Operator, Expression | Condition).
- Operator → "or" | "and" .

Several types of conditions based on medications of a patient, lab test results, counter of the generated alert, or its severity may be defined:

- Condition → CounterCondition | MedicationCondition | SeverityCondition | LabResultCondition.

A *CounterCondition* is defined as follows:

- CounterCondition → (Comparator, Threshold).
- Comparator → "<" | ">" | "=" | "<=" | ">=".

Activation and inactivation of alerts may be based on their counter. For instance counter condition {"Comparator" : ">" , "Threshold" : 5} will be satisfied for a condition when its counter is 6 or greater.

- SeverityCondition → (Comparator, Threshold).

As we discussed previously, severity of a condition may change as the counter of the alert is changing. For instance, the severity condition (<, 0.5) is satisfied if severity of the generated alert is less than 0.5.

- MedicationCondition → (MedStatus | DosageChange | (Comparator, Threshold), MedicationName | MedicationCategory) .
- MedStatus → "active" | "onHold".

We can define conditions based on medications that exist in the health record of the patient. For instance, we can define a medication condition that is satisfied when a specific medication is *on hold*. Upon satisfaction of this condition based on patient record, the corresponding alert will be inactivated and removed from the list of active alerts shown to the user.

- LabTestCondition → ("existence" | (Comparator, threshold, unit) | TimesUpperLimit), labTestName.

Conditions based on lab test information of patients can also be defined. This type of condition can check existence of a specific lab test and whether its result is less or more than a specific threshold. The *TimesUpperLimit* value shows how many times value of the lab test result should be greater than the upper normal limit so that the corresponding condition is satisfied. For instance, {"existence", "labTestName" : "TSH"} will be satisfied if a TSH test result is present in the electronic medical record of the patient.

AlertConfig

AlertConfig represents how alerts are communicated with the user and aggregated in our framework. Receiving several alerts in one communication can potentially reduce the alert fatigue as relevant alerts are communicated and attended together.

- AlertConfig→ (CommunicationMedium, [AggregationConfig])
- CommunicationMedium → "SMS" | "e-mail" | "web-dashboard".
- AggregationConfig → ("non-aggregatable" | ("aggregatable", maxWait4Aggregation)).

CommunicationMedium represents the medium of communication for the generated alert. Alerts sent through a common communication medium can be aggregated if they are "aggregatable". *MaxWaitForAggregation* shows the maximum amount of time that sending a message can be delayed so that it can be aggregated with other messages. We will see an example of *AlertConfig* and alert aggregation in the next section.

Alert Management Engine (AME)

AME exposes RESTful web services that can be used by AGS to submit their generated alerts. Each incoming alert is a quadruple representing the AGS that has generated the alert, patient ID, the generated alert, and its time stamp. Incoming alerts will be used to update the corresponding JSON documents in CouchDB that represent the history and status of that alert-patient-user combination. In the rest of this section, we describe components and capabilities of AME.

Alert Management Algorithm

Upon receiving and incoming alert by AME, the following steps are performed in order to manage an alert:

1. Update alert's time stamps in CouchDB.
2. Update the alert's counter based on the time stamps.
3. Update alert's severity based on the counter.
4. Evaluate conditions.
5. Evaluate expressions based on conditions.
6. Alter state of alerts based on satisfaction of Inactivation and Activation Expressions.
7. Perform aggregation if possible.

HL7-CDA Parser

Medication and lab test conditions are evaluated based on patients' records. To connect to EMR, we assume patient records are received in Clinical Document Architecture (CDA) documents that is an XML based HL7 standard. HL7-CDA documents represent a snapshot of the patients' record at the time of creation. HL7-CDA documents are transformed to JSON and stored in CouchDB. HL7-CDA parser uses the Java JSON library to evaluate medication and lab test conditions. AME uses these evaluation results to calculate satisfaction of medication and lab test results conditions.

Adaptability and Personalization

We enable personalization in our framework by allowing each user-patient combination to have a separate configuration for each alert. Adaptability enables an alert management engine to tune its parameters in order to fit the needs of a specific user. Existing AGS provide this capability by enabling users to modify parts of the alert generation rules such as the

threshold for the blood pressure alert rules. Tuning AGS rules can be time-consuming and requires extensive knowledge of the AGS domain. We propose a mechanism to provide adaptability based on user feedback. Users of AME can provide two types of feedback: (1) an alert is being activated too frequently for a patient, and (2) an alert is being activated less frequently than necessary. This feedback can be used to tune the alert lifecycle parameters accordingly in the following two ways:

(a) Based on the received feedback, parameters that are responsible for the activation frequency of the alert are multiplied by a pre-defined coefficient. For instance, if the feedback is that an alert is being activated less frequent than necessary, frequency parameters are modified in the following way: *resetDuration* *= 1.05, *DurationBeforeIncrease* *=0.95, *MinSeverity* *= 1/0.95, *steps* = round (1/0.95 * *step*). Hence, our alert management framework can adapt to users' needs based on the received feedback from them.

(b) If the user is knowledgeable about the internal workings of AME, he can choose a specific lifecycle parameter such as *ResetDuration* or *MinSeverity* to be modified based on his feedback. As a result, that specific lifecycle parameter is multiplied by a predefined coefficient. For instance, if the user indicates that an alert is generated more often than needed because of *ResetDuration* parameter, this value is multiplied by 0.8 so that the counter is reset more often leading to less frequent activation of that alert.

Aggregation

To understand how aggregation is performed, we go through a simple example. Suppose that two alerts are of the same *AlertConfig* as listed below:

```
{"AlertConfig": { "Aggregatable" : "yes" ,
   "AggregationMedium" : "e-mail",
   "maxWait4Aggregation" : "15m"}}
```

Imagine the following alerts are generated for two different patients (PatientIDs = 12 and 33) and are supposed to be sent to a specific physician (UserID = 7):

```
{"alert": "Warfarin is recommended",
 "patientID": 33, "UserID": 7, "Status" : "active"
 "DocumentID" : "1eb7ee96b33fa120c89"}
{"alert": "patient at high risk of bleeding",
 "patientID": 12, "UserID": 7, "Status" : "active"
 "DocumentID" : "9eb9ee96b88fa000c57"}
```

These two alerts are aggregated by creating the following document in CouchDB by AME:

```
{"DocumentType" : "aggregatedAlert"
 "AlertDocumentIDs" : ["9eb9ee96b88fa000c57",
                       "1eb7ee96b33fa120c89"]}
```

Alert Lifecycle Categories

In order to define the lifecycle of alerts in the IMPACT-AF project[1], we defined 3 general categories of alert lifecycles, made a template for each category, and fleshed out that template for each alert in that category. In the remainder of this section, we review these categories.

Category1: Cut Off Point Alteration

This category represents the lifecycle of alerts that compare patient data to a pre-defined cut off value. To avoid alert fatigue, these alerts can be ignored until that patient's value passes an alternative cut off value. As an example, according to the domain expert, output of the rule "*IF bilirubin is greater than its upper normal limit THEN patient might have abnormal liver function*" can be ignored until bilirubin is greater than two times the upper normal limit*:*

```
{"ActivationExpression" :
  {"LabTestCondition" :
      {" TimesUpperLimit" : 2,
       " MedicationName" : "bilirubin"}}
```

Bolded values in the above example can be replaced to represent lifecycle of other alerts in this category. In the same fashion, different alternative cut off values can be defined for dosage of medications

Category2: Medication and Lab Test based Lifecycles

By considering the type and dosage of medications taken by patients, several irrelevant alerts can be suppressed. As an example, according to the following rule, a heart rate below 60 bpm is considered abnormal: "*If (heart rate < 60) → patient's heart rate is abnormal*". However, this alert would be of less clinical significant if it is not associated with taking a rate control medication. Filtering low heart rate alerts that are not accompanied by such a medication will potentially avoid alert fatigue without compromising patients' safety or unnecessarily interrupting clinicians' workflow. We define the corresponding lifecycle as follows for this purpose:

```
{"ActivationExpression" :
  {"MedicationConditon" : {"MedStatus"  : "active" ,
       "MedicationCategory" : "rate control"}}}
```

As long as the above expression is not satisfied, alert *patient's heart rate is abnormal* will not be shown to the user. Bolded values in the above example can be replaced to represent lifecycle of other alerts in this category. As another example of this category, to avoid alert fatigue, alert pertaining to the following rule should be inactivated when patient starts taking warfarin: "*If the patient has CHA2DS2-VASc score >= 2 THEN alert physician that Warfarin is recommended*". To accommodate this alert fatigue prevention strategy, we define the lifecycle of the above rule as follows:

```
{ "InactivationExpression" :
  { "MedicationConditon" :
    {"MedStatus"  : "active" ,
       "MedicationName" : "Warfarin"}}}
```

Category3: Counter and Severity based Lifecycles

Some alerts can be suppressed until they are generated a certain number of times over a predefined period. For instance, Canadian guideline for management of Atrial Fibrillation recommend tailoring dose of heart rate control medications to bring resting heart rate of a patient to < 100 bpm. The corresponding rule is implemented as follows in the IMPACT-AF rule engine: "*If (heartrate > 100) → patient's heart rate is uncontrolled.*" Setting 100 as a cut point will probably fire too frequent alerts if patient is right on the edge. When presented this matter to the Cardiologist acting as the principal investigator in the IMPACT-AF project, he suggested ignoring this alert unless the average heart rate is more than 120 bpm over 72 hours with readings recorded at least 12 hours apart. If 24 hours passes and the rule engine does not generates any alerts, we start counting again. To accommodate this alert fatigue prevention logic, we defined the lifecycle of this alert as follows:

```
{"counterConfig" :  {"ResetDuration" : "24h" ,
  "DurationBeforeIncrease" : "12h"},
  "ActivationExpression" :  {"CounterCondition" :
"{"Comparator" : ">", "Threshold" : 5}}}
```

Evaluation

To evaluate AMSL, five general practitioners were given a 20 minutes presentation on purpose of this language, its role in our framework, and several real world examples. Subsequently, participants were asked to assign an integer score from the range 1 to 5 (score 1 means that physician does not agree with the statement at all, and score 5 means that she completely agrees with the corresponding statement). Table 1 represents the percentage each score is chosen by the domain expert for the corresponding statement.

Table 1- AMSL Evaluation Statements and Percentages Each Score Is Give to each Statement[2]

Statements	Received Score				
	1	2	3	4	5
1.Purpose of AML elements are clear	0%	0%	0%	40%	60%
2. AML is easy to use	0%	0%	20%	60%	20%
3. AML can represent all aspects of alert fatigue prevention strategies	0%	40%	20%	20%	20%
4. All concepts in AML are useful for alert fatigue prevention	0%	20%	20%	40%	20%

Table 1 shows that majority of the participants find AMSL clear, easy to use, useful for and capable of representing alert fatigue prevention strategies. In the second part of the evaluation, we asked a domain expert to design 10 patient scenarios each composed of a sequence of 15 events making changes to health record of a patient (e.g., addition of a blood work or heart rate). Feeding these events to the IMPACT-AF rule engine generated 63 alerts. AME suppressed 34 of these messages. The remaining 29 alerts were aggregated into 14 atomic and composite alerts. We asked 5 general physicians to assign a number from the range 1 to 5 to statements 1, 2 and 3 for each aggregated alert, suppressed alert, and inactivated alert respectively. Table 2 represents the percentage that each score is given to the corresponding statement by domain experts.

Table 2 – AME Evaluation Statements and Percentages Each Score Is Give to each Statement[2]

Statements	Received Score				
	1	2	3	4	5
1. Aggregation is correct	3%	3%	11%	20%	63%
2. Suppression is correct	0%	1%	7%	21%	71%
3. Inactivation is correct	0%	0%	6%	4%	90%

Table 2 shows that most of the aggregations, suppression, and inactivation of messages have been performed successfully by AME according to the participants.

Conclusion

In this paper, we proposed a novel alert management framework that introduces unique features, such as: (1) a counter that filters effects of alerts that are too old or too new to be relevant, (2) alert severities that change by time, (3) possibility of defining conditions related to patients medications and lab test results, (4) adaptability based on users' feedback, (5) centralized management of alerts in case several AGS are generating alerts concurrently, (6) aggregation of alerts (possibly from different AGS) to reduce the number of alerts shown to the user, and (7) capturing communication medium information.

Moreover, our review of the literature shows that most of the alert management strategies are implemented for rule based decision support systems. Since our alert management framework is AGS dependent and does not make any assumptions regarding alert generation mechanism, it can be used to avoid alert fatigue in a variety of clinical decision support systems that use alternative technologies, such as neural networks or Bayesian belief networks.

An interesting future work is to explore the effects of alert management in general, adaptation, and personalization of alerts, in particular on patients' safety. For instance, in cases where physicians are heavily reliant on specific alerts for patients' safety, unpredictability of alerts due to varying parameters may potentially have perilous effects. In our framework, we defined a minimum severity to avoid this scenario. Other potentially dangerous scenarios should be identified and taken into consideration.

Abstract

An influence diagram (ID) is a method of graphical representation of uncertain knowledge, which can be employed to support decisions in health care using probabilistic reasoning. We aimed to describe the development of an ID to support the decision-making process in phase II at Cardiopulmonary and Metabolic Rehabilitation Program (CPMR). The development of the ID was carried out through the identification of relevant variables and their possible values, as well as the identification of details of each variable, in order to find a network structure that appropriately connects the nodes that represent the variables, with arcs linking acyclic graphs, and to build the graph using specialized knowledge and the conditional probability table for each node in the graph. In spite of the complexity of the interactions, the model obtained with the ID seems to contribute in the decision-making process in phase II CPMR, providing a second opinion to the health pratictioner and helping in diagnostic, therapeutic and decision-making processes, since it is useful in situations with non-linear modeling or with absent or uncertain information.

Keywords:
Cardiovascular diseases; clinical decision support systems; influence diagram; physical and rehabilitation medicine, probabilistc networks; rehabilitation.

Introduction

The Influence Diagram (ID) appeared for the first time in the United States during the 1980's as a way to represent a decision-making problem [1]. It is even more compact than a decision tree and can make explicit the probabilistic dependencies among variables. An ID is a graphical structure that allows the modeling of uncertain variables and decisions that explicitly reveal probabilistic dependency in a flow of information [2].

There are several benefits in the evaluation of a problem through ID operations such as: the algorithm executing the entire inference and analysis automatically; the analysis being made available in a representation which is natural for decision making; and the use of ID resulting in gains in processing, as it considerably reduces the size of intermediary calculations and the need for greater memory spaces.

Recent work has shown the viability in the use of ID in processes where variables are uncertain and decisions need to be taken starting from the probabilistic dependency in a flow of information as, for instance, in the Medical field [3-5], and Risk Evaluation [6].

The ID is presented in this paper is the selection of the best Cardiopulmonary and Metabolic Rehabilitation (CPMR) option for cardiac patients chosen in a safe and effective way.

Many studies about the enormous prevalence of heart disease suggested some treatment possibilities to minimize the negative effects of these disorders in a patient's quality of life [7-9]. There emerged the possibility of a non-pharmacological treatment: the Cardiopulmonary and Metabolic Rehabilitation (CPMR) [10, 11].

CPMR is the sum of the activities needed to ensure patients with heart disease achieve better physical, mental and social conditions [8-10]. Patients who adhere to CPMR programs experience improved quality of life, hemodynamic stabilization, metabolic changes, and improved vascular and psychological states, which are associated with better control of risk factors and improvement in lifestyle [15-16]. Studies have already demonstrated the cost-effectiveness of CPMR, which became necessary for the rehabilitation of patients affected by these diseases [8-9, 12].

However, there are several uncertainties surrounding the professionals who work in CPMR. Although the beliefs are strengthened and the uncertainties are reduced over years of experience and professional practice, there will always be a degree of uncertainty in each decision. A classic example observed in clinical practice is the prevalent use of the treadmill, with the use of the stationary bicycle restricted to patients who have a physical or mental limitation that prevents treadmill training. However, there are still uncertainties about whether the equipment chosen by the professional is suitable for the patient's specific clinical picture [11, 13].

Thus, based on the technological advances, the possibility of building decision support systems, the high prevalence of heart disease and the growth and recognition of the CPMR, this study aims to build a ID to support clinical decision for phase II CPMR in cardiac patients. This aims to assist non-specialist professionals in choosing the best CPMR option for cardiac patients in a safe and effective way.

Methods

This is a methodological study approved by the Research Committee (ComPesq) of the Federal University of Health Sciences of Porto Alegre (UFCSPA) under number 011/2013.

Participants

The data used in this study were obtained from the medical records of a cohort of cardiac patients in phase II CPMR, assigned by a referral center for cardiopulmonary and metabolic rehabilitation in the state of Rio Grande do Sul, Brazil.

Influence Diagram development

The methodology used to generate the ID began by reading the selected references and isolating clinical information that may influence the diagnosis [13], prognosis and treatment, or be related to the measures taken. The bibliography search and choice of variables was done by a field expert, with the choice of variables and future connections between them based on his knowledge of the field. This study used the variables listed in the scientific literature through consensus, guidelines and norms for CPMR [7, 10, 14, 17, 18].

The structure building can be carried out manually and was designed precisely this way, taking into account the causal relationships between selected variables [13]. The estimating probabilities was obtained from a cohort of data provided by a referral center for CPMR.

However, this does not invalidate the ID, because remains the exact same principle used by the expert to make the decision in scenarios where the quantitative knowledge of the problem is not known or clear [21, 23-25]. At this point, the cohort data provided by the referral center was critical, because it helped to quantify the frequency of clinical outcomes.

Validation

Data for validation [13] of the ID were obtained from the records of another cohort of patients in phase II CPMR, kindly provided by a referral center for CPMR in the State of Rio Grande do Sul called Instituto de Cardiologia do Rio Grande do Sul. Therefore, to assist with the observed frequencies, both situations were considered: the frequency of observations performed on data from the referral center and the decision based on expert's opinion.

Results

The quantitative data used for modeling the shape ID were obtained from a cohort of patients who attended a referral center from April 2012 to April 2013. Characterization of variables in this sample is described in the tables below.

Table I - Characteristics of the sample of 264 patients in phase II CPMR from a referral center

Variables	Mean	±SD
Age (years)	62	±12.35
Weight (Kg)	81	±16.67
Height (m)	1.65	±0.09
Systolic blood pressure (mmHg)	125	±19.35
Diastolic blood pressure (mmHg)	74	±12.11
Heart rate (bpm)	72	±13.18
Partial pressure of O_2 (%)	96	±10.54
Indirect Vo2	15	±5.61
Maximum voluntary ventilation (L)	51	±23.48
Predicted percentage of maximum voluntary ventilation	90	±46.81
Sits and stands	11	±3.51
Maximum inspiratory pressure	74	±33.08
Predicted percentage of maximum inspiratory pressure	79	±37.95
Maximum expiratory pressure	88	±42.91
Predicted percentage of maximum expiratory pressure	91	±49.29
6-minute walk test (m)	406	108.18
Predicted percentage of 6-minute walk test	82	±35.69
Gender-n(%)		
Male	160	(60.6)
Female	104	(39.4)
Ethnic group - n(%)		
Caucasian	223	(84.5)
Black	32	(12.1)
Other	9	(3.4)
Body Mass Index - n (%)		
Underweight	4	(1.5)
Normal weight	48	(18.2)
Overweight	102	(38.8)
Obesity (Grade I)	71	(26.9)
Obesity (Grade II)	27	(10.2)
Obesity (Grade III)	12	(4.5)
Main complaint -n(%)		
Fatigue	79	(29.9)
Dyspnea	26	(9.8)
Fatigue associated to dyspnea	29	(11)
Pain in lower limbs	13	(4.9)
Thoracic pain	13	(4.9)
Medicated for cardiac condition - n(%)	244	(92.4)
Time from event to recovery - (months)(median - Q1-Q3)	1	(1-3)
Main symptoms - n(%)

Table III – Major risk factors presented by 264 patients in phase II CPMR reference center

Risk Factor	Yes n	%
Dyslipidemia	150	56.8
Systemic hypertension	210	79.5
Sedentary	186	70.5
Diabetes mellitus	78	29.5
Obesity	73	27.7
Smoker	17	6.4
Former smoker	116	44.0
Active alcoholism	34	12.9
Ex-alcoholic	16	6.1
Positive family history	173	65.5

Legend: *n=absolute frequency, %=relative frequency.*

From the variables defined according to the guidelines and consensus and the data obtained in the cohort of patients, we obtained the ID below:

Figure 1: Influence diagram structured to assist in decision making to perform cardiopulmonary and metabolic rehabilitation.

The DI can represent the mutual and hierarchical relationships among many variables using probabilistic rules and therefore, in many cases, their application is more suitable for prognosis and diagnosis.

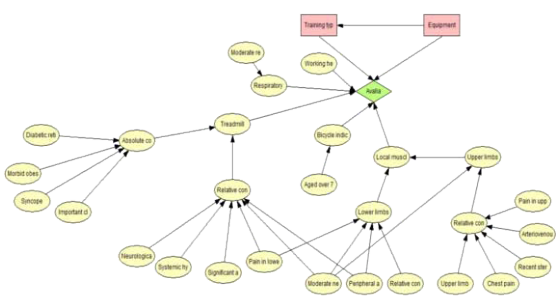

Figure 2: Influence diagram structured to assist in decision making (after entering the cardiopulmonary and metabolic rehabilitation program) regarding type of equipment and training to be used.

We present 3 randomly selected cases from the database to display the variables, the decision of the expert and the decision of the ID.

1. Patient W.L.B., male, 86 years old, 83Kg, 1.60 m height, BMI (body mass index) = 32 kg/m2, resting HR (heart rate) 41bpm. Main complaint is fatigue that comes to feel dizzy, but also refers severe pain in lower and upper limbs. Has positive family history of CAD, is sedentary, stress test is abnormal, predicted maximum inspiratory pressure at 115%. The decision of the expert is to send this patient for the following conduct:. Stretches (flexibility), bike to a HR of 96bpm working with the Borg scale below 3. There is no need for FES (functional electrical stimulation) and IMT (inspiratory muscle training) at the time and would not tolerate the treadmill.
   The decision proposed by the ID was: In failure to perform treadmill, perform bike; indicates the FES, with lower value indicates the RML (located muscle strengthening), does not indicate the IMT and indicates the flexibility. ID also makes reference to the preferable aerobic intensity.
2. Patient L.A.P., male, 48 years old, 76.5 kg, 1.68 m height, BMI (body mass index) = 27kg/m2, resting HR 67 bpm. Main complaint is chest pain. Patient referred not having other symptoms or risk factors such as dyslipidemia, hypertension and family history. Was treated with beta-blockers, anticoagulants and statins; lacked effort and the predicted maximum inspiratory pressure is 105%. The decision of the expert is to send this patient for the following conduct: Stretches (Flexibility); if the patient was not on betablockers, he could be working at a HR of 130bpm, with a range of less than 4 borg There is no need for FES and the IMT. The decision proposed by the ID was: Biggest indication to perform the wake of that bike, indicates the FES, with lower value indicates the RML, and does not indicate the IMT; indicates flexibility. The most indicated type of training is aerobic rather than anaerobic.
3. Patient A. D. S., female, 58 years old, 142Kg, 1.60 m height, BMI = 55Kg/m2, resting HR 136 bpm. AP (arterial pressure) 190/140. Main complaint is fatigue associated with shortness of breath at rest, chest pain, which in some cases reaches fainting and dizziness. Among the risk factors are dyslipidemia, hypertension, decompensated DM, smoking, family history of CAD. Patient states that she has prescriptions but forgets to take the medication. Referred pain in MIE; when the expert did a physical examination he noticed swelling, heat, redness and increased local temperature. The decision of the expert is to send this patient to consult with the specialist because he believes that under such conditions the patient is not able to perform CPMR.
   The decision proposed by ID contraindicated CPMR.

The predictions obtained with this method can inform the patient and the health practitioner whether a given treatment is being effective or whether a given condition is under control.

Discussion

In the simulation of case 1, ID agreed with the expert regarding CPMR and all conducts suggested by the expert are also suggested by the ID, such as opting for bicycle due to advanced age and dizziness presented by the patient. However, the expert, in his daily routine practice, does not

normally use the FES as a therapeutic resource and neglects this feature. Nevertheless, the ID patterned to act as an expert does not rule out the possibility of using the FES, and it indicates the treatment since there is no absolute contraindication [17] for possible use. The ID suggests the most appropriate type of training against HR proposed work, which is too often overlooked to the detriment of a care with the Borg scale and not HR work.

In case 2, the expert, based on information obtained from the patient, opted for the treadmill rather than the bike [19], but the ID, while proposing higher value which realizes the treadmill it, also elected the bicycle as an option. This is because for the ID there is a contraindication to prevent the person from doing bicycle, and only values the use of the treadmill by the patient's condition as favorable for further improvement when using the treadmill. The specialist professional unconsciously and routinely chooses the treadmill over the bike, forgetting that this is also a treatment option in some moments [20]. Since the patient has no inspiratory muscle weakness, both the expert and the ID do not suggest the use of IMT [18, 19].

In the third case, the instability presented by the patient is so great that the expert believed that the risks outweighed the benefits and chose not to indicate the CPMR. The expert guided the patient to return to the doctor and redo the query to stabilize her clinical condition, and then return to CPMR only after that [20,21]. The proposed ID according to the consensus of cardiac rehabilitation when informed with the information available on the patient also indicated that the ideal choice is to not perform CPMR at the moment [8, 10, 11, 14, 16, 22].

In the present study, we attempted to integrate the information obtained in the consensus guidelines, the current scientific literature, and the data obtained in a cohort of patients with the interpretation by experts in order to propose a model to implement a ID. This method explains all the relationships between the predictors and outcomes in a graphical model that incorporates uncertainty through the conditional probability associated with each node [21, 23-25].

The ID subsequently provides the possibility to interpret the relations between the variables and the possibility of intervening in the one that is actually negatively influencing the others. Despite the complexity of interactions, the model obtained in the implementation of an ID seems to be able to adequately describe the relations among the variables.

We understand that the BN and ID can be used in decision support systems in the CPMR. The influence diagram, which is a BN modified [22] for decision making, can provide the necessary tools to generate ideas about the decisions to be made [24, 25].

After defining the outcomes to be considered and the observed frequencies, the ID was modeled to support decision making regarding two moments in the CPMR process. At first, the ID was modeled to help decide whether the patient should perform CPMR. In a second stage, another ID was modeled so that if the answer to the first is "YES", the patient performs CPMR, while the second ID should help to define the modalities of CPMR and what type of equipment and training are best recommended to the studied patients.

Our study was limited regarding validation and statistical analysis of the first ID, since it considers the variables from medical records prior to CPMR and this information was not available in the databank. The databank was exclusive for patients already assigned to CPMR, and theoretically the first ID answered “yes” to follow to the second propagation.

It is expected to continue in the evolution of this research and to associate the ID built to the Simulator of Clinical Cases in Health, in order to obtain a tool to be used in cardiac rehabilitation classes. We also intend to develop an application software for smartphones based on this ID, and make it available to academic students of physical therapy to assist in the learning of phase II CPMR.

Furthermore, our research group aims to improve the development of this ID for CPMR and to develop an ID that addresses all phases of CPMR.

Our group will continue with this form of work and wants to further address the temporal matter. The temporality of the relations between the nodes of the BN is known and generates problems in building them due to false causal effects.

This difficulty is already known and described, and is especially important for networks that express this type of causal relationship between variables (nodes) over time. However, causality can arise from multiple contexts where every node has an influence on a child node. The structural contingencies that may modify these influences, if modified over time, make it more difficult to adequately represent the knowledge in the form of a BN. Many clinical decisions have temporal relationship. Appropriate measures in the initial phase of a condition may be inadequate in the late phase, and vice versa.

Conclusion

It is believed that the ID can significantly contribute to the construction of knowledge, assist in the decision making process and encourage future physical therapists to associate health with biomedical informatics.

Despite the complexity of the interactions, the model for the implementation of the ID seems to be able to predict the scenarios in which the new variables can be incorporated or analyzed, contributes in the health customization process, and ultimately provides a second opinion for the health professional helping the diagnostic, therapeutic process and decision making of the physiotherapist.

Abstract

By the use of extended intelligent information technology tools for fully automated healthcare-associated infection (HAI) surveillance, clinicians can be informed and alerted about the emergence of infection-related conditions in their patients. Moni—a system for monitoring nosocomial infections in intensive care units for adult and neonatal patients—employs knowledge bases that were written with extensive use of fuzzy sets and fuzzy logic, allowing the inherent un-sharpness of clinical terms and the inherent uncertainty of clinical conclusions to be a part of Moni's output. Thus, linguistic as well as propositional uncertainty became a part of Moni, which can now report retrospectively on HAIs according to traditional crisp HAI surveillance definitions, as well as support clinical bedside work by more complex crisp and fuzzy alerts and reminders. This improved approach can bridge the gap between classical retrospective surveillance of HAIs and ongoing prospective clinical-decision-oriented HAI support.

Keywords:
Healthcare-associated infections; Automated surveillance and monitoring; Clinical alerts; Fuzzy sets and fuzzy logic; Moni.

Introduction

During the last two decades, healthcare-associated infection (HAI) surveillance evolved from rather limited research projects to widespread mandatory quality management (QM). Since HAI surveillance depends on clinical data collected by experienced healthcare workers and infection control practitioners (ICPs), it requires human resources that are usually not continuously available or interfere with other equally important healthcare requirements.

Provided that relevant data can be automatically collected and analyzed by intelligent software, fewer human resources are required to make surveillance data available for infection prevention and control (IP&C), adverse event monitoring, and other fields of patient safety and clinical QM.

Now that systems for IP&C have been established and become more sophisticated, we seem to have reached a point where the actual benefit of these measures is questionable and needs to be assessed [1]. Although HAI surveillance and control have a strong ethical background, the demand for evaluating IP&C in terms of its cost-effectiveness and its relevance in health economy is justified.

This infers a higher level of complexity, calling for new methodological measures to deal with the system appropriately and economically. Here information technology (IT) will play a significant role. With the transformation and results of the Moni system for IT-backed clinical HAI monitoring, we show the potential of this new approach.

Moni was initially designed as a bacteria and antimicrobial resistance monitoring tool. Later it was expanded to clinical data acquisition and was attached to a complex knowledge-processing rule engine, allowing for the interpretation and aggregation of clinical and laboratory findings in patient records. It was intended for automated detection and surveillance of HAIs and their retrospective reporting [2].

From our clinical colleagues we learned that the generally accepted international HAI definitions are of limited value in routine bedside work. Using almost the same dataset, they prefer sensing changes in their patients' clinical condition in a prospective patient-specific manner. This implied extension of terms and definitions in the existing surveillance systems. In particular, uncertainties in definitions and propositions must be considered when trying to assess borderline cases. To address these aspects, fuzzy-set- and fuzzy-logic-based technology was implemented for data and rule processing in Moni. This fundamentally new approach opened new perspectives.

Methods

Moni IT system

Moni is a system for automated nosocomial infection monitoring and surveys, alerts, and reports. This large-scale IT system is in operation at the Vienna General Hospital (VGH), the main teaching hospital of the Medical University of Vienna, with approximately 2,100 beds and 14 intensive care units (ICUs).

The system provides two separate clinical applications: Moni-ICU for adult patients and Moni-NICU for neonates. Moni's main characteristics are fully automated data transfer from electronic sources, the implementation of medical knowledge bases, and the use of specific processing algorithms that rely on these knowledge bases and evaluate, aggregate, and interpret clinical data in a stepwise manner until patient data can be mapped to the included HAI definitions.

Data sources

Moni's data sources are the ICU's patient data management systems (PDMSs), which include administrative and clinical patient data as well as data from the central medical-chemical laboratory information system (LIS). In addition, microbiology data are derived from a separate LIS. All data are sent through a communication interface to Moni's data warehouse, which is the starting point of all subsequent data processing steps.

HAI surveillance and alert definitions

Moni's surveillance is based on the criteria and textual definitions issued by CDC/NHSN, Atlanta [3], ECDC, Stockholm [4], and the KISS criteria issued by the German National Reference Center for Surveillance of Nosocomial Infections, Berlin [5]. Moni's alert criteria are based on established surveillance rules, but were adapted to clinical needs. For instance, parameter definitions of clinical concepts were changed to avoid over-alerting [6].

Arden Syntax

The HAI surveillance and alert definitions were translated into Arden Syntax, version 2.7 [7], by a small team of clinical informaticians and experienced infection control specialists and clinicians. Arden Syntax is a medical knowledge representation and processing scheme for the development of clinical decision support systems. The syntax is maintained by Health Level Seven International [8], and new versions are regularly approved by the American National Standards Institute. A recent report on the Arden Syntax software (compiler, engine, server, database connector) embedded into state-of-the-art service-oriented software architecture can be found in [9].

Data and knowledge processing

Administrative, clinical, laboratory, and microbiological patient data from the PDMSs and the LISs are processed in a stepwise pipeline of aggregation, interpretation, and evaluation [10]. The first steps are pre-processing (checking for missing data and plausibility) and feature extraction (e.g., calculation of means and scores). This is followed by interpretation and intermediate to high-level clinical concept evaluation, for which a package of hierarchically interwoven medical logic modules (MLMs)—the building blocks of Arden-Syntax-based knowledge representation—was established. The topmost clinical concepts are the HAI surveillance and alert definitions to be evaluated. Many of the encoded clinical entities are modeled as fuzzy sets and the inference steps are performed by applying fuzzy logic.

The result of this automated processing is a list of HAIs whose definitions are either fulfilled or fulfilled to a certain degree. This evaluation is based on all available patient data, not only of the selected day but dating back to seven days. HAIs whose definitions are not fulfilled are not displayed.

Fuzzy terms and fuzzy logic

When trying to model uncertainty in clinical medicine, a distinction must be made between linguistic and propositional uncertainty.

Most clinical entities, such as fever or leukopenia, are linguistic concepts with gradual or fuzzy transitions between normal and pathological states—this is known as linguistic uncertainty. Such entities are formally modeled by fuzzy sets introducing a borderline range or transition zone between neighboring concepts.

Propositional uncertainty, in contrast, refers to uncertainty in medical conclusions. This is modeled by truth values between zero and one. One example is a patient in intensive care whose body temperature is in the normal range, but the patient is on external thermoregulation. He/She needs external cooling to decrease his/her body temperature and reduce risk. Since we have a strong but indirect hint towards "fever", the proposition "if thermoregulation then fever" is assigned a truth value smaller than 1.0 (here we assigned 0.8).

Table 1 shows the thresholds of the clinical concepts *increased body temperature, increased C-reactive protein, leukopenia,* and *leukocytosis*. The column "pathological range" contains thresholds as defined in the HAI surveillance definitions published by CDC/NHSN [3], ECDC [4], and KISS [5]. Data assigned to this column are constitutive elements of the surveillance results of these HAIs—provided the other relevant clinical concepts for this infection also fall into this definite pathological range.

The column "borderline range" is an additional range for borderline values and for assigning fuzzy degrees to the respective concept under consideration. By doing so, a body temperature of 37.9 °C signifies increased body temperature to the degree of 0.8. This column will include those patient days for which the clinical concept evaluation yields a near-pathological value, but misses the crisp thresholds defined for classical surveillance.

In classical surveillance, all data in the "normal range" and under the "borderline range" will be regarded as non-pathological and not concurring with the respective HAI surveillance definition. They are cut by a crisp threshold into "black and white". In contrast, the HAI alert criteria are furnished with borderline ranges to recognize tendencies and sense clinically important developments in the patient's state.

Table 1 – Four clinical concepts and their definition by fuzzy sets in the Moni-ICU knowledge base

Clinical Concept (Unit)	**Fuzzy Set**		
	Normal Range	**Borderline Range**	**Pathological Range**
Increased body temperature (fever) (°C)	< 37.5	37.5 – 38.0 [1)]	> 38.0 [2)]
Increased C-reactive protein (CRP) (mg/dl)	< 1.0	1.0 – 6.0 [3)]	> 6.0 [3)]
Leukopenia (WBC/mm^3)	> 5,000	4,000 – 5,000 [4)]	< 4,000 [2)]
Leukocytosis (WBC/mm^3)	< 11,000	11,000 – 12,000 [4)]	> 12,000 [2)]

[1)] as defined by clinicians
[2)] as defined by CDC/NHSN [3], ECDC [4], and KISS [5] for retrospective surveillance purposes
[3)] as defined by clinicians; CRP is an early phase protein, useful as an "infection radar" for prospective purposes
[4)] as defined by clinicians; white blood cell count (WBC) is a slowly reacting indicator, important for surveillance purposes

Study on fuzzy terms and fuzzy logic

In a retrospective study encompassing data for the whole of the year 2011, we analyzed all patient stays in ten ICUs for adult patients of the VGH. All patients aged 18 years or older were included, except admissions for less than 48 hours and the first 48 hours of longer admissions [4]. All clinical concepts and all included HAI surveillance definitions were established according to [4]. However, the borderline ranges were defined by clinical experts from the VGH in our group, referred to as clinicians.

The aim of the study was to determine the extent of borderline pathological states and borderline HAI results in the population under investigation, as a result of applying fuzzy terms and fuzzy logic.

For the analysis, data filtering and cleaning were done in both Python and Microsoft Excel 2007.

Results

Moni's routine operation

At present Moni is established at the VGH for ten ICUs with 87 beds for adults, and four neonatal ICUs with 51 positions. The ICUs and the microbiology department provide about 30,000 relevant data items for Moni-ICU and Moni-NICU every day. For each of the 138 patients, the available knowledge packages containing 72 MLMs for Moni-ICU and 160 MLMs for Moni-NICU are invoked automatically. Clinical concepts, higher-level intermediate clinical concepts, and the topmost HAI definitions are evaluated.

Results of fuzzy terms and fuzzy logic study

During the study period, 2,105 patients stayed at one or more of the selected ICUs; 1,253 patients were male (59.5%) and 844 female (40.1%); gender was not recorded for eight patients. The patients' ages ranged from 18 to 98 years (median 61 years; inter-quartile range 22). In total, 2,429 patient stays were recorded, amounting to 24,487 patient days. The duration of the stay ranged from 2 to 135 days (median 6 days; inter-quartile range 8). Of the 24,487 patient days, 162 were unaccounted for due to export and registration problems, which left 24,325 for data analysis.

For the analysis, we considered the definitions of bloodstream infection (BSI), general central-venous-catheter-associated infection (CRI2), microbiologically confirmed symptomatic urinary tract infection (UTI-A), and not microbiologically confirmed symptomatic urinary tract infection (UTI-B) [4]. Pneumonia was omitted because radiology findings are not yet part of the automated data importation into Moni-ICU. We also did not include local central-venous-catheter-associated infection (CRI1) because its definition in the knowledge base did not contain any fuzzy sets or fuzzy rules.

Table 2 (the first four lines) shows that a significant number of patient data fall into the established borderline ranges (11,474 of 97,300 = 11.8%). This is a relatively high number and indicates a possible near miss in case of HAI surveillance, but a clinically useful indication for HAI alerting.

As shown in Table 2 (last line), in 12.5% of the patient days, at least one of the definitions of the included HAIs (BSI or CRI2 or UTI-A or UTI-B) was fulfilled; a further 2.5% yielded a borderline result, i.e., fulfilled to a certain degree. Notably, in the case of several fulfilled HAI definitions only one was counted, where "present" superseded "borderline" and "borderline" superseded "absent". Moreover, in 606 patient days these data constellations obviously yielded an HAI borderline result. These borderline HAI results are shown, the data are explained fully, and clinicians have the option to explore and judge these results.

Furthermore, the majority of HAI surveillance definitions require microbiology test results. If not available (no specimen for culture taken), classical surveillance would record the respective patient day with "no HAI" despite the presence of clinical signs of infection. Applying "weaker" definitions of HAI surveillance definitions, many of those patient days will fall into the "borderline" category.

Validation of fuzzy sets

Whether the definitions of the fuzzy sets for clinical concepts were adequately chosen to capture those borderline values that rightly generate borderline HAI surveillance results were tested and reported on in a previous study [11]. This investigation was based on central-venous-catheter-associated infections (CRIs) and confirmed, in statistical terms, that most of the expert-defined fuzzy sets and logical constructs currently included in the knowledge base of Moni-ICU are an accurate representation of the CRI borderline patient population.

Clinical studies

Studies addressing the aspect of efficacy have shown the excellent conformance of Moni-ICU with an established clinical reference standard, as well as Moni-ICU's superiority in minimizing time demands on the infection control team with respect to electronically supported versus purely human surveillance. The results can be found in [12, 13].

Table 2 – Frequency distribution of the results of four clinical concepts modeled by fuzzy sets, as well as the topmost HAI definitions (based on a total of 24,325 patient days)

Clinical Concept	Absent n (%)	Borderline n (%)	Present n (%)
Increased body temperature (fever)	16,074 (66.1)	3,421 (14.0)	4,830 (19.9)
Increased C-reactive protein (CRP)	4,383 (18.0)	5,841 (24.0)	14,101 (58.0)
Leukopenia	22,991 (94.5)	668 (2.8)	666 (2.7)
Leukocytosis	15,169 (62.4)	1,544 (6.3)	7,612 (31.3)
BSI or[1)] CRI2 or UTI-A or UTI-B	20,687 (85.0)	606 (2.5)	3,032 (12.5)

[1)] inclusive disjunction with precedence of "present" over "borderline" over "absent"

Table 3 – 3x3 contingency tables for four clinical concepts and the topmost HAI definitions

Clinical Concept		**BSI or[1)] CRI2 or UTI-A or UTI-B**		
		Absent	**Borderline**	**Present**
Increased body temperature (fever)	*Absent*	13,911 (57.2)	484 (2.0)	1,679 (6.9)
	Borderline	2,855 (11.7)	122 (0.5)	444 (1.8)
	Present	3,921 (16.1)	0	909 (3.7)
Increased C-reactive protein (CRP)	*Absent*	4,130 (17.0)	152 (0.6)	101 (0.4)
	Borderline	4,890 (20.1)	453 (1.9)	498 (2.0)
	Present	11,667 (48.0)	1 (0.0)	2,433 (10.0)
Leukopenia	*Absent*	19,578 (80.5)	564 (2.3)	2,849 (11.7)
	Borderline	569 (2.3)	42 (0.2)	57 (0.2)
	Present	540 (2.2)	0	126 (0.5)
Leukocytosis	*Absent*	13,201 (54.3)	551 (2.3)	1,417 (5.8)
	Borderline	1,306 (5.4)	54 (0.2)	184 (0.8)
	Present	6,180 (25.4)	1 (0.0)	1,431 (5.9)

[1)] inclusive disjunction

Discussion

"Crisp" and "fuzzy" definitions

Surveillance as well as benchmarking count on unambiguous consensus definitions, which can easily be shared in networks, but are often compromises negotiated in long expert discussions. Clinicians and intensive care specialists dislike stolid definitions; they prefer a more flexible interpretation of patient data with focus on transition from normal to pathological states, and on borderline situations.

The Moni IT system provides retrospective population-specific infection surveillance related to classical infection surveillance, as well as prospective patient-specific high-level data aggregation for clinical support in early detection of infection. Here, fuzzy logic revealed its potential and aroused the interest as well as cooperation of intensive care specialists.

Benefit of borderline

It should be noted that our analysis counted patient days in which HAI criteria were present and not HAI episodes, each of which usually lasts for several days. International networks report their rates in numbers of HAI episodes per, such as 1,000 patient days or device days (which means days under specific exposure).

Patient days with fever, increased CRP, or leukocytosis were counted more often than days with fulfilled HAI definitions (see last column in Table 2). This can be explained by two facts: a) infection is only one of several conditions which trigger such pathologies, b) HAI definitions are composed of a number of pathologies, often including microbiological verification of the infective agent, all of which must be present. Since microbiological verification of the infective agent is a significant part of many HAI definitions, omission of specimens for microbiological investigations leads to underreporting of HAIs and might explain at least part of the borderline group in our analysis.

The borderline HAI group (2.5% of the totally tested 24,325 patient days) is not very large, but adds another fifth to the number of days with HAIs. It is—by the design of surveillance definitions—not relevant for retrospective surveillance. For the clinician, however (especially when he/she checks Moni's results at least once a day), it might serve as a "radar" for early detection of an incipient HAI. This is very valuable prospective information and a priceless benefit for the individual patient.

The absence of elevated body temperature in 6.9% of patient days, although the patients' data were fully compatible with one of the HAIs (Table 3, first line), might be explained by the frequent use of external thermoregulation for patients with fever (for instance with a cooling blanket). Hence, body temperature was considered normal in patients receiving external thermoregulation. The latter is captured by a separate fuzzy rule, which was not investigated in the present study.

Patient days with fever, increased CRP, leukopenia or leukocytosis fell either into the "absent" or the "present" class of the topmost HAI definitions, but never in the respective "borderline" class—except for one patient day with increased CRP and one with leukocytosis (Table 3, middle column). This can be explained by the following: a) a single clinical concept may or may not be part of a specific HAI definition, and b) a HAI definition is fulfilled when only one of a number of clinical concepts applies (i.e., when the rule defines that either A or B or C is present). We regard this as further proof of the previously reported [12] excellent precision of Moni's interpretation of infection-relevant clinical data.

The numbers and percentages in Table 3 in the borderline categories need further analysis, which will be the subject of another study. It may be stated here, however, that the numbers reflect the previously mentioned difference between clinical concepts as part of HAI definitions and the entire HAI definition itself, as well as different "constituents" of different HAI definitions.

Legal considerations

As long as Moni is applied for surveillance purpose—whether for in-hospital, national, or international quality benchmarking—it is not regarded as a medical device in accordance with the European Medical Device Directive 93/42/EEC. Even when the surveillance functionality of Moni is used by ward physicians at the patient's bedside to evaluate the patient's clinical condition (with potential impact on diagnosis and therapy), the intended use of Moni—as defined by the manufacturer—is strictly confined to surveillance.

Moni's alert component differs in this regard. The medical purpose here—as defined by the manufacturer—is to alert the attending physician, identify infection as early as possible, and incorporate the fact into the patient's treatment and care. Thus, the alert component is a medical device.

At present, the application of Moni's alert section is under clinical evaluation. It is being used and tested by several key clinical users who have received appropriate instructions.

Methodological perspectives

Moni-ICU was designed as a purely knowledge-based system with detailed explanatory capabilities. It does not rely on machine learning. The applied clinical knowledge for HAI surveillance is based on international consensus surveillance criteria, which are well known to the medical community. In addition, extended clinical experience is employed to establish useful alert criteria. The explanatory system clearly states what is included in the system and what is not, thus providing full transparency of any inferred clinical result. The approach of stepwise abstraction and aggregation is very similar to human reasoning in clinical medicine. Fuzzy set theory and logic avoid "jumps" in reasoning.

Conclusion

High precision of surveillance results, fully automated acquisition of relevant clinical and laboratory data, and significant time saving for ICPs have been prominent features of earlier versions of this electronic surveillance tool. Now, with broad application of fuzzy set theory and fuzzy logic, the scope of the system has been widened significantly. Comprehension of the inherent uncertainty of linguistic clinical terms and clinical or practice-based propositions, and thus straightforward "intelligent" processing of patients' borderline values, make it a powerful clinical extension of classical infection surveillance.

Abstract

Treatment recommendation is a nontrivial task – it requires not only domain knowledge from evidence-based medicine, but also data insights from descriptive, predictive and prescriptive analysis. A single treatment recommendation system is usually trained or modeled with a limited (size or quality) source. This paper proposes a decision fusion framework, combining both knowledge-driven and data-driven decision engines for treatment recommendation. End users (e.g. using the clinician workstation or mobile apps) could have a comprehensive view of various engines' opinions, as well as the final decision after fusion. For implementation, we leverage several well-known fusion algorithms, such as decision templates and meta classifiers (of logistic and SVM, etc.). Using an outcome-driven evaluation metric, we compare the fusion engine with base engines, and our experimental results show that decision fusion is a promising way towards a more valuable treatment recommendation.

Keywords:

Clinical decision support system, Decision fusion, Treatment recommendation.

Introduction

Clinical Decision Support (CDS) provides recommendations from organized medical knowledge and patient information to improve healthcare delivery. A variety of CDS systems have been proposed and implemented. From the perspective of methodology, some CDS systems are knowledge-driven, such as the computerization of clinical practice guidelines, and some are data-driven, such as the discovery of unknown patterns and trends in a large volume of patient data. From the perspective of analytics, some CDS systems are descriptive, such as getting the most frequently used drugs from similar patients, some are predictive, such as the estimation of clinical outcome for taking a certain drug, and some are prescriptive, such as a long-term planning for the optimal intervention at every possible patient state.

Considering that each CDS system has its own strength and weakness, we might not only leverage a single CDS system, but also apply decision fusion technologies to combine multiple CDS systems' results. Actually, in real life, it is natural to consult "several experts" before making a final decision. As it si said, two heads are better than one. The extensive benefits of decision fusion have been shown up in the Netflix Grand Prize in 2009 [1], which was an open competition to predict user ratings for films, and the winner combined the previous three teams' results to achieve a 10.09% improvement. In addition, the Heritage Health Prize in 2012 [2] was an open competition to predict how many days a patient would spend in a hospital in the next year. Again, fusion methods were widely used by both milestone winners and final winners in this competition.

In literature, the research field of "decision fusion" is known under various names, such as multiple classifier systems, mixture of experts and ensemble learning [3]. A general solution of prior arts is the fusion of different (data-driven) learning algorithms with different parameter settings, e.g., trying various features and datasets. However, for clinical decision support, esp. in evidence-based medcine, not only the data-driven learning algorithms are useful, but also the knowledge-driven modeling techniques are greatly helpful. In this paper, we propose a decision fusion framework for a treatment recommendation system, which combines both knowledge-driven and data-driven approaches.

To be convinced of the benefits of decision fusion, we need evaluation metrics, comparing the results from base decision engines with the results from our fusion engine. However, we observe that state-of-the-art evaluation metrics [4], such as precision, recall and RMSE (Root Mean Square Error), are not applicable for evaluating treatment recommendation systems, due to the *partially observed ground truth*. In machine learning, the term "ground truth" refers to the known facts about the training data set in terms of the learning tasks. Taking the Netflix Grand Prize as an example, the ground truth is the actual user ratings for films, while taking the Heritage Health Prize as another example, the ground truth is the actual days a patient would spend in a hospital in the next year. However, as far as for treatment recommendation, what's the ground truth? A naïve answer might be the actual prescription in real data. But, is that right? Suppose that drug A was recommended by a decision engine, and the physician did choose drug A as the prescription, but unfortunately, the patient outcome of using drug A was bad. In this respect, could we mark the recommendation of drug A as correct? Another story is that drug B was recommended by an analysis module, but the physician chose drug C as the prescription, and the patient outcome of using drug C appeared good. Thus, could we mark the recommendation of drug B as incorrect? What if the patient outcome of using drug B becomes better than using drug C? Therefore, we call it the *partially observed ground truth* (i.e., not all decision options are completely observed with outcomes), and in this paper, we propose an outcome-driven measure for evaluating treatment recommendation systems. Here, we remark that the fusion itself has no impact on the "partialness" of the ground truth. Actaully, it is the "partialness" that brings challenges for evalution of treatment recommendation systems, including the base and fusioned ones.

For experiments, we implement a decision fusion framework, which combines three base decision engines. The first engine is a knowledge-driven engine based on clinical practice

guidelines (CPG [5]). The other two are data-driven engines, of which one is a descriptive analytics based on patient similarity (PSA [6]), and the other engine is a predictive analytics based on outcome prediction (PRE). Using different fusion algorithms (such as decision templates and meta classifiers), we compare the evaluation results and conclude that fusion does help to provide treatment recommedations in a more valuable way.

Methods

We first present a decision fusion framework, followed by the introduction of three base decision engines. Next, we describe the fusion engine with a variety of fusion algorithms. Finally, an outcome-driven evaluation metric is defined, which will be used to compare the fusion engine with base decision engines.

Decision fusion framework

As shown in Fig 1, we propose an open framework for decision fusion. A number of decision engines can contribute to the fusion framework. We implement a fusion engine that gets input from base decision engines. On the client side (such as the clinical workstation or mobile apps), we display the treatment recommendations from each of the component, as well as the final decision from the fusion engine. End users have the privilege to see the outcome from all engines.

The fusion engine has two phases. First is the training phase, where all the results from base decision engines will be fed into a fusion engine to learn a fusion model. Second is the testing phase, where an instance that uses the output of base decision engines as features is created, and the trained fusion model predicts the final outcome. Every base decision engine has been either trained well by its own data source (such as PSA and PRE) or modeled well by its own knowledge source (such as CPG). The training and testing phases are meant for the fusion, rather than any base decision engine.

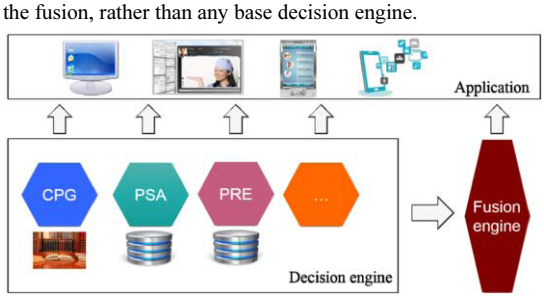

Figure 1 - The decision fusion framework

Decision engine

A decision engine itself provides treatment recommendations, but its methodology and analytical principles may differ from each other. Table 1 shows three different perspectives. The differentiation of decision engines results in the requirement to consult "several engines" before making a final decision.

Technically, CPG [5] is a knowledge-driven decision engine, which computerizes the NICE clinical guideline for Type 2 diabetes. At design time, guidelines are defined as standard (XPDL)-based business processes, where clinical conditions are represented using GELLO expressions. At run-time, a process engine would invoke a query adaptor to retrieve clinical data and a GELLO engine to evaluate clinical conditions whenever a decision-making is needed during the care process. Consequently, clinical recommendations are generated for lifestyle intervention and drug therapy, etc. For example, given a patient who is overweight and whose blood glucose is inadequately controlled by lifestyle interventions alone, CPG would recommend to start Metformin.

Table 1 – Decision engines

	Methodology	Analytics	Source
PSA	Data-driven	Descriptive	An EHR dataset
PRE	Data-driven	Predictive	An EHR dataset*
CPG	Knowldege-driven	Prescriptive	The NICE clinical guideline for Type 2 diabetes

Whereas, PSA [6] is a data-driven decision engine based on the patient similarity analytics that uses an EHR dataset from one of the largest hospitals in China and its affiliated community centers in order to manage type 2 diabetic patients. For example, given a patient encounter, the descriptive analytics of PSA reports that 75% similar patients take Metformin, while 15% similar patients take Insulin, and the rest take a combination of Insulin with oral anti-diabetic drugs. We employ various feature selection algorithms to identify the factors that affect physicians' prescription decisions. Given a patient encounter, his/her clinical conditions are represented using a vector of selected features, and we would find out the K most similar prescription instances, where the similarity is measured by the Euclidean distance between the representing feature vectors. Finally, PSA outputs a list of frequently presented medication options (among the K most similar prescription instances), and each option is attached with its occurrence percentage.

PRE is also a data-driven decision engine based on the outcome prediction analytics. The engine uses the same EHR dataset used by PSA but different features. For example, given a patient encounter, the predictive analytics of PRE reports that taking Insulin would get good outcome with support degree of 0.78, while taking Metformin would get good outcome with support degree of 0.54. Given a decision option, we collect the instances whose prescription is the same as the given decision option, and label its outcome as good or bad by comparing the next HbA1c test result after treatment with the current one. Thus, instances are grouped by different decision options, and we perform the feature selection (correlation based) and model training (logistic regression) per group separately. Then, given a patient encounter, for each decision option, his/her clinical conditions are represented using a vector of selected features, and we test it with the corresponding trained model. Finally, PRE outputs a list of decision options, and each option is attached with its support degree of good outcome.

Fusion engine

In the book [3], numerous methods for decision fusion have been presented. Based on the output of base decision engine, the fusion types are categorized into two: one is the fusion of label outputs, and the other is the fusion of value outputs. As described earlier, our base decision engines, CPG outputs labels, while PSA and PRE output values. It's easy to transform the CPG outputs as values, by assigning the label (which CPG recommended) with value of 1, and others (which CPG did not recommended) with value of 0, given a

patient at an encounter. Also, we can transform the PSA and PRE outputs as labels, but unavoidably, would have information loss. For instance, we could choose the most frequently presented medication option as the label for recommendation in PSA, and we could choose the decision option with the highest support degree as the label for recommendation in PRE. In this way we only keep the top one recommendation and ignore the lower ranked decision options – such a transformation from values to labels is not desirable. Consequently, our decision fusion framework is unified as a fusion of value outputs (and we will do a transformation from labels to values, if any base engine outputs labels).

Next, we will present a formal definition for our fusion engine. Suppose $E = \{e_1, ..., e_n\}$ be the set of base decision engines, $O = \{o_1, ..., o_m\}$ be the set of decision options, $v_{ij}(x)$ is the value that a decision engine e_j gives to the decision option o_i, for an instance x, $1<=i<=m$ and $1<=j<=n$. The fusion engine will take the following matrix $v(x)$ as an input, for each instance x.

$$v(x) = \begin{pmatrix} v_{1,1}(x) & ... & v_{1,n}(x) \\ ... & v_{i,j}(x) & ... \\ v_{m,1}(x) & ... & v_{m,n}(x) \end{pmatrix}$$

For fusion algorithm, we first apply the approach of decision templates [7]. At training phase, we calculate a decision template DT_i (as defined below) for each decision option o_i, where S_i is the set of training instances whose presecription is the same as the decision option o_i with good outcome, and N_i is the number of S_i. That is, DT_i is the mean of values of all training instances who take the decision option and get good outcome. Here, we highlight that S_i consists of training instances with good outcome, because our fusion is outcome-driven, instead of just learning the physicians' decisions (i.e. prescriptions, which do not always result in good outcomes).

$$DT_i = \frac{1}{N_i} \sum_{x \in S_i} v(x)$$

At testing phase, we calculate the squared Euclidean distance $d_i(x)$ between a decision template DT_i and $v(x)$ for an instance x, where $DT_i(k, j)$ is the $(k, j)^{th}$ entry in DT_i.

$$d_i(x) = \frac{1}{m \times n} \sum_{k=1}^{m} \sum_{j=1}^{n} (DT_i(k, j) - v_{k,j}(x))^2$$

The fusion engine outputs a list of decision options, and each option is attached with its distance value.

Besides decision templates, we also leverage various meta classifiers provided by Weka (a Java libarary for data mining [9]) to implement fusion algorithms. The main idea is to consider the values generated by base decision engines as new features, and feed them into a classifier for classification. Specifically, for each decision option o_i, we learn a model Mi, and the training data consists of instances x whose prescription is the same as the decision option o_i. The feature vector of x is $<v_{i1}(x), ..., v_{in}(x)>$, with label of 1 for good outcome and label of 0 for bad outcome, where $v_{ij}(x)$ is the value that a decision engine e_j gives to the decision option o_i, for 1<=j<=n. Thus, a variety of classifiers such as logistic and SVM (support vector machine) could be used for this meta-classification problem to decide whether the decision option o_i is a recommendation for an instance x.

Evaluation metrics

The motivation of decision fusion is "to do better" than base decision engines. This wish of "to do better" needs some evaluation metrics. As mentioned above, the often used metrics [4] such as precision, recall and RMSE are not applicable, when evaluating treatment recommendation systems, because we have only the partially observed ground truth – i.e., not all decision options are completely observed with outcomes. Formally, we denote $q(x) \in O$ as the prescription of an instance x, i.e., $q(x)$ is one of the decision option in O. Next, we denote $t(x, q(x))$ as the outcome of an instance x taking the prescription $q(x)$, where $t(x, q(x))=1$ means good outcome and $t(x, q(x))=0$ means bad outcome.

Back to the output of engines. All engines ouput values, but the values have different meanings. For example, PSA outputs the percentage of similar patients who takes the same decision option, and PRE outputs the support degree of good outcome which takes the given decision option, while the fusion engine outputs the distance between the decision template and the given decision option. Therefore, a value itself contributes little for evaluation, but a ranked list ordered by values does mean a lot. In particular, a rank score is calculated according to the position of prescription in a ranked list, which avoids to be overlooked when it's lowerly ranked.

For a formal representation, we denote $r_j(x) = <p_1, ..., p_m>$ as the ranked list of an instance x recommended by an engine $e_j \in E \cup \{e_0\}$ where each $p_k \in O$ is a decision option in O, and the subscript k means its position at the ranked list. Here, the base decision engine set E is union of the fusion engine e_0. We note that both PSA and PRE approach gets the recommended ranked list in descending order (because the more similar patients or the more supports, the better for recommendation), while our fusion algorithm of decision templates would get the recommended ranked list in ascending order (because the shorter distance, the better for recommendation).

Next, we denote $g_j(x)$ as the rank score of an instance x, given an engine $e_j \in E \cup \{e_0\}$. The following calculation means that, given a ranked list $r_j(x) = <p_1, ..., p_m>$ as recommended by an engine e_j, for any $0<=j<=n$, the prescription $q(x) = p_k$ is located at the position k, if an instance x taking the prescription $p(x)$ has good outcome, then $g_j(x)=(m-k)/(m-1)$, else $g_j(x)=(k-1)/(m-1)$. In particular, if the ranked list for recommendation does not contain the prescription, then its position is set as $k=m$. We note that, in spite of the partially observed ground truth (i.e. prescription with its outcome in real data), this calculation takes all recommended decision options into account, with information loss as little as possible.

$$g_j(x) = \begin{cases} \frac{m-k}{m-1} & if\ t(x, q(x)) = 1 \\ \frac{k-1}{m-1} & if\ t(x, q(x)) = 0 \end{cases}$$

$$where\ r_j(x) =< p_1, \ldots, p_m > and\ p_k = q(x)$$

The score of an engine e_j is calculated as $g_j = \frac{\sum_x g_j(x)}{\sum_x 1}$ for any $0<=j<=n$. Using this outcome-driven evaluation metric, we can directly compare the score g_0 of our fusion engine e_0 with other scores g_j of base decision engines $e_j \in E$.

Results

Our experimental dataset is an EHR dataset from one of the largest hospitals in China and its affiliated community centers that manage type 2 diabetic patients. After anonymity, it consists of 3150 encounter instances of diabetic patients. Their prescriptions are categoried as 7 types of decision options: METFORMIN (metformin alone), ARFA (either insulin secretagogues or α-glucosidase inhibitors), TZD (either thiazolidinediones or DPP-IV inhibitors), BI (two oral anti-diabetic drugs), TRI (three oral anti-diabetic drugs), INSULIN (insulin alone), and COMBINED (insulin and oral anti-diabetic drugs). For the outcome of glucose control, we use the widely adopted clinical ranges (also cited in [8]): HbA1c <= 6.4: normal; 6.5 <= HbA1c < 7: well controlled; 7 <= HbA1c<9: moderately controlled and 9 <= HbA1c: poorly controlled. Each patient's prescription outcome is labeled by comparing the next HbA1c test result after prescription with the current one. The outcome is labeled 1 (good) if the HbA1c level moves into a lower range, or remains in the well-controlled range, otherwise it is labeled as 0 (bad). In our dataset, there are 2574 instances of 3150 as labeled 1.

Given an instance, different base decision engines use different feature vectors as the input. Specially, CPG has 19 features, including overweight (BMI>24), old (age>70), etc. By feature selection, PSA identifies 39 features, such as average of glucose, value of HbA1c, and maximum value of HbA1c, etc. It's interesting that CPG considers the age status (e.g. old if age>70), while PSA considers the age (e.g. age of 72) and the age at the earliest diabetes diagnosis (e.g. age of 45). A more complicated case is PRE, which has 7 learning models for the 7 types of decision options. For example, the METFORMIN model in PRE has 13 features, while the ARFA model in PRE has 8 features.

In spite of different input features, the base decision engines have a uniform output format, i.e. v_{ij}, the value that a decision engine e_j gives to the decision option o_i, for an instance x, where e_1=CPG, e_2=PSA, e_3=PRE, and o_1=METFORMIN, o_2=ARFA, o_3=TZD, o_4=BI, o_5=TRI, o_6=INSULIN, o_7=COMBINED.

Regarding the fusion engine as e_0, it also follows the unified output format, and below is the sample output for an instance x. According to the real data, this instance x is prescribed o_2=ARFA, as having good outcome.

	CPG	*PSA*	*PRE*		*FUSION*
*o*1	1	0.4	0.6068		0.4286
*o*2	0	0.31	0.6943		0.2772
*o*3	0	0.01	0.7489		0.3196
*o*4	0	0.18	0.6580	⇒	0.5817
*o*5	0	0	0.5761		0.6454
*o*6	0	0.09	0.6674		0.4961
*o*7	0	0.01	0.5939		0.6164

The ranked list of x recommended by CPG is $r_1(x)=<o_1>$, PSA is $r_2(x)=<o_1,o_2,o_4,o_6,o_7,o_3,o_5>$ in descending order, PRE is $r_3(x)=<o_3,o_2,o_6,o_4,o_1,o_7,o_5>$ in descending order, and after fusion using algorithm of decision templates, it is $r_0(x)=<o_2,o_3,o_1,o_6,o_4,o_7,o_5>$ in ascending order.

The rank score of x given by CPG is $g_1(x)=(7-7)/(7-1)=0$, because $r_1(x)=<o_1>$ does not contain o_2, and its position is set as $k=m$, where $m = 7$ is the number of decision options. It makes sense, since CPG does not recommend o_2 which however results in good outcome in real data, and such a CPG recommendation gets the score of 0. For PSA, $g_2(x)=(7-2)/(7-1)=5/6$, because the position of o_2 in $r_2(x)$ is $k=2$ and $m=7$. It also makes sense, since o_1 is preferred by PSA than o_2, and such a PSA recommendation cannot get the full score of 1, but only 5/6. Similarly for PRE, $g_3(x)=(7-2)/(7-1)=5/6$. Here, we point out that, although PSA prefers o_1 while PRE prefers o_3 for the top one recommendation, the prescription o_2 is located at the same position $k=2$ in both PSA and PRE, so the rank scores $g_2(x)$ and $g_3(x)$ are the same. Finally, for fusion, $g_0(x)=(7-1)/(7-1)=1$, because the position of o_2 in $r_0(x)$ is $k=1$ and $m=7$. It matches the practice that such a fusion recommendation is appreciated.

Fig. 2 illustrates these treatment recommendation results, which could be integrated to the clinician workstation or mobile apps, and end users could have an overview about the engines' opinions in a comprehensive way.

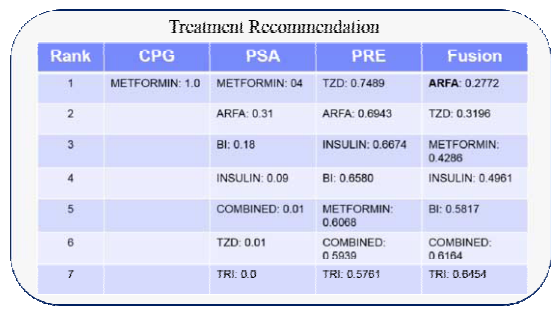

Figure 2 – Treatment recommendation results

To compare the evaluation results, we do 10-fold cross validation. That is, the total of 3150 instances is randomly partitioned into 10 equal size subsamples. Of the 10 subsamples, a single subsample (of 315 instances) is retained as the validation data for testing, and the remaining 9 subsamples (of 2835 instances) are used as training data.

Table 2 – Evaluation results

Treatment recommendation systems		Rank score
Decision engine	CPG	0.6771
	PSA	0.6815
	PRE	0.6062
Fusion engine	Decision templates	**0.6917**
	Logisic classifier	0.6826
	SVM classifier	0.6773
	SVM classifier –s 3	0.6823
	Naïve Bayes	0.6776
	Naïve Bayes -K	0.6824

As shown in Table 2, among base decision engines, PSA has a higher rank score (0.6815) than CPG (0.6771) and PRE (0.6062). After fusion, the engine of decision templates outforms all of the base decision engines, getting the highest rank score (0.6917). Also, the logistic classifier is promising and gets the rank score of 0.6826. Although we observe that

fusion engines using the default SVM classifier and Naïve Bayes have the rank scores lower than the base decision engine PSA, it's not a big drop since using machine learning algorithms always require careful tuning. Actually, we set an option "–K" for Naïve Bayes, which indicates to use kernel density estimator rather than normal distribution for numeric attributes, the rank score improves from 0.6776 to 0.6824. Similarly, we set an option "–s 3" for the SVM classifier, which indicates to use the SVM type of Epsilon-SVR rather than C-SVC, the rank score improves from 0.6773 to 0.6823.

Discussion

Fusion is not a new topic in machine learning and data mining, and its great success has been shown in a series of KDD Cup competitions from 2007 to 2014, as well as other open competitions such as the Neflix Grand Prize in 2009 [1] and the Heritage Health Prize in 2012 [2]. However, related work mainly focuses on the fusion of different learning algorithms with different parameter settings, and pays little attention to the knowledge sources. Furthermore, the evaluation metrics used in prior arts are based on the ground truth, but we have only the partially observed ground truth in treatment recommendation. To address these problems, we have two contributions as presented in this paper. First is a decision fusion framework for treatment recommendation systems, which combines both knowledge-driven and data-driven decision engines. Second is an outcome-driven evaluation metric, which has no information loss while facing the partially observed ground truth. As for experimental results, the fusion engine gets better performance than base decision engines.

Also, we realize our limitations. First, we assume that base decision engines output a uniform format. However, this assumption is challenged, if the labels (from different decision engines) are heterogenous. For example, suppose CPG just recommends using one of oral anti-diabetic drugs, but does not specify which one. Meanwhile, the decision options of PSA are still the 7 types: METFORMIN, ARFA, TZD, BI, TRI, INSULIN, and COMBINED. Now, one of oral anti-diabetic drugs could be METFORMIN, ARFA or TZD, how to assign values for such CPG recommendation? In our current work, CPG outputs label all the 7 types, and we do a simple transformation from these labels to the value of 1 or 0. Actually, we observe that normalization of heterogenous labels with values has not been mentioned or well addressed in previous work, because previous work is about multiple classifier systems, whose base engines are all classifiers to be trained for the homegenous labels. However, in our framework, we take both knowledge-driven and data-driven modules into account, which are heterogenous in nature. This situation would become more common, when facing the cloud-based decision services. We cannot assume each cloud-based decision service outputs a uniform format, but we still want to leverage the fusion of those services towards a better final decision. Therefore, the normalization for fusion would be our ongoing work.

Besides, in this paper, we only use three base decision engines of CPG, PSA and PRE for fusion. This is not enough, and we are planning to inclue more base decision engines involved towards an open (e.g. cloud-based) fusion platform. Moreover, we observe there is some contraindication information in the domain knowledge for treatment recommendation, e.g. you should not use statins for a woman becoming pregnant. Such contraindication information is hard to discover for learning algorithms, but it can be easily represented by knowledge modeling. Our future work will develop some novel fusion algorithm to get more benefits from both knowledge and data.

Last but not least, the so-called "partialness" of the ground truth deserves more investigation. For intervention in diabetes, we could regard the HbA1c value as partially observed, however, for a more nebulous topic, like antibiotics for fever, the partially observed ground truth may actually never have a known answer.

Abstract

Health organization management is facing a high amount of complexity due to the inherent dynamics of the processes and the distributed organization of hospitals. It is therefore necessary for health care institutions to focus on this issue in order to deal with patients' requirements and satisfy their needs. The main objective of this study is to develop and implement a Decision Support System which can help physicians to better manage their organization, to anticipate the overcrowding feature, and to establish avoidance proposals for it. This work is a part of HOST project (Hospital: Optimization, Simulation, and Crowding Avoidance) of the French National Research Agency (ANR). It aims to optimize the functioning of the Pediatric Emergency Department characterized by stochastic arrivals of patients which leads to its overcrowding and services overload. Our study is a set of tools to smooth out patient flows, enhance care quality and minimize long waiting times and costs due to resources allocation. So we defined a decision aided tool based on Multi-agent Systems where actors negotiate and cooperate under some constraints in a dynamic environment. These entities which can be either physical agents representing real actors in the health care institution or software agents allowing the implementation of optimizing tools, cooperate to satisfy the demands of patients while respecting emergency degrees. This paper is concerned with agents' negotiation. It proposes a new approach for multi-skill tasks scheduling based on interactions between agents.

Introduction

The rapid technological advances in computer science, telecommunication, and networking fields have led to the birth of a new paradigm for health care field referred to as eHealth; and also the integration of modern networking technologies in the medical process. In fact, in the last decades the link between engineering and medicine has become closer. Intelligent systems are created in order to automatically process medical data and provide support for medical decisions [1]. Information Technologies (IT) have provided major breakthroughs over the last several decades. Breakthroughs in health care emergency structures which have decided to work out an information system of health control supplied by the emergency services; and the establishment of internal information systems supporting the pre-hospital activities and downstream emergency services. An effective information system is considered by emergency professionals as a major element in the efficient functioning of the emergency structure. It should allow patient flow and medical records management, knowledge of availability of medical staff members, and a qualitative and quantitative knowledge of the service activity [2]. This information system can also promote more effective management of health care systems (dashboards, personalized program information system, summary measure of activity, computerization of medical practices, coding acts, etc.). Health care systems are being developed to provide support for medical decisions using health information networks; and portable communicable systems combined with many other tools and applications based on Information and Communications Technology (ICT) in order to assist physicians/medical experts in patients' treatment and health monitoring and management [3, 4].

Our collaboration with the Regional University Hospital (RUH) of Lille has led to the HOST ANR national project. This project is a scientific research work aimed at health care field with fallouts for the Pediatric Emergency Department (PED) of Lille RUH. The ubiquity of the emergency problem in France and in Europe, the strategic place of the PED in health establishments, patients' dissatisfaction, and rising costs of health care services are primarily responsible for the high level of our interest in PED. We aim through this project to study PED modeling, optimization of its functioning, and development and implementation of a Decision Support System (DSS). This is to anticipate overcrowding feature in the hospital and to establish avoidance proposals for it.

In this paper, we propose a distributed architecture designed for health care organization management, where actors provide smart negotiation in order to execute and control health care treatment tasks. The presented solution comprises use of an agent-based framework including an optimization and negotiation scheme to solve multi-skill health care tasks scheduling.

Methods

Multi-agent system architecture

Several models exist to design a dynamic system with a collective behavior. Since patients' health care in emergency department is a complex problem that requires a good division of tasks and data, a Multi Agent System (MAS) is used to model the PED organization. It is capable of identifying the

main functions of the system, as well as tasks, goals, and missions. Intelligent agents are therefore a good option for designing a decision support system for emergencies services [5, 6].

The literature on health care logistics shows that distributed decision-making agent-based paradigm provides an interesting approach to improve quality of care services provided by health care facilities. The Telemedicine-Oriented Medical Assistant (TOMAS) is a health research project developed using agent-based architecture. It is used by each specialist to transfer microscopic images and patient data in order to develop a diagnostic in collaboration with other colleagues in pathology department [7]. The Intelligent Healthcare Knowledge Assistant (IHKA) is an intelligent assistant in health care field using MAS for dynamic collection of knowledge, filtering, adapting, and care units acquiring [2]. Zachewitz developed an agent-based system to improve immunization rates in Germany [8]. Agents have been developed to maintain the consistency of patient's medical file at the pharmacy, at the level of specialists, and assigned doctors.

To improve logistics planning, we propose a dynamic multi-agent architecture (Figure 1).

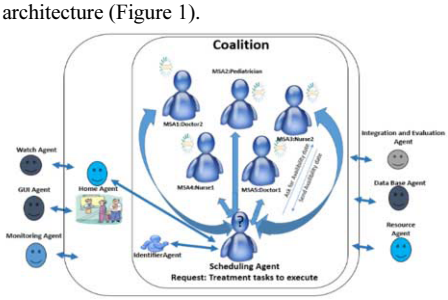

Figure 1- The proposed agent based architecture

It considers each actor in the PED as an autonomous agent capable of exchanging information with other actors in a self-sufficient way [9]. An agent can represent a real physical entity involved in the system as patient, medical staff, etc. or functional entity to resolve to solve complex problems such as scheduling, identification, etc. Autonomous agents and MAS have led to a new way to view, analyze, model, and design complex software systems.

Physical agents

Physical agents represent the parts which are really acting in the PED. These include different members of the medical staff charged to treat patients, reception nurses, orientation nurses, etc. In the proposed architecture we have:

Home Agent (HA): It represents activities of the reception nurse. When a patient arrives to the PED, it is responsible for receiving patients, their orientation, and for process pathology identification. HA has all skills required by the rules of registration plan, medical diagnosis plan, and patient orientation plan. HA deals with the problem formulation and then sends it to the Identifier Agent (IA) corresponding to the creation of a medical record through the IA triggered by an administrative nurse.

Identifier Agent (IA): It models the orientation nurse activity. It receives different information from HA about the medical problem and identifies skills needed for treatment referring to medical protocols. It consults the database of different pathologies and needed resources for patients' treatment.

Medical Staff Agent (MSA): MSA models medical staff activities. It is a mobile software agent which can move intelligently from one medical team to another in the PED in order to treat patients. It is characterized by two variables (skills and availability). In our proposed system, we use mobile medical staff agents to travel through the PED architecture to treat patients according to their availabilities and to the emergency degree of patients; and to collect intelligently, needed information related to patient health state in order to update the system data. This special type of agent has a smart behavior and is composed of data, states, and a code. Once MSA achieves a treatment task, it can shift to another medical team for new task execution. Therefore, while scheduling we must take into account this aspect when assigning human resources to tasks. Each task represents a service which can be performed by different possible MSAs, with different cost.

Software agents

These agents have the role to insure functioning of proposed systems. They allow development and implementation of various optimizing tools, different interactions, and communication protocols. The software agents in our system include:

Scheduling Agent (SA): This agent is responsible for optimizing choice of resources for patients' treatment taking into account our system constraints. It has to assign resources to patients' treatment tasks minimizing total cost and patients waiting time in order to respect emergency degrees. It organizes queue of patients who need treatment taking into account their emergency degree. It then assigns resources to different tasks.

Integration and Evaluation Agent (IEA): This agent is responsible for the whole system performance control. It calculates performance indicators of the system such as waiting time of patients and treatment costs in order to evaluate overall schedule of patients in PED.

GUI Agent (GA): This agent interacts with system users particularly medical staff in PED.

Resource Agent (RA): This agent is responsible for resources monitoring.

Monitoring Agent (MoA): This agent is notified of every decision taken and every task completed. It represents the coordinator between all software agents; and an informer for the physical agents about actions and patients status.

Scheduling strategy: Negotiation protocols

The coordination of distributed planning approach focuses on interactions between agents' plans. An interaction protocol allows agents to have conversations in the form of structured exchanges of messages [10]. In an emergency service, medical staff members are often faced with treating multiple patients simultaneously. Thus, a patient can be treated by various doctors and nurses. Consequently, medical staff in the PED is organized in a cooperative group that shares same resources, that is to say, patients. The medical staff of the PED is working on basis of dynamically generated plans by SA which contains details of treatment tasks operations to execute. This coordination is achieved by appropriate protocols of interaction between agents.

To carry out scheduling, SA needs information about medical staff availabilities to execute treatment tasks. SA sends a request to MSA for execution of processing task and negotiations between SA and various mobile agents modelling medical staff members occur.

The SA is the initiator of the negotiation. It ignores relevant information to various resources to be allocated to patients'

treatment tasks, but it knows all information about patients, their pathologies, and their requests.

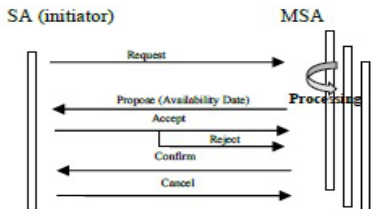

Figure 2 - Negotiation Protocol

The initiator (SA) sends a request to MSA deemed qualified to execute health care operations. The message form is as follows:

<SA, MSA_k, Request, AvailabilityDate (k), $V_m(t)$>, where ;

AvailabilityDate (k) is earliest time at which medical staff member MS_k is able to execute the set of treatment tasks $V_m(t)$.

Vm (t) is set of operations to be treated by MS_k on different patients at time t.

When a MSA receives a query, it analyses, calculates in real time its availability date, and sends response to SA which makes a comparison between availability dates provided by all MSA then decides (accept or reject proposal). The MSA with the earliest availability date is chosen. The availability date of each medical staff member depends on his skills as well as current medical treatment task evolution.

Simulation and Results

Our partner is the PED "Jeanne de Flandre" of RUH of Lille (North France). We noted 47,188 visits during 2011-2012 ranging from neonates to 18 years. 19% of them were hospitalized in Short-stay Observation Unit while 81% of the patients were of Outpatient Care Unit. We focused our study on the second population, the source of crowding. In fact, length of stay usually does not exceed 8 hours otherwise patient is transferred to Short-stay Observation Unit.

System implementation

Our system is developed with JADE (Java Agent DEvelopment framework) platform [11]. JADE simplifies implementation of MAS through a middleware that complies with FIPA (Foundation for Intelligent Physical Agents) specifications and provides a set of graphical tools supporting debugging and deployment phases. Figure 3 shows evolution of message exchange between the different agents through "sniffer" tool useful for debugging.

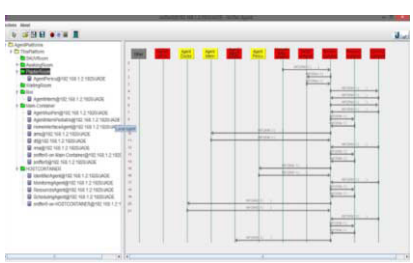

Figure 3 - Messages exchange

JADE system supports coordination between several agents and provides a standard implementation of communication language FIPA-ACL, which facilitates communication between agents which complies with FIPA specifications [12]. JADE is written in java language. It supports mobility. In this paper, we used a JADE graphical tool which sniffs message exchange between agents. This tool is useful to debug a conversation between agents.

All the system is implemented as a decision support tool; software based on a MAS. So, we programmed scheduling approach and we have integrated different calculation formulas. It is a flexible tool where we can adjust and act directly through ergonomic interfaces.

To better explain our approach solving the discussed scheduling and optimization problem; and functioning of our system, we propose the following illustrative example showing different aspects and logic followed by our proposed scheduling system. We start with the system up and running in PED department with patients already signed up with registration nurse. The initial situation is thus with medical staff already treating patients. We start from $t=t_0$, where a new patient arrives at the PED reception. Patients' information is requested by nurse and processed into our system in order to make new patient's data available to HA. Data received by HA will then pass through a pathology test in order to collect various data including emergency degree, pathologies, and needed resources.

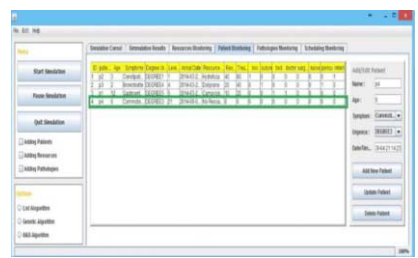

Figure 4 - Adding a new patient

These data will be used to generate a priority degree affected to the newly arrived patient giving him a position in the waiting queue.

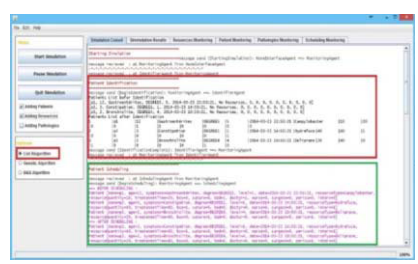

Figure 5 - Patients' identification and scheduling

The position is generated using List Algorithm with dynamic and flexible priority rules. Therefore, all patients' position will change according to the new scheduling in order to satisfy all patients in a matter of emergencies and waiting time.

As a result we will have an initial scheduling (Figure 6) consists of 9 care operations, for example, assigned to two medical staff "nurse" and "doctor" able to execute them. Medical care procedures can be done at the same time (for example, in case of concussion, a doctor makes a diagnosis

while a nurse is doing a careful neurological exam for the same patient). Therefore, operation can be performed carefully by mobilizing members of Medical Staff at same time and with same duration; or with varying execution times according to the skills required for the treatment realization.

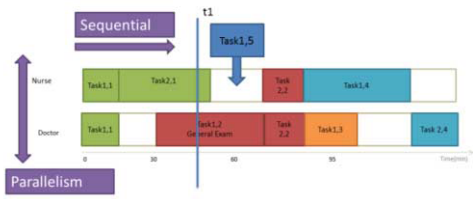

Figure 6 - Tasks scheduling

The affectation of medical staff is based on needed skills and on availabilities. Therefore, we use a real time and dynamic Time Table algorithm for human resources scheduling aiming to reduce idle time which leads to costs minimization. This scheduling takes advantage of agents' mobility to optimize patients' treating and waiting time; and also to optimize medical staff operating time which leads to cost minimization.

We always start by treating the most urgent request using available resources. For human resources, if the member of medical staff has needed skills to treat a treatment request, the most urgent treatment task is allocated to him. The decisions are the result of coordination and negotiation between our system's agents and are taken in a dynamic manner.

At $t=t_1$, a new patient arrives. A doctor is needed for his treatment. Thus, the doctor (MSA) leaves the box where patient 1 is being treated to go to another box to treat patient 5. An operation may also be accomplished or interrupted by an emergency.

The graph in Figure 7 represents evolution of patients' pathways and health care activities being completed for each patient. The parallel line to x-axis represents time spent in PED.

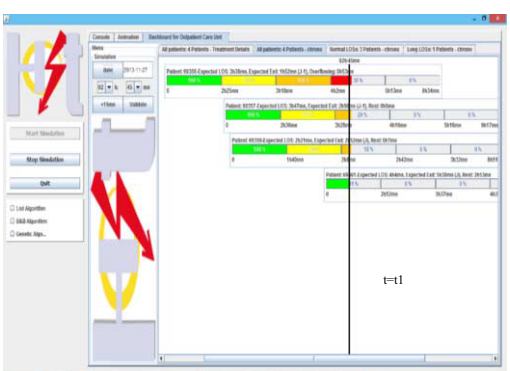

Figure 7 - Patients tracking

For example we have in figure 7 above 4 patients; the first one has arrived first, then patient 2, patient 3, and 4. At $t=t_1$, length of stay of first patient is the longest one, so he needs attention. However, the last patient has already arrived, so if his emergency degree is not high, we consider that he undergoes normal treatment process and there is no need to worry about him at the moment. This tracking helps to know at each moment how many patients we have as well as evolution of their treatment process. It also improves service quality and information delivery through indicating length of stay of each patient in the PED.

Simulation scenario

To characterize our model, we used the 3-year data collected in the PED of CHRU of Lille. We have information about 23,150 patients' admissions in 2011 and 24,039 in 2012 (Figure 8). In order to protect individual privacy, patients' data were previously strictly anonymized.

Figure 8 - 3-year data of CHRU of Lille PED

We considered the scenario of November 28th, 2013 because it presents the highest level of crowding throughout the first 11 months of 2013 according to physicians. So, we will use it as simulation scenario for our results validation. At 08:00, we had two patients, then arrivals gradually increased until reaching a first peak of 17 patients at 11:15, then three hours later, a second peak of 27 patients at 14:15.

Figure 9 shows that the proposed decision support system allows smoothening of PED activities and absorption of large demand load. Indeed, use of the discussed methods reduces peaks of activity and minimizes patients waiting time. The green curve represents PED activities without using the decision support system and the black curve shows optimization effect.

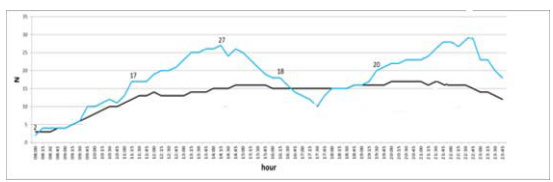

Figure 9 - PED activities smoothing

Medical Staff Members Activities

MSA in the PED, because of their different properties (autonomy, communication and interactions, cooperation, etc.) may have different features of activities. Indeed, at a given time t, some agents negotiate between them, others transmit commands while others are executing scheduling tasks. During an observation in the PED, we identified four modes of activity, according to Figure 10;

- Parallel Activities: In this example, the four proposed agents are working simultaneously, non-sequentially. Agent waits at end of an activity to begin another.
- Staggered Activities: All of the agents work with a lag. An agent can start a new activity even if a previous activity is still being executed.

- Interruption: A MSA that can stop an activity already begun, if it receives an update or a more urgent task to execute.
- Different durations: The activities of agents are of different durations. These durations depend on type of activity being carried out.

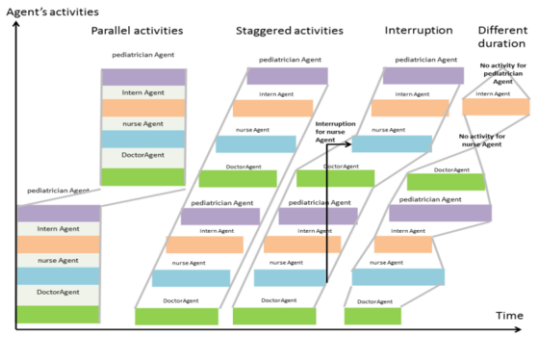

Figure 10 - Agents activities

Discussion

During our study, we noticed significant stress upon medical staff members; and dissatisfaction of some patients because of long waiting times. We have also noticed difficulties in management of patients especially in cases of an overcrowded PED. So, health care specialists should get involved in new actions aiming to improve care services. Requirements to satisfy patients' requests impose need to adopt new approaches to solve problems related to patients' treatment process management; and human and material resources allocation.

Our primary consideration in this work is development of decision support solutions to simplify the work of medical staff in the PED. From monitoring screens, medical staff can have complete and accurate feedback of the global state of the PED. The proposed software is capable of determining medical staff availabilities which are uncertain and depend on the experience level of the health care provider; and evolution of the medical act being executed. Because time is important in emergency services, poor control of availability of professionals can generate a worsening of the condition and cause of preventable care. Our solution for rapid and effective treatment of patients is based on alliance between MAS paradigm and optimization tools; and improving use of human resources through cooperation of different members of the medical staff; and dynamic and reactive generation of treatment plans. The use of intelligent agents in medical field has been demonstrated as a complementary technique to improve performance of computer. Traditional centralized control mechanisms show insufficient flexibility to deal with sudden changes of needs. In fact, in the PED, information circulates poorly between medical staff members and is sometimes missing. So, to ensure real time negotiation between the different actors of PED, MAS is the most suited tool for real time interaction and negotiation. MAS modeling consists of modeling agents with their activities and interactions.

Conclusion

In this paper, we have proposed a distributed scheduling system for care of patients in the PED. This system can contribute to health care quality improvement, costs minimizing and waiting time reduction. Our research has therefore focused on definition of an agent-based approach to execute patient treatment tasks. This application displays utility of a decision support tool which can help to manage patients' treatment in the PED. For future work, we believe that there is need for further improvement of the scheduling algorithm to be integrated in the system.

Abstract

Process mining allows for discovery, monitoring, and improving processes identified in information systems from their event logs. In hospital environments, process analysis has been a crucial factor for cost reduction, control and proper use of resources, better patient care, and achieving service excellence. This paper presents a new component for event logs generation in the Hospital Information System or HIS, developed at University of Informatics Sciences. The event logs obtained are used for analysis of hospital processes with process mining techniques. The proposed solution intends to achieve the generation of event logs in the system with high quality. The performed analyses allowed for redefining functions in the system and proposed proper flow of information. The study exposed the need to incorporate process mining techniques in hospital systems to analyze the processes execution. Moreover, we illustrate its application for making clinical and administrative decisions for the management of hospital activities.

Keywords:

Hospital environment; Process mining; Event logs; Hospital Information System; Process model.

Introduction

Demand for medical services at an international level is increasing. The costs related to search and implementation of strategies and tools to meet the medical needs of populations push for an improvement in the execution of clinical and administrative tasks in health institutions. In order to address this situation, hospitals need to find alternatives that make their processes more efficient. The improvement in quality of processes implies higher productivity [1], so the design of new methods to optimize performance of processes is necessary.

The business process management approach allows for identification and management of processes that are interrelated; in order to analyze organizational performance and make continuous improvements of the results, eliminating errors, and redundant processes in the institution. Process mining allows for understanding how processes are really executed in the system. Its application helps to identify bottlenecks, anticipate problems, record policy violations, recommend countermeasures, and simplify processes [2] for improving business performance. This technology allows getting information about how the process has behaved, the times it takes in the executions, as well as variations between reality execution and the prescribed model. The complexity of this approach is proportional to the amount of data stored; making it invaluable information for decision-making. These data are usually stored in the databases of the systems that support organizational processes. From these databases, certain information could be extracted to create event logs.

An event log is the evidence of events that occur in the computer systems and the networks of an organization [3]. The records are composed of input events. Each entry contains related information to an action or specific operation that was executed on the information system and its corresponding timestamp. These event logs should be formatted as MXML [6] or XES [7].

Currently, to obtain event logs from information systems, it is necessary to use specialized tools like: XESame [4] and Nitro [5]. Even though these software are efficient, their high complexity related to technical configurations and database structures make them inconvenient for inexperienced or non-expert users.

With the aim to computerize, the processes of secondary healthcare level have been developed into a Hospital Information System (HIS) at the University of Informatics Sciences (UCI), in the Center for Medical Informatics (CESIM). This HIS supports the fundamental processes carried out at this level of healthcare and was designed to meet the needs of: storage, processing, gathering, and interpretation of the medical-administrative data generated.

The HIS from UCI does not have a component to generate event logs from the execution traces stored in the system; thus precluding application of process mining techniques for analysis of running processes. Medical and administrative staff have limited access to this source of knowledge for clinical and administrative decision-making.

Due to the above inconveniences, we propose to develop a software component that allows generation of event logs from the Hospital Information System without relying on other external tools. This system component generates event logs with the same characteristics, format, and structure as obtained with XESame tool; but can be used by non-expert users. This solution allows analysis of healthcare process using process mining techniques.

This article has two main sections. The first deals with implementation of a software component to extract traces from the Hospital Information System. The second section focuses on process analysis with process mining techniques, starting from an event log generated using the developed component.

Materials and Methods

Processes mining in a hospital environment

An intelligent approach to healthcare is use of information to create knowledge about patient care and improve performance of the hospital institution. Healthcare organizations increasingly have more data, which involves a large amount of information and few alternatives for analysis; a result of the lack of effective tools or methods that allow for obtaining the decision criteria about execution of the system processes.

The process mining techniques allow extraction of useful and nontrivial information from execution logs stored in information systems [8]. There are three types of process mining techniques: discovery, conformance checking, and enhancement or extension. All these techniques allow us to analyze actual execution of processes. The discovery technique is used to extract process models from an event log. Conformance checking techniques are used to monitor deviations by comparing the model and the event log and improving existing models from its extension [9].

Investigations carried out provided evidence that process mining is a novel and effective technology for analysis of hospital processes. In Gynecology and Oncology [10], process mining techniques helped to optimize, from dotted points, the trajectory of patients through the process of care. Also, discovering the busiest times in the area of Emergency [11] allowed for control and allocation of resources to this hospital sector. Other research in the area of Emergency [12] presented the detection of eventualities (incomplete assignments, missing information, little correspondence between the business process and system) in the process activities using process mining techniques. Its application in the Electronic History Records [13] allowed for enhancement of patient care processes.

Maruster [14] proposed the application of Petri Nets based on Process Mining for modeling hospital information. Moreover, the application of process mining on hospital systems allowed monitoring use of resources such as surgical implements, for nursing and external consultation. Process mining applications in other environments [15-18] demonstrate its effectiveness in detecting malfunctions, such as deviation of resources, extra stay time of a product in a warehouse stock or loss of any product, in such a way that allows for adjustment of product ordering frequency. From the engineering point of view, programming errors in the processes definition and activities that do not run properly or are simplified could be identified. Process mining techniques allows finding bottlenecks in information flow.

Event Log

To formalize the structure of event logs used in process mining, two standards were defined: Mining eXtensible Markup Language (MXML) and eXtensible Event Stream (XES). MXML is a format based on XML for the exchange of event logs. MXML was the first standard that emerged in 2003 and was adopted by the process mining tool ProM [19].

MXML establishes a standard notation to store dates, resources and types of transactions. In 2010, XES replaced MXML as the new process mining format independent of the tool [17]. XES is a standard based on practical experiences of MXML, and is less restrictive and truly extensible. Its main purpose is to provide an interchange format for event logs between tools and application domains [7].

To ensure a successful analysis of process mining, the quality of the storage format of the event log should be ensured. This is defined from three fundamental aspects: reliability, completeness, and security. Reliability stands for that ability to safely assume that the recorded events really occurred and that the attributes of the events are correct. Completeness is the characteristic of not missing any event in a certain context. In addition, any registered event must have well-defined semantics. The event data are considered safe when considerations of privacy and security are taken on, when events are registered [18].

Attributes of Event Log

An event log contains evidence of processes execution stored like traces. This record of elements can also contain attributes. As the registration of elements is created only once, the impact of including many attributes in the registry is minimal [6]. It is important to include relevant information describing the contents and origin of the event log. The following attributes should be taken into consideration for trace recording:

- **Process Name**: The name of the process under which the log will record its execution.
- **Data Source**: A description of the information system from which the event log is extracted from.
- **Source Organization**: The name of the organization providing the data.
- **Description**: A brief description of the contents of the event log.
- **Version**: An identifier to differentiate versions of event logs.
- **Author**: Name and contact details of who defined the conversion.
- **Process Mining Project**: A reference to the Process Mining Project or purpose of the event log.

Development environment

We proceeded with the implementation of the software component from the theoretical study of event logs. The following technologies and tools were used:

Eclipse Ganymede 3.4.2: Eclipse is an IDE (Integrated Development Environment) open and multiplatform code that has achieved a high degree of maturity in the development of what are known as "rich client applications". It has tools to develop console applications and web services with different application servers such as JBoss, Websphere, and Glassfish. It was originally developed by IBM (International Business Machines) and its future is now in the hands of Eclipse Foundation, an independent nonprofit organization that fosters an open source community and a set of complementary products, capabilities and services.

JBoss Application Server 4.2.2: JBoss Application Server is a Java EE (Java Enterprise Edition) free software implemented in pure Java. Being based in Java, it can be used on any operating system that supports it. It provides a full range of services for Java EE 5 and expansion of business services, including clustering, caching, and persistence. JBoss is ideal for Java applications and applications based on the web. It also supports EJB 3.0 (Enterprise Java), making applications development much simpler.

JBoss Seam V2.1.1: JBoss Seam is a powerful framework for developing Web 2.0 applications by unifying and integrating technologies such as AJAX, JSF, EJB, Java Portlets and BPM (Business Process Management). Another important feature is that POJOs (Plain Old Java Objects) can be validated in addition to directly handling the application logic and business sessions from beans.

Java V1.6: Java is an object oriented programming language developed by Sun Microsystems in the early 1990s. The language itself borrows much of its syntax from C and C ++ but has a simpler object model and eliminates tools of low level, which can cause many errors such as direct manipulation of pointers or memory.

Hibernate V3.3: Hibernate is an ORM (Object Relational Mapping) tool for Java platform. It facilitates the mapping of attributes between a traditional relational database and the object model of an application using declarative XML files or annotations, on the beans of entities that allow for establishing these relationships.

Facelets V1.1: Facelets is a simplified presentation framework where it is possible to freely design a web page and then associate specific JSF components. It provides more freedom to the designer and improves error reporting, having JSF. It allows for definition of disposition of pages based on a template, the composition of components, creating custom labels, and facilitates friendly development for the graphic designer and creation of component libraries.

Results

Figure 1 shows the user interface for the component developed to generate event logs in XES format. This component requires a process name as input, specified by the user to identify the process. It is needed to select the process to be analyzed and delimits start and end date for the events that will be inputted in the event log.

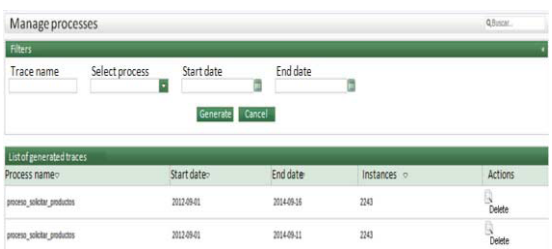

Figure 1 - Component to generate an event log in the HIS.

Below is an excerpt of the event log (see Figure. 2) obtained from the component developed. The extensions and attributes mentioned above are reflected in this image.

Figure 2 – Event log excerpt.

An event log related to the process: Request Product of HIS Warehouse module, was obtained from the developed component. The Warehouse module, among other activities, manages the flow of information on the various movements that a product can have in a warehouse. There are three types of product requests: tendering request, application warehouse, and request for surgical block (see Figure 3). To show the usefulness of the developed component, the Request Product process from Warehouse Module of the Hospital Information System created at UCI, was selected. An event log related to this process was extracted and analyzed with the ProM tool as shown below.

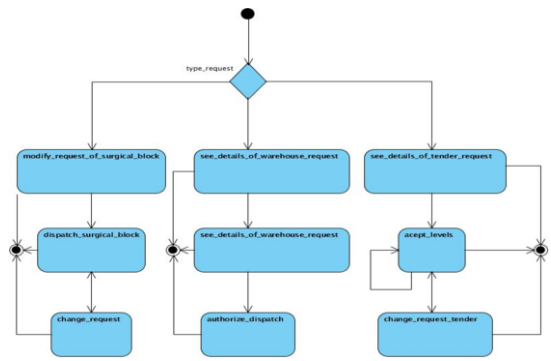

Figure 3 – Business Process Diagram of Request Product.

This event log was loaded on the ProM tool in order to conduct the process mining analysis. The process model showed on Figure 4 was obtained by applying the technique “Mine Net using Heuristic Miner”. This process model is a representation of the actual process behavior recorded in the event log during its executions on the HIS.

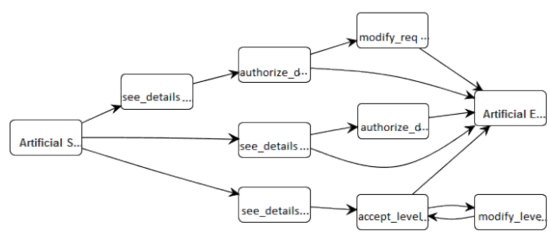

Figure 4 – Model obtained by applying the technique Mine for a Heuristic Net using Heuristic Miner.

This technique shows the similarities between the formal definition of the process and the event log obtained from the traces of their execution. In this model, there exists a difference with respect to the reference model; the process never ends directly after see_details_tender_request activity and whether it should end.

In comparing Figures 3 and 4, the applied technique shows that the process execution in the system is in concordance with the formal definition of the business process. The system has been implemented in the way it its business was conceived.

Figure 5 illustrates the observed result of the technique: "Analyze using Dotted Chart". The Dotted Chart shows an overview of the process where the X-axis shows the time, the Y-

axis shows the process execution instances and each point represents an event; the colors of the points refer to the different activities.

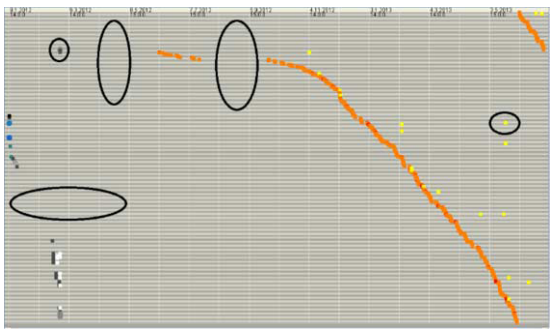

Figure 5 – Aplication of technique "Analize using Dotted Chart" whit black circles representing noise.

The runtime process was extended over seventeen months and three distinct moments with different behaviors could be distinguished. The first moment corresponds to system testing stage, where see_details_of_warehouse_request and authorize_dispatch activities were not executed. Afterwards, the system does not record any execution of the process for three months. The second and third phase were extended a month and a half to nine and a half months, respectively, with a downtime of two months between them; only see_details_of_warehouse_request and authorize_dispatch activities were running. Because of these characteristics, this process shows an anomalous behavior as 6 of the 8 activities making up the final version of the process are left to run.

The next model (Figure 6) represent the technique Replay a log on Petri net for Performance/Conformance, that allows some cases to define in a simple way, for example, the more common activities flow that runs in the system process under analysis.

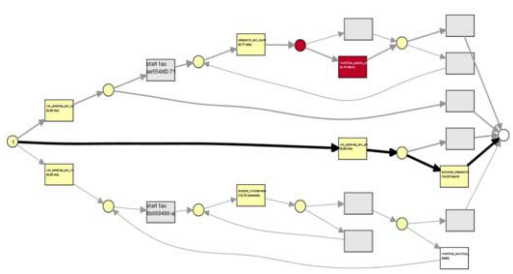

Figure 6 – Aplication of technique "Replay a log on Petri net for Performance/Conformance".

This technique establishes that while darker and thicker lines in the figure indicate a transition, a greater amount of times have been carried out for the activity represented in the flow.

This model allows identification of the flow of the more executed activities in the processes under analysis. Therefore, in the process Product Request, the flow with more executed activities can be defined as composed by the activities see_details_of_warehouse_request and authorize_dispatch.

In comparing the difference of maximum and minimum waiting times between modify_request_of_surgical_block and authorize_dispatch activities, we see that:

- The minimum waiting time of the first activity (3.29 seconds) is less than the second one (4.43 minutes).
- The timeout of the first activity (5 months) is greater than the second activity (7.45 days).
- The average time of the first activity (14.38 hours) is less than the second activity (3.31 days).

These analyses allowed receipt and dispatch of products from the warehouse, as well as detection of a bottleneck in the activity authorize_dispatch to be controlled. The understanding and correct interpretation of the process models obtained from process mining techniques have been discussed in the literature, as challenges [19] to analyze the behavior of computer systems by non-experts in the field of knowledge are the same.

Conclusions and future works

Process mining is presented as an effective alternative to show a radiograph of the actual process execution. However its models are far from favorable to non-experts.

The application of process mining techniques in the hospital environment is novel because there are only a few cases of its study around the world. However there is support for its use in this key social sector.

We developed a component for extracting traces of the HIS, which overcomes the problems raised above. From the analysis of the traces generated by the developed component using process mining techniques, we concluded that they contain valuable information useful for process analysis.

The solution developed guarantees that data persist permanently in the trace processes records. As a part of the developed component, it ensures transformation of stored records in the HIS to processes event logs. It also allows to export the to XES format.

After applying multiple modeling techniques to the event log obtained, was stated that the obtained models are not suitable for understanding by health personnel. The incorporation of process mining techniques to the HIS where models are generated, allowing for analysis by non-experts, is plotted as a goal of this research. Towards this goal, we conduct research on what elements are essential to the analysis and understanding of process execution.

The component developed is a starting point for incorporation of process mining techniques and algorithms of the HIS, in order to support clinical and administrative decision-making. This component becomes the first of its type, designed to analyze processes in the systems HIS.

Understanding the process model (in terms of accuracy and efficiency of understanding) is a function of the characteristics of the model and the characteristics of the user who interprets the model [20]. The visual design of the model is a primary factor analysis. Recker has conducted research on how process models can be designed to maximize their understanding [21].

Abstract

The objective of this paper is to evaluate the extent to which early determination of diagnosis-related groups (DRGs) can be used for better allocation of scarce hospital resources. When elective patients seek admission, the true DRG, currently determined only at discharge, is unknown. We approach the problem of early DRG determination in three stages: (1) test how much a Naïve Bayes classifier can improve classification accuracy as compared to a hospital's current approach; (2) develop a statistical program that makes admission and scheduling decisions based on the patients' clincial pathways and scarce hospital resources; and (3) feed the DRG as classified by the Naïve Bayes classifier and the hospitals' baseline approach into the model (which we evaluate in simulation). Our results reveal that the DRG grouper performs poorly in classifying the DRG correctly before admission while the Naïve Bayes approach substantially improves the classification task. The results from the connection of the classification method with the mathematical program also reveal that resource allocation decisions can be more effective and efficient with the hybrid approach.

Keywords:

Artificial Intelligence; Diagnosis-Related Groups; Hospital Costs; Linear Programming.

Introduction

Several recent studies have highlighted the challenges facing many OECD (Organization for Economic Cooperation and Development) countries with rising pressure on healthcare systems due to increasing demand and expenditures for healthcare [1]. As a countermeasure, cost-containment policies such as diagnosis-related groups (DRGs) were introduced [10] and are evaluated continuously [11]. When hospital resources such as beds, diagnostic devices, human resources and operating room availability become scarce, the coordination of patient care and patient flow becomes a challenge. The problem is even more complicated when detailed information about patients who seek hospital admission is captured in an unstructured form or is likely to be incomplete in early stages of care.

DRG-based reimbursement of patient services

Within DRG systems, patients are classified into groups with homogeneous clinical characteristics and resources required during treatment. After the treatment, patients' health insurance pays a fixed amount for treatment depending on the assigned DRG. Within this context, uncertainties in care delivery information play an important role in the effective planning of healthcare processes. In early stages of care, the patients' DRG is unclear, because of potentially missing information and unstructured documentation of patient information using free-text [6]. This introduces a significant challenge to the hospital's operations management when assigning patients to scarce hospital resources while economic objectives such as contribution margin maximization are pursued [5].

The role of hospital information systems to improve hospital-wide patient scheduling decisions

By structuring patient information that is documented when patients seek admission, hospitals can leverage this information to better predict patients' resource requirements. When information about each patient's DRG, resource requirements, and clinical pathway [12] is made available before admission, a hospital can potentially improve the effectiveness and the efficiency of resource allocation decisions.

In this paper, we investigate whether machine learning methods can increase the classification accuracy of an inpatient's DRG as compared to the current approach of using a DRG grouper. In particular, our focus is to classify the patient's DRG before admission in order to improve admission decisions via novel statistical models.

We analyze inpatient data from one year consisting of more than 16,000 records from a 350-bed hospital. Our results show that, in general, machine learning approaches can substantially increase early DRG classification accuracy, especially for elective patients who contact the hospital before admission. Moreover, we demonstrate that machine learning techniques combined with mathematical programming can lead to improved resource allocation decisions.

The remainder of this paper is structured as follows. In the next section, we present two approaches demonstrating how early DRGs can be classified. The first classification approach can be seen as the current approach used by our study site, while the second one uses a Naïve Bayes classifier. We then develop a statistical model for patient admission and scheduling under several constraints, such as precedence constraints between clinical activities and resource constraints. The results section describes the data that we employed in our analysis and presents results of the classification and resource allocation task followed by a discussion. In the final section, we summarize our results and provide directions for further research.

Methods

In the following, we present two DRG classification approaches and a model for combining and planning patient flow with admission decisions.

Early DRG classification techniques

Current approach using a DRG grouper

To determine a DRG at discharge, typically, a simple flowchart-based method is used. The method is implemented in a commercial software called DRG grouper. Figure 1 illustrates the DRG-grouping.

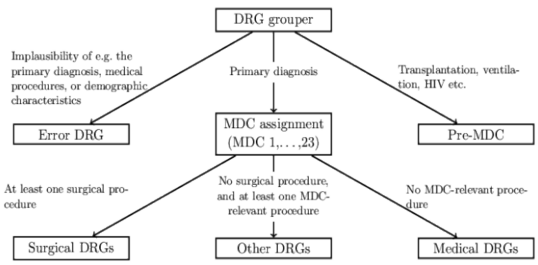

Figure 1 – DRG grouping using a DRG grouper, see Schreyögg et al. [9]

Before the execution of the DRG grouper, parameter values such as the primary and secondary diagnoses, clinical procedures, age, gender, as well as weight in the case of newborns, have to be entered into the software. Diagnoses are coded using the International Statistical Classification of Diseases and Related Health Problems (ICD). The first 3 letters of an ICD code correspond to DRGs. The algorithm first determines one of 23 Major Diagnostic Categories (MDC). These are defined by the primary diagnosis (i.e. the reason for the hospitalization). However, if the primary diagnosis is imprecisely documented, an error DRG will be returned. On the other hand, if the patient has a transplantation, for example, a Pre-MDC (a DRG with high-cost procedures [2]) is returned. After determining the MDC, clinical procedures and co-morbidities lead to the patient's DRG which can be categorized into surgical, medical and other DRGs. Finally, within these categories, the age of the patient, or the weight in the case of newborns, may lead to a different DRG-subtype.

When sufficient information is available, there is valid reason to use a DRG grouper not only at discharge, but at any stage of care in order to obtain real-time information about the patients' DRGs. Therefore, we assume that in every stage of care of a patient and in particular before admission that sufficient information is available to classify the patient's DRG.

Naïve Bayes Classification

Let D be the set of all DRGs, A the set of attributes (e.g. gender, free-text diagnoses) and I be the set of labeled patient instances. The naïve Bayes classifier assumes that all the attributes are conditionally independent given the inpatient's DRG $d \in D$. Under this assumption, the prior probability $p(d)$ of each DRG d is learned from the training data by maximum likelihood estimation, i.e. $p(d)$ is set equal to the proportion of training examples which belong to the class d. Similarly, the conditional likelihood of each value $v_{i,a}$ given instance $i \in I$ and attribute $a \in A$ of each DRG $d \in D$ is learned from the training data by maximum likelihood estimation. This means that $p(v_{i,a} \mid d)$ is set equal to the proportion of training examples of class d which have value $v_{i,a}$ for attribute a in instance i. Afterwards, the classifier assigns the DRG d_i^* to the test instance i by employing Equation (1):

$$d_i^* = \arg\max_{d \in D} \left\{ p(d) \cdot \prod_{a=1}^{|A|} p(v_{i,a} \mid d) \right\} \quad (1)$$

Resource allocation model

In what follows, we present our resource allocation model which is an extension of Gartner and Kolisch's [5] patient flow problem with fixed admission dates. We further extend their model by taking into account admission decisions.

Planning horizon, patients and activities

We have a set of days in which patients can be scheduled and which represents our planning horizon. We have a set of patients who seek admission and can be planned during the planning horizon. The patients have a target admission date and a set of activities to be scheduled within the set of days. For example, an activity can be a computer tomography scan, a surgery or a therapy. Within each patient's set of activities, we have a specific activity which we denote as the discharge activity and which is the final activity of the patient during his/her stay in the hospital.

Time windows, clinical pathways, contribution margin

Each patient's activity has a time window in which it can be scheduled. Once we schedule the discharge activity, the hospital receives a length of stay-dependent contribution margin. The clinical pathway of each patient is represented by precedence relations; each of them can be assigned an integer time lag, which means that the successor activity cannot be scheduled until a certain (waiting) time after the predecessor activity has elapsed. This is necessary to capture recovery times, for example.

Resources, resource capacity and resource requirement

We split hospital resources into a set of day resources and overnight resources as follows: Day resources represent, for example diagnostic devices or the operating room; while overnight resources represent beds since they are typically allocated for at least one night. On the supply-side, each resource has a day-dependent capacity while on the demand-side, each patient's activity has a resource requirement. An activity can require multiple day-resources on the same day, such as when a surgical activity requires the surgery room and the surgeon. Also, an activity does not necessarily require the same amount of time from two distinct resources. For example, a surgical activity may require 100 minutes of surgery room time (including set up time, surgery time, cleaning time, etc.) while the actual time required from the physician may be no more than 80 minutes. Naturally, the documentation task executed by the surgeon follows the surgery and has to be executed before the patient's discharge.

Capacity requirement of overnight resources is typically measured in terms of bed utilization. An overview of all parameters is provided in Table 1 in the Technical Appendix.

Decision variables

Our mathematical model uses binary decision variables to decide whether or not a clinical activity is executed on a day within the activity's time window. Another set of decision variables decides whether the admission of a patient should be avoided. These decision variables inform a decision maker whether or not patients provide the hospital enough of a contribution margin to schedule them along their clinical pathway.

Objective function and constraints

Our mathematical model (its algebraic formulation is shown in the Technical Appendix) maximizes the overall contribution margin of all admitted patients in the hospital by assigning each patient to a discharge date within that patient's discharge time window, see Objective Function (2). Constraints (3) ensure minimum time lags between clinical activities. Note that if we have a time lag of 0 days, the predecessor and successor activity, for example a magnetic resonance tomography and a neurosurgery procedure, respectively, can be performed on the same day. Incorporating the admission variables into the constraints ensures that the constraints are satisfied if the patient is not admitted. Constraints (4) depict the limited capacity of day resources. For each resource and day, capacity demands that all activities performed on that day must not exceed resource capacity. Note that the dimension of resource capacity can be, for example, time or slots in a master surgical schedule or minutes available by a physical therapist. Constraints (5) denote the resource constraints for overnight resources. For each patient, the bed allocation starts with the patient's admission date and the discharge activity releases the bed. Naturally, a patient's resource requirement only sums if he is admitted. Constraints (6) ensure that a patient's activity is scheduled at most one time within the activity's time window. However, once the activity is scheduled, all of the activities corresponding to that patient are scheduled, as required by Constraints (7). Finally, expressions (8)-(9) are the decision variables and their domains.

A bed allocation example

Suppose we have a planning horizon which consists of 7 days and we have two patients to be admitted and scheduled within the planning horizon. Assume that both patients have the actual DRG F21C which means "other surgical procedures with cardiovascular diseases, without complex procedure, without complex skin transplantation and myocutaneous flap surgery of the lower limb admission". The property of the contribution margin function of this DRG reveals that on day 6, it has its maximum. Before that length of stay (LOS), the patient's LOS is below the low LOS trim point. Accordingly, the hospital receives a deductible if the patient is discharged before that day. If the patient's LOS is between the low and high LOS trim point, the contribution margin function is monotonicly decreasing due to LOS-dependent costs for activities such as bed cleaning. We assume that the clinical pathway of the patient requires a minimum time lag of 5 days between surgery and discharge. As a consequence, the time window of the discharge activity has a lower bound for the LOS, which is 5. Since the planning horizon is 7 days, the discharge time window is between 5 and 7 days. We assume that we have one overnight resource and no day resource. The overnight resource is required by both patients. Therefore, only one patient can be admitted and thus, only one admission decision variable is equal to 1. Table 2 in the Technical Appendix gives the algebraic solution of the bed allocation example.

Results and Discussion

In the following, a computational and economic analysis of the scheduling problem is provided.

Data and instance generation

We evaluated our model using data from a mid-sized hospital in the vicinity of Munich, Germany. We joined the hospital data with data from the German institute for reimbursement in hospitals [8]. The latter contains information on the DRG attributes such as low and high length of stay (LOS) trim points, fixed revenue as well as per day reduction and addition. We learned the classifier from January 2011 until June 2011. We ran the simulation experiments from July 1, 2011 until the rest of the year, where each day is solved independently.

Classification results

The classification results of our experiments reveal that the DRG grouper could not classify any of the patients' DRG before admission. One explanation for this phenomenon is that the grouper cannot deal with free-text information. A more detailed analysis revealed that the "error-DRG" 960Z was always assigned to the patients. In contrast, the true positive rate of the Naïve Bayes approach was, on average, 25.3%.

Contribution margin analysis

Our contribution margin analysis revealed that scheduling patients using their DRG, as classified by Naïve Bayes, can substantially increase the hospital's contribution margin, depending on the input parameters of the model and their uncertainty. Our results revealed up to 17% improvement in contribution margin, depending on the planning day. A more detailed analysis reveals that patients classified by the DRG grouper may not be admitted at all because they compete for scarce resources with those patients whose contribution margin is obtained using the Naïve Bayes-classified DRG.

Discussion

The connection between our early DRG classification and the patient admission and scheduling problem should be seen as preliminary results of a sensitivity analysis regarding the extent to which better DRG prediction leads to more effective resource allocation. These models and methods can now be embedded in a real-time decision support system that can inform a decision maker in a hospital about the value of early availability of information about patients to increase classification accuracy and, as a consequence, lead to better resource allocation decisions. This approach for early classification of patients' DRG is not only applicable for elective patients but can also be used for emergency patients, as shown in [6].

Another result of our decision support system based on the mathematical model is that a decision maker can be better informed about patients who would be admitted or scheduled based on a hospital's patient admission and scheduling policy. Furthermore, the decision variables of the model could also reveal that admitting and scheduling patients based on the model's recommendations may lead to higher contribution margins. Identifying these opportunities can also be supported by the approach and tool discussed in this paper which can be included in the platform of Gartner and Padman [7].

Finally, these models and methods provide a rigorous, systematic and evidence-based approach to integrating and analyzing financial objectives of healthcare delivery organizations with operational decisions that are driven by

clinical requirements as well as planning and resource allocation constraints.

Conclusion

In this paper we have presented a novel approach to link classification methods with a discrete optimization model for the problem of scheduling elective patients hospital-wide. The objective is to maximize the contribution margin for elective patients using real-world data from a mid-sized hospital. The results show that if hospitals pursue an objective of making admission decisions based on DRGs, basic machine learning techniques such as Naïve Bayes can lead to more efficient resource allocation decisions as compared to the use of a hospital's current approach using a DRG grouper.

Several streams deserve further research. In order to make the model more applicable in hospitals, our goal is to incorporate overtime flexibility into the model and to consider more specific assignments of patients to a variety of resources, for example, human resources such as surgical teams. Following the approach of Gartner and Arnolds [3], we will also incorporate uncertain clinical pathways into the scheduling process. Preliminary results on a simplified model are shown in prior work [4]. Furthermore, we will evaluate other machine learning techniques such as decision trees, Bayesian networks and logistic regression in combination with the early DRG classification and resource allocation task. Another task is to break down the results into a length of stay analysis, and an evaluation of the confusion matrix in combination with admission and scheduling decisions.

Technical Appendix

Sets, indices, parameters and decision variables

Table 1 provides an overview of the sets, indices, parameters and decision variables.

Table 1 – Sets, indices, parameters and decision variables

Set	Description
A	Activities, Attributes
A_p	Activities for patient $p \in P$
D	DRGs
E_p	Precedence relations
P	Patients
R	Resources
R^d	Day resources
R^n	Overnight resources
T	Days
W_i	Time window for activity $i \in A$
Index/parameter	**Description**
α_p	Admission date of patient $p \in P$
$a \in A$	Attribute
b_p	Specialty requirement of patient $p \in P$
d	DRG
d_i^*	DRG to which instance i is assigned
$d_{i,j}^{\min} \geq 0$	Minimum time lag corresponding to precedence relation $(i,j) \in E_p$
E_i	Earliest day to schedule activity $i \in A$
i	Instance
$i \in A$	Activity
(i,j)	Precedence relation between activity $i \in A$ and $j \in A : i \neq j$
L_i	Latest day to schedule activity $i \in A$
$p \in P$	Patient
$p(d)$	Prior probability of DRG d
$p(v_{i,a} \mid d)$	Conditional probability of DRG d given instance i's value of attribute a
$\pi_{p,t}$	Contribution margin for patient $p \in P$ discharged at day $t \in W_{\phi_p}$
ϕ_p	Discharge activity for patient $p \in P$
$r_{i,k}$	Resource requirement of activity i from resource k
$t \in T$	Day
$v_{i,a}$	Value of instance i's attribute a
Decision variable	**Description**
$x_{i,t}$	1 if activity i is scheduled for day t, 0 otherwise
z_p	1 if patient p is admitted, 0 otherwise

Mathematical program

$$Maximize \sum_{p \in P} \sum_{t \in W_{\phi_p}} \pi_{p,t-\alpha_p} \cdot x_{\phi_p,t} \quad (2)$$

Subject to

$$\sum_{t \in W_j} t \cdot x_{j,t} \geq \sum_{t \in W_i} t \cdot x_{i,t} + d_{i,j}^{\min} \cdot z_p \quad \forall p \in P, (i,j) \in E_p \quad (3)$$

$$\sum_{i \in A : t \in W_i} r_{i,k} \cdot x_{i,t} \leq R_{k,t} \quad \forall k \in R^d, t \in T \quad (4)$$

$$\sum_{p \in P : b_p = k, t \geq \alpha_p} \left(z_p - \sum_{\tau = E_{\phi_p}}^{\min\{t, L_{\phi_p}\}} x_{\phi_p,\tau} \right) \leq R_{k,t} \quad \forall k \in R^n, t \in T \quad (5)$$

$$\sum_{t \in W_i} x_{i,t} \leq 1 \quad \forall i \in A \quad (6)$$

$$\sum_{i \in A_p, t \in W_i} x_{i,t} = |A_p| \cdot z_p \quad \forall p \in P \quad (7)$$

$$x_{i,t} \in \{0,1\} \quad \forall i \in A, t \in W_i \quad (8)$$

$$z_p \in \{0,1\} \quad \forall p \in P \quad (9)$$

A bed allocation example

An example with two patients is presented in Table 1.

Table 2 – A bed allocation example for two patients

t	1	2	3	4	5	6	7
$x_{\phi_1,t}$	-	-	-	-	0	1	0
$\sum_{b_1=1, t \geq 1} \left(z_1 - \sum_{\tau = E_{\phi_1}}^{\min\{t, L_{\phi_1}\}} x_{\phi_1,\tau} \right)$	1	1	1	1	1	1	1
$x_{\phi_2,t}$	-	-	-	-	0	0	0

$$\sum_{b_2=1,l\geq 1}\left(z_1-\sum_{\tau=L_{\phi_2}}^{\min\{\tau,L_{\phi_2}\}}x_{\phi_2,\tau}\right) \quad 0 \quad 0 \quad 0 \quad 0 \quad 0 \quad 0 \quad 0$$

In this example, we assume that we have a planning horizon of $T=\{1,2,...,7\}$ days and that both patients $p=1$ and $p=2$ have an admission date $\alpha_1=\alpha_2=1$ and a discharge time window of $W_{\phi_1}=W_{\phi_2}=\{5,6,7\}$. Moreover, we assume that we have one overnight resource $R^n=\{1\}$ and, for simplicity, no day resource $R^d=\{\}$. The overnight resource is required by both patients. Accordingly, the bed requirements for both patients come up to $b_1=b_2=1$. Assume, that patient $p=2$ cannot be admitted and therefore decision variable $z_2=0$. The table reveals that a bed is allocated for patient $p=1$ from his admission in period $t=1$ until his discharge in period $t=6$. In contrast, patient $p=2$ does not allocate a bed since he is not admitted and, because of constraints (7) he is not discharged.

This study is exempt from IRB because it analyzes de-identified data.

Abstract

There is an important knowledge gap in food allergy management in understanding the factors that determine allergic reactions to food, in gathering objective reports of reactions in real time, and in accessing patients' reaction-histories during consultations. We investigate how eHealth methods can close this knowledge gap. We report experiences with an online tool for reporting allergic reactions that we have developed as a web application. This application has been successfully validated by participants from Ireland and the UK, and is currently being used in a pilot where participants report allergic reactions in near-real time.

Keywords:

E-Epidemiology; Recall Bias; Web-based Reporting; Allergic Reaction; Food Allergy; Personal Health Record; Self-care.

Introduction

Allergic disease is a growing health risk [1],[2], while its management by clinicians and patients is challenging [3],[4],[5].

Food allergy has reached epidemic proportions in developed parts of the world [6],[7] with up to 20 million European citizens suffering from food allergy [8] and reports of increasing prevalence in developing countries [9]. The reasons for such an increase are not well understood. The estimated worldwide prevalence of food allergy varies according to age with 3-8% reported prevalence among children and 1-3% among the adults [10]. Unsurprisingly, food allergy is a leading cause of anaphylaxis seen in emergency departments across the USA and UK [11],[12].

We can identify the following problems in food allergy:

1. There are gaps in current scientific and societal knowledge, in terms of linking food allergy complaints from patients to evidence. Correlates of risk perception, risk taking behaviours, and psychosocial aspects have been largely overlooked in the literature of the topic.
2. During typical clinician consultations with food allergy patients, the clinician has only a short time (e.g., 20 minutes), and normally no access to consistent detailed information about the patient's previous reactions. Inexperienced doctors may misinterpret both mild and severe allergic reactions. Also, patients describing previous reactions tend to exhibit a recall bias, recalling better the more severe reactions, and failing to report the mild reactions.
3. Food manufacturers often don't have post-marketing information on the incidence of accidental allergic reactions due, for instance, to cross contamination as there is no system in place for reporting real-time allergic reactions in the community setting.

Scientific aim and objectives

Our aim was to improve the capture of objective information on accidental allergic reactions to food in order to address the knowledge gap in food allergy.

Our primary objective was to develop a system that can be used by food allergy sufferers to report information about suspected allergic reactions. This system is intended for collecting data in validation and pilot studies as part of the iFAAM EU FP7 project (integrated approaches to food allergen and allergy risk management), seeking the factors related to food reactions. Data will be integrated into the iFAAM informatics platform Allerg-e-Lab.

Our secondary objective was for this system to be developed as a prototype reporting tool that could be used by clinicians and patients to report and view previous allergic reactions in a clinical context.

Relationship to similar existing systems

There are a number of spontaneous reporting systems for reporting adverse events in areas of blood transfusion [13], medical equipment, drugs or tissues [14],[15], and foods [16]. These tend to be nationwide systems for the capture of reports of adverse reactions for regulatory reasons where there may be a mandatory requirement to enable adverse events to be reported; they never have a clinical function. In contrast, we are developing a system with eventual application in clinical consultations, giving clinicians access to patient-reported historical allergic reactions.

Our approach has been to understand food allergy and the context of reactions as opposed to just a context of foodstuffs (i.e. a register of products leading to adverse events). We capture a range of factors specific to food allergy, photos, food sample descriptions, and a questionnaire regarding the reaction.

Methods

Developing the system requirements

The stakeholders/users of the system are:

- clinicians, researchers, nurses, and study staff at University Hospital South Manchester (UHSM), UK;
- research staff and clinicians at University College Cork, Ireland (UCC);
- study participants recruited online, through the Anaphylaxis Ireland website, the Anaphylaxis campaign website, and UHSM allergy clinic.

The system requirements were developed in an iterative cycle of discussing requirements, implementing a draft solution, and incorporating feedback from stakeholders into refinements.

Questionnaire structure

In order to capture necessary information about food allergy reports from participants, to address our primary objective, the allergic reaction in the community (AlleRiC) questionnaire instrument was developed. This took place between March-October 2013 following 16 focus groups of adults and children diagnosed with food allergies. The instrument was developed in Ireland and the United Kingdom by experienced clinicians and researchers with an active contribution of patients' organisations. Transcripts were then analysed using the grounded theory approach, which involved coding and categorising codes into emergent themes. Items selected from the themes found in the transcripts were taken verbatim and then rephrased into a question format. Items were constructed to reflect the most prevalent characteristics and circumstances of food-allergic incidents as experienced in the real world.

Three experts in the field were consulted in person and via an exchange of e-mails; all disagreements were dealt with by negotiations till consensus was reached. Finally, the recent relevant literature in the field was reviewed to triangulate the above contributions.

In total there are 81 question items including conditional questions. When the participant first logs in they are asked to complete four enrollment questions. The incident questionnaire is then answered for each future reported reaction.

These questions were based on what consumers themselves told us were their main concerns related to the aims of the study, so are grounded in everyday lives and behaviours and therefore one aspect of good construct validity.

The questionnaire captures information about the following factors: subjective intensity measure (Figure 1), location and social context, food/meal/allergen details, physical and psychological symptoms, co-factors such as exercise, trip abroad, period, medication used, and follow-up, labelling and other allergen information, community and professional support, and additional comments.

Validation study

We carried out an initial feasibility study in the form of a validation study, to check that participants are able to use the system to report reactions. A separate group of adult patients diagnosed with food allergies in Ireland and the UK was recruited between December 2013 - February 2014 to evaluate the system by reporting an historic reaction. Participants were recruited online through charities that support food allergy sufferers: the Anaphylaxis Ireland website (www.anaphylaxisireland.ie), the Anaphylaxis Campaign website (www.anaphylaxis.org.uk), and UHSM allergy clinic.

Individual question items of the tool were psychometrically assessed via a novel Evaluative Scale (ES). ES was developed by researchers and patients to allow for the evaluation of five distinct aspects of the prototype questions: ease of understanding, reasonableness, usefulness, ease of answering, and clarity of instructions.

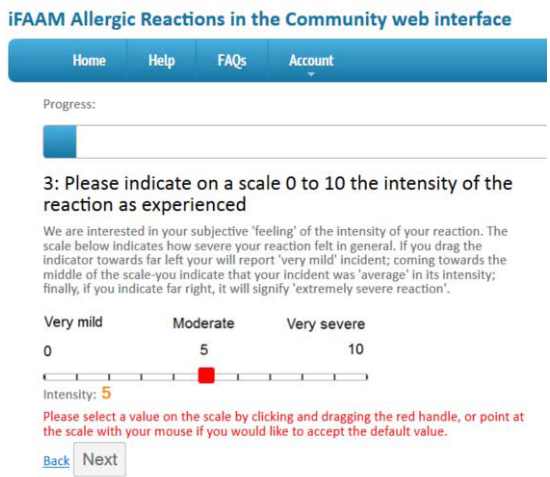

Figure 1 – Screenshot with reaction intensity question

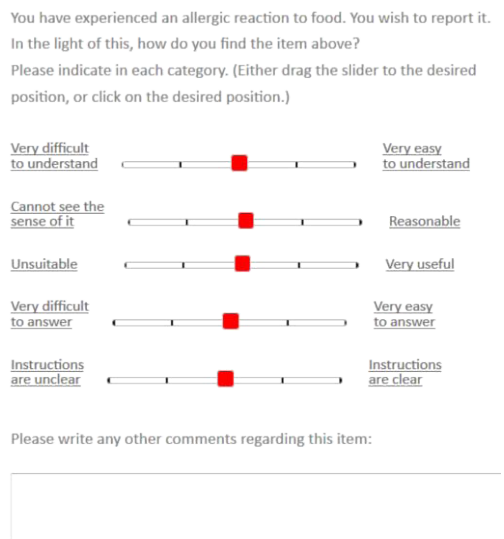

Figure 2 - Evaluative scale as implemented online

Figure 2 shows the evaluative scale as implemented in the AlleRiC system graphically.

ES uses a Likert-type response format on a five-point left-to-right scale range from "0" standing for "very negative evaluation" to "4" standing for "very positive evaluation".

Hence, each question item consists of the question, and the validation section of five drag and drop scales, and a textbox for comments on the question item.

Results

Requirements

Study participant requirements

Study participants need to use the system for three main tasks: 1) when using the system for the first time they should

complete the consent form if they are have not done so in a clinic, view training materials and complete the enrollment questionnaire; 2) if they experience a suspected allergic reaction to food, they will need to complete an incident questionnaire to describe their reaction, if available they can upload photos of skin symptoms or food; and 3) users should be able to access a list of their reported reactions by date, but not extract any data from the system in the current stage of the project.

Clinician requirements

For the pilot study, clinicians needed to use the system to report severity scoring of any skin symptoms. They will view photographs of skin symptoms using a separate system, and select the severity of symptoms in this system using drop-down menus within this application.

Research study staff requirements

Research study staff should be able to carry out activities such as adding and managing participant accounts, and viewing participants responses in the system.

During the pilot stage of the study, the participants are asked to obtain food samples, and upload photographs of packaging where possible. Based on this information, the LanguaL [17] food thesaurus will be used by researchers to describe the food(s) identified by the participant, using relevant faceted classifications. After describing the food(s) with the LanguaL food product indexer [17], the classifications can be exported as XML and the system should allow these to be imported, with the data linked to the reported incident.

The system should allow email notifications to be sent to research staff to assist in organizing the study. These should include: notifying them of participants starting/finishing reporting an allergic reaction; uploading photographs; availability of food samples, LanguaL™ food descriptions being attached to an incident; and clinicians inputting severity scoring based on photos of skin symptoms.

Lead research staff requirements

The requirements of the lead research staff summarize the high level goals for the study using the system.

Properties

Realizing challenging requirements

Here we discuss the realization of requirements into properties of the system.

Recruitment and informed consent

The system allows participants to be allocated to a centre (UK or Ireland for the validation and pilot studies) and will automatically generate their study ID. The system presents an online consent form to participants recruited remotely and not in person through attendance at a clinic.

Workflows

When participants log in for the first time, if they are recruited remotely they are presented with the online informed consent form. The data captured by the system is divided into an enrollment questionnaire and an incident questionnaire. The enrollment questionnaire is done once (gender, age, diagnosed food allergy and asthma diagnosis). The incident questionnaire is completed each time the participant reports a suspected allergic reaction. Once the participant has answered the first question of the incident questionnaire, they can upload photos using the *My reactions* page, which lists the completed/uncompleted allergic reaction reports, with dates.

Once the incident questionnaire is completed, the research study staff can use the system to allocate a food sample to be analysed (if one is available). The LanguaL™ food descriptions and symptom severity scores can be uploaded at this point. The system has a list of incidents, and for each incident the status of questionnaire completion and upload of food descriptions and severity scores can be seen.

Photographs

Participants are requested to upload photos, including foods, packaging, and skin symptoms. The photos of skin symptoms are used by clinicians to carry out a reaction severity scoring. After participants upload the photos they can add descriptive text before confirming the upload. As these photos could be personally identifiable, the system only allows participants to upload the photos, after confirming the photo and providing a description, and displays information that photos have been uploaded but does not allow participants to download or view the photos from within the system. Also, clinicians use a separate secure system to view the photos when they complete the severity scoring.

Customizations for mobile devices and tablets

We made a number of modifications so that participants could access the system using a tablet or mobile device. For example, customizations so that more of the page is available to the question items for tablets. Tablets and mobiles do not have a cursor, so we made changes to the system based on hovering over items so that it would work correctly.

Mobile accessibility/web browser

We considered developing a mobile phone application, however due to resources and the large size of the questionnaire, we decided to develop a web application, with some modifications to enable it to work on mobile devices and tablets. However it requires use of a web browser and a network connection to communicate with the server.

Developing a phone application would have the advantage that participants could complete the questionnaire without a network connection and submit the data once a network connection is found. Participants are reminded not to report reactions until they have fully dealt with their symptoms, and the system is a prototype, so we thought this was an acceptable trade-off. Developing a mobile application would consume more resources as we would have needed to use a number of different technologies to produce software for each operating system. With a web application we only need to develop and support one system.

Participants have a *My reactions* page, listing their reported reaction incidents. Once participants start reporting a reaction and have answered the first question item, an incident is added to this list, and they can click a link to upload photos. If they log into the system from a mobile or tablet device supporting the HTML5 media capture *camera* tag they can upload a photograph directly from their device. As there are at most 42 items, we expect most participants to complete the questionnaire via a web browser at a computer or via a tablet, and use a mobile phone primarily as a camera and not to answer the questionnaire.

Source documentation

There is a requirement from clinical staff to be able to print off source documentation, including online consent forms and report reaction incident questionnaire responses.

As the system does not store any names of participants, when printing the consent form (for remotely recruited participants) the clinician can input the names of the participant, and clinical staff and print a hard copy. The system then records that the consent form has been printed.

Validation study results

There were three separate units of analysis at this stage of validation: 81 items of the prototype evaluated using an ES; ES as a psychometric construct; and the initial questionnaire as a psychometric construct.

Thirty-nine adults from Ireland and UK, diagnosed with food allergy, evaluated the prototype online. Tables 1 and 2 show the demographics of the 39 adults, with Figure 3 showing the age distribution. Fifty-four percent of the adults also had asthma, the most common allergies being peanut and treenut.

Individual items were evaluated positively or very positively by participants (60-70% of positive scores across the ES). Qualitative thematic analyses identified four main topics of concern, however these did not relate to the prototype or any of the items, so this data was not used in the subsequent refinement of the prototype.

Reliability of ES was assessed by Cronbach's Alpha statistic with any figure over 0.7 being regarded as good validity. ES yielded .991 Cronbach's Alpha demonstrating a very good internal reliability.

Acceptance during validation study

Our aim is to develop a system that is used to report reactions, here we assess basic measures of the use of the system: the number of questions answered, approximate time to complete the questionnaire, and the number of users evaluating the system by reporting a reaction. This is linked to what users want/need to be able to report accurately and conveniently.

Sixty-three usernames were allocated for the validation study, 39 questionnaires were successfully completed. For the uncompleted questionnaires, only four people started but failed to complete, the remainder did not start the questionnaire.

We recorded the time the first and last question items were submitted to use the difference to crudely approximate the time taken to complete a response. This assumes that participants complete the questionnaire in one session, without stopping. This measure will not capture the duration correctly if for example they log out of the system and log back in later to resume the questionnaire, or pause completing the questionnaire. We have discounted any reporting times over one hour which we can be reasonably sure involved leaving the questionnaire and returning later. The average time for the remaining completion times was 27.5 minutes (minimum 10, maximum 62 minutes). The time to complete the validation questionnaire is likely to be significantly longer than the pilot study, due to the evaluative scale present for each question item; this scale is not used during the pilot study.

Participants did not need to complete all 81 items due to the conditional nature of some question items, the maximum number of items in a completed response was 42, and minimum 29 items. Tables 1 and 2 show baseline characteristics of the participants.

Table 1– Baseline characteristics during validation study

Gender	Ireland	UK	Total
Male	3	2	5
Female	18	16	24
Total	21	18	

Table 2 — Diagnosed allergies during validation study

Allergy	Participants with allergy	Allergy	Participants with allergy
Peanuts	28%	Milk	7%
Treenuts	24%	Wheat	3%
Seafood	9%	Fruit/veg	13%
Egg	11%	Other	5%

Discussion

We developed a prototype system to enable the reporting of suspected allergic reactions in near-real time, capturing a range of information about the context and nature of the reactions. This system has been successfully used in a validation study with 39 participants from the UK and Ireland using it to report an historical reaction.

Our system has some limitations, for example, as it is accessed via a web browser, we require network connectivity to access the system. Participants are asked to upload photographs if these are available. This can be done either by uploading the photos via a web browser from a computer, or, by logging into the system on a phone/tablet with a web browser, in which case the camera on the device can be used. The results of the pilot study will enable us to see whether participants upload many photos; we did not ask participants to upload photos during the validation study.

The validation data indicated some issues with distribution resulting from the voluntary nature of the recruitment, most notably, the sample was not representative of a wider population with 90% of all participants being female. This gender bias will need to be addressed in the next stages of the validation process.

The study asks participants to deal with their symptoms before reporting a suspected allergic reaction, this will result in a delay between the reaction and reporting the reaction. The amount of time passing before reporting symptoms influences the reported symptoms. Therefore as the system captures the time of reaction as a question, and records the time the questionnaire was submitted, in the analysis we could control for time lag between reaction and report.

In regard to the length of the questionnaire, and the validation process, it is important to note that during validation participants only used the system once. For the pilot study they may report along the full spectrum of severity – this is novel because usually only the severe end of the spectrum is presented in accident and emergency hospital departments. This type of information may be used to inform future integrated dynamic models of 'severity' and behaviours.

The validation and pilot studies have involved recruiting participants through clinics, and anaphylaxis campaign websites, and these populations may not be representative of the general population in terms of engagement with the system.

AlleRiC is currently undergoing further validation in its pilot stage, which involves live-reporting of food-allergic reactions.

This phase runs from October 2014 for a period of 18 months. The recruitment strategy for the UK is the University of Manchester population, the UHSM allergy clinic, and Anaphylaxis campaign, and for Ireland includes University College Cork population (there is no clinical involvement in Ireland), GPs, private allergy clinics, Anaphylaxis Ireland members, and through social media. Both UK and Ireland use online recruitment. The eligibility criterion are: adults aged over 18, capable of giving consent, with a physician diagnosed

food allergy. Participants will use the system to report suspected allergic reactions over this period. The resulting dataset will be analysed quantitatively (aspects of food eaten, treatment etc.). A qualitative analysis will be done on suitable text fragments, e.g., open ended text questions, to investigate participant experiences related to allergic reactions to food.

After the completion and analysis of results of the pilot study, cross cultural validation will be undertaken using a multi lingual version of the system across four distinct geographic regions in Europe.

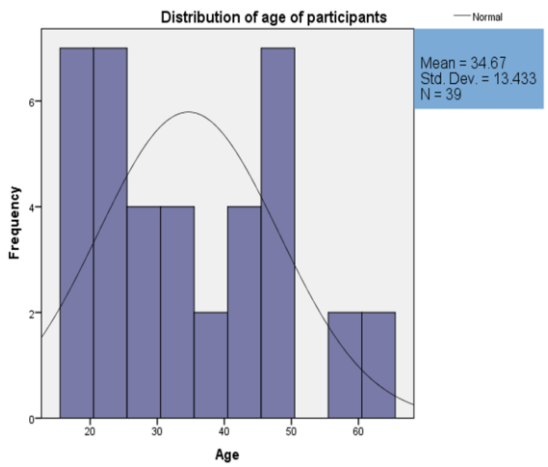

Figure 3 –Age distribution for initial feasibility study

Conclusion

A web based system, AlleRiC has been developed and now enables reporting of suspected allergic reactions to food in near-real time. The system has been used in a validation study with 39 adults from the UK and Ireland who have diagnosed food allergies – successfully reporting historical reactions and evaluating the system. The system is now deployed in a pilot study in the UK and Ireland where participants are reporting reactions prospectively in near real time.

As more people spend more of their lives online there is an epidemiological opportunity to tackle recall bias in ways that might otherwise increase sampling bias due to diferences in technology access. We have used this e-epidemiology tipping-point to address a big gap in food allergy knowledge.

Acknowledgements

The iFAAM project has received funding from the European Union's Seventh Framework Programme for research, technological development and demonstration under grant agreement No KBBE.2012.2.4-04. Supported also by MRC Health eResearch Centre, Farr Institute (MR/K006665/1). We thank Anaphylaxis Ireland, the Anaphylaxis Campaign UK, and the study participants for their help with the studies.

PancreApp: An Innovative Approach to Computational Individualization of Nutritional Therapy in Chronic Gastrointestinal Disorders

Konrad Stawiski[a], Alicja Strzałka[a], Anna Puła[a], Krzysztof Bijakowski[b]

[a] *Faculty of Medicine, Medical University of Lodz, Lodz, Poland*
[b] *Faculty of Computer Science, Electronics and Telecommunications, AGH University of Science and Technology, Cracow, Poland*

Abstract

Medical nutrition therapy has a pivotal role in the management of chronic gastrointestinal disorders, like chronic pancreatitis, inflammatory bowel diseases (Leśniowski-Crohn's disease and ulcerative colitis) or irritable bowel syndrome. The aim of this study is to develop, deploy and evaluate an interactive application for Windows and Android operating systems, which could serve as a digital diet diary and as an analysis and a prediction tool both for the patient and the doctor. The software is gathering details about patients' diet and associated fettle in order to estimate fettle change after future meals, specifically for an individual patient. In this paper we have described the process of idea development and application design, feasibility assessment using a phone survey, a preliminary evaluation on 6 healthy individuals and early results of a clinical trial, which is still an ongoing study. Results suggest that applied approximative approach (Shepard's method of 6-dimensional metric interpolation) has a potential to predict the fettle accurately; as shown in leave-one-out cross-validation (LOOCV).

Keywords:

Personalized medicine; nutritional therapy: machine learning; chronic gastrointestinal disorders.

Introduction

The experience of pain and complaints associated with gastrointestinal disorders determines patient's fettle and has an impact on the recovery rate. Nutrition therapy, although complex in nature, has a meaningful role in various gastrointestinal disorders such as chronic pancreatitis [1], inflammatory bowel diseases (Leśniowski-Crohn's disease and ulcerative colitis) or irritable bowel syndrome.

Pancreatitis is commonly defined as a continuous, chronic, inflammatory process of the pancreas, characterized by irreversible morphologic changes. For the majority of patients with chronic pancreatitis, abdominal pain is the most common symptom. This intermittent pain may worsen after eating or drinking. There is a sizeable list of reported etiological factors of pancreatitis which can be categorized into: (1) toxic and metabolic (connected mostly with alcohol intake), (2) genetic, (3) autoimmune, (4) recurrent acute or severe acute pancreatitis, (5) obstructive and, lastly, (6) idiopathic. According to a paper from 2008 by Shallu et al. the main issues in chronic pancreatitis are exocrine insufficiency and pain – which are also the two main reasons of diet regime and malnutrition in pancreatitis patients. Unquestionably, the dietary regime can soothe inconveniences and thus self-control is as crucial as clarity of recommendations [2]. However, guidelines may not be appropriate for every individual, thus personalization is needed. Lack of the individualization can affect directly the compliance, as guidelines are usually complex and can be misinterpreted by patients. Personalized therapy applied in other scenarios, has recently shown positive results [3, 4, 5].

Individualized diet can increase fettle and improve the compliance of patients suffering from chronic gastrointestinal disorders. Diet-related patterns are also being constantly searched for in inflammatory bowel diseases and in the irritable bowel syndrome. This is driven by the fact that etiology of these diseases is still unclear.

The aim of this study is to develop and evaluate a solution with the purpose of supporting patients' self-control and adjust diet to the best possible fettle based on an individualized machine learning model. The proposed solution iscalled – PancreApp (fig. 1).

Figure 1 – Logo of PancreApp project.

Materials and Methods

This paper describes the process of idea development and application design, feasibility assessment using a phone survey, preliminary evaluation on 6 healthy individuals and the earliestresults of the clinical trial, which is still an ongoing study (21 patients involved so far).

Idea development and application design

PancreApp is designed as a multiplatform, cloud-based digital diet diary, which not only enables regular control of the disease, but also tries to predict diet-related changes of fettle using computational methods. The application considers the details of diet and associated disease manifestations as input. The aim of the data processing is to provide patients with an individually computed multidimensional profile of their

disease which can be applied in the estimation of fettle for the next meals. In this model continuous acquisition of new data enables constant calibration of prediction; in general a concept of machine learning algorithms. (fig. 2)

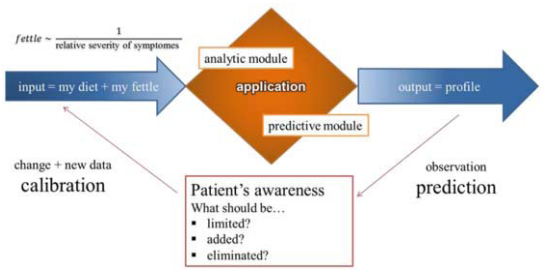

Figure 2 – Graphical representation of PancreApp core concept.

We developed two distributions of the software. The first one, for Microsoft Windows OS (using C# programming language based on .NET Framework CRL, Microsoft Visual Studio 2013 Professional) and the second one - a mobile version for Android OS users (JAVA programing language). Applications, being in bilateral connection with server (python-based, HTTPS protocol, XML format), allow the user to use software in every scenario. The application is harvesting data as the user is determining the diet and fettle after the meal (on a scale).

Entering data is facilitated by the fact that food products available in the market are almost always described quantitatively, based on basic ingredient content. It offers a possibility to count how much of the basic compositions (fat, carbohydrates, fiber, proteins and energy) the users consume during a selected meal and also provides patients with a possibility to archive their diet faster (via simple selection, rather than manual calculation). Our product database contains over 2200 products that are available in the Polish market. When the diet is known, users can define their fettle (associated with a particular meal). The fettle can be determined by the user on a scale from 1 to 10 (where 10 is the best) and should reflect the severity of symptoms. Screenshots of the general user interface are shown in figure 3.

The application, in addition to the prediction model, contains a reach analysis module wherein the patient can find statistics and charts visualizing his diet. The user can ,for example, put together the amount of of consumed fat and the associated fettle. This particular relationship may be clinically relevant in chronic pancreatitis.

The prediction model allows the user to estimate the fettle of future meals based on previous meals and fettle (training set). Its screenshot is presented in figure 4. Among all the methods, we were looking for a simple one that would give users results quickly, even on devices where central processing units have low clock rates. -, PancreApp's prediction model is using Shepard's method of 6-dimensional (multivariate) metric interpolation; as inverse distance weighting is the simplest interpolation method. Specifically, multi-dimensional euclidean distance is calculated and then applied for weighting. Fettle is predicted on the previously described scale and its value is specific for each patient.

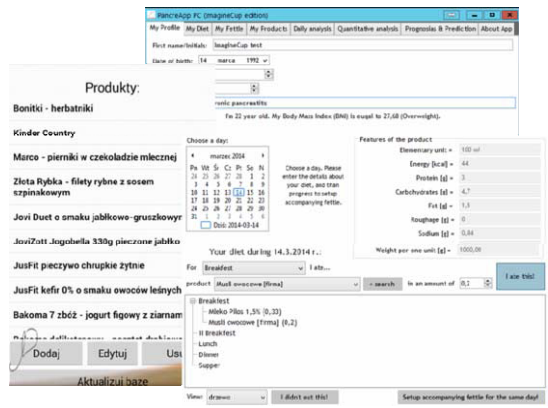

Figure 3 – Screenshots of PancreApp's general user interface. Right-sided pictures present the application for Microsoft Windows OS, left – for Android OS.

The latest version of the application is available for MEDINFO participants to download and test. Links are attached in the references. [6]

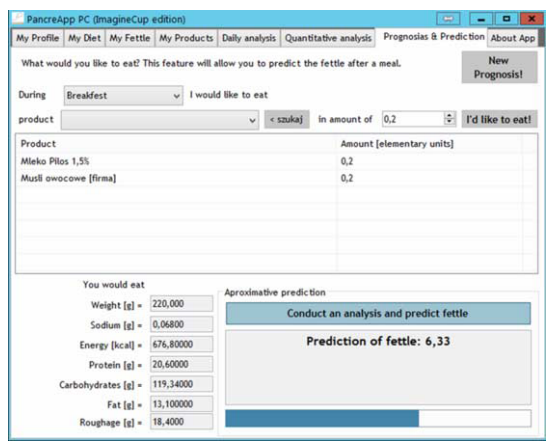

Figure 4 – Example of prediction.

Preliminary evaluation

Preliminary evaluation has been conducted on 6 healthy individuals that were using the software on a daily basis for 2 weeks. We focused on a comparison of relative difference between a real fettle set by the user and a potential prediction that could be calculated using the rest of the training set. This applied technique is henceforth referred to as the leave-one-out cross-validation (LOOCV). STATISTICA (StatSoft Inc.) and our proprietary software were used for data analysis.

We have also conducted a phone survey on 9 patients with chronic pancreatitis after pancreatic drainage/resection during the last 3 years to assess if the proposed idea reflects the needs of the target group. We asked about pain, depression (PHQ-9), food intolerance and access to a personal computer or to a mobile phone with Android.

Clinical trial

Since October 2014 this project has been financed by the Polish Ministry of Science and Education as a grant for student researchers. We enrolled adult patient-volunteers with chronic pancreatitis, inflammatory bowel diseases

(Leśniowski-Crohn's disease and ulcerative colitis) or irritable bowel syndrome. The only requirement was possessing a device with continuous access to the internet and the completion of the application tutorial. Enrolled patients were randomly divided into the control and experimental group and were then using the application for the 3 following weeks. The experimental group was able to use the prediction model, while the control group could use PancreApp only as a simple diet diary. At the beginning and at the end of the trial we measured patients' basic physical parameters and PHQ-9 score (assessment of depression that may affect compliance). To this day, 21 out of 100 patients (planned) have been enrolled into the trial, while 10 of them have finished it. In the analysis we want to assess how well this algorithm can predict fettle (by correlation coefficient and root mean squared error as well as LOOCV), how often the prediction model is used (frequency) and if patients experience time-related changes in fettle. We also want to analyze z-scores of fettle, compared to the amount of consumed basic compositions.

Results

During preliminary evaluation, the study group consisted mainly of young people with normal BMI (mean: 20.06; mean age; 24.3; mean energy consumed: 1408.4 kcal). Related-Samples Wilcoxon Signed Rank test showed that median difference between the well-being (fettle) value described by the tester and the well-being value predicted using Shepard's algorithm (based on all data except for tested; LOOCV) was not statistically significant (p=1.00). The absolute error of prediction was equal to 0.6454, while the relative error of prediction equaled 7.59% of fettle value.

The survey showed that studied patients with pancreatitis (mean age: 52.4) have a depression according to PHQ-9 score (fractions: minimal 0.11 vs. mild 0.55 vs. moderate 0.33). Food-specific intolerance was noted by 8 out of 9 surveyed patients. All surveyees were interested in participation. Only one of surveyed patients had a phone with Android OS. The rest of the patients would prefer using PC with Windows OS.

In this paper we would also like to describe the early results of the clinical trial that will end in May 2015. As described above, 10 patients finished the trial so far, however only 4 of them completed it successfully (used the application over the full testing period). The analysis of patients who dropped out has shown that 2 out of 6 patients were using the application irregularly (despite of reminders), 3 out of 6 never used the application after training meetings and were unreachable for further contact, while one patient was affected by a compatibility issue between .NET Framework 4.5, ClickOnce installer and Windows XP. None of the enrolled patients have , so far, decided, to use the Android version of the application. There was no significant difference between patients who completed the study and patients who dropped out, also in the PHQ-9 score. Patients presented a mean age of 29.8, weight of 68.6 kg, height of 176.2 cm and PHQ-9 score of 8.

The analysis of the 4 patients who have completed the trial so far, has shown good properties of Shepard's method. Two of those patients have Crohn's disease, one has ulcerative colitis and one irritable bowel syndrome. The chart in figure 5 presents the comparison between the predicted value of fettle and the real one, set by the user. Please note the distance between native data and ideal prediction showed by the red line. It is visible that a 95% confidence interval of regression almost contains the line of ideal prediction. The root mean squared error is equal to 0.80, while Spearman's correlation coefficient between predicted and real values is equal to 0.87 (p=0.000). Time-related changes and the usage of the prediction model will be assessed when the trial is completed. The performed analysis considered only whole days, without division into separate mealtimes.

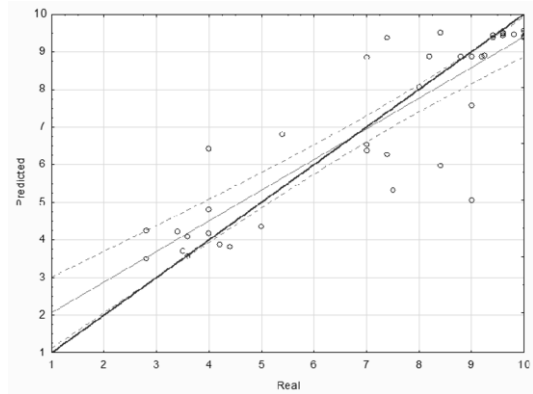

Figure 5 - Comparison between the predicted value of fettle and the real one. The solid thick line presents ideal prediction (f(x) = x), while the thin one (with concomitant dashed lines) shows the linear regression (and 95% confidence intervals). Analyses were performed for whole days. Please note that days without determined fettle change were excluded.

Discussion

Doctors of medicine frequently complain about therapeutic compliance. Lack of faith in treatment is one of the factors predisposing reduced compliance [7], while the therapeutic effect may be strictly dependent on feedback from a patient. PancreApp targets both problems. Machine learning and data-mining techniques are very promising and widely used in various aspects of science. The algorithm applied here is one of the simplest. It can, however, be quickly deployed in an everyday scenario (on low-end devices). It is also necessary to notice the need to test and compare different regression methods on data harvested from this study (retrospectively).

So far, the idea of PancreApp is appreciated by patients and doctors. Despite the fact that we have analyzed early results, from a clinical point of view the prediction accuracy of PancreApp is good. However, several limitations should be noted. Firstly, usage of fettle as a self-assessment of clinical state is disputable, and modern medicine is going to be focused on the quality of life rather than on simple survival. Also, the Hawthorne effect, or selection and technology bias cannot be excluded as a convenient sample is being enrolled. Patients without basic computer skills cannot either benefit from this study. However, based on the results, PancreApp seems to be intuitive enough for usage. Current compliance is in the expected range, as all patients (qualified so far) are in a remission state.

It is also notable that not one patient has chosen an Android device so far (even if they have such an opportunity), suggesting that personal computers are more approachable when it comes to complex data entry.

Conclusion

In this paper we present an innovative approach to computational individualization of nutritional guidelines. Early results from evaluation have shown that the applied approach has a potential to predict the fettle accurately and with low error. A possible broad spectrum of application (pancreatitis, obesity, kidney and liver disorders) encourages us not only to finish the current trail, but also to check whether PancreApp could be applied in different scenarios (diseases). Furthermore, PancreApp can be used in evidence based medicine as an easy available data-gathering service. The main advantage is the flexibility achieved by individualized models. Data collected by this tool could also be used in retrospective analysis of studied disorders, and as a source of valuable inferences. The software has been approved by the local ethical committee. More details about the project can be found at www.pancreapp.pl

Abstract

According to facts given by the World Health Organization, one in ten deaths worldwide is due to an external cause of injury. In the field of pre-hospital trauma care, adequate and timely treatment in the golden period can impact the survival of a patient.

The aim of this paper is to show the design of a complete ecosystem proposed to support the evaluation and treatment of trauma victims, using standard tools and vocabulary such as OpenEHR, as well as mobile systems and expert systems to support decision-making. Preliminary results of the developed applications are presented, as well as trauma-related data from the city of Cuenca, Ecuador.

Keywords:

Clinical Decision Support Systems; Emergency Medicine; Mobile Applications; Injuries.

Introduction

Trauma is considered a pandemic worldwide that mostly affects young persons. Therefore, it has a negative impact on the production system of any nation [1][2]. This situation is not different in Ecuador, where since 1995 the injury burden has been documented in a national statistics database [3][4][5]. In this database, external causes of injury are not grouped as a single category, but rather are identified as separate etiologies such as traffic accidents, falls, violence, burns, animal bites, among others [6][7].

According to the Ecuadorian Institute of Statistics and Census (INEC), in 2011, the leading cause of death was diabetes mellitus with 7.15%, while land transportation accidents were the fifth leading cause, and homicides occupied seventh place. f we add up all the traumatic events, trauma becomes the leading cause of mortality at 8.76% [8].

For almost two years now, trauma care in the province of Azuay ha-s been provided at the Vicente Corral Moscoso Regional Hospital, by an Integrated Security System (SIS ECU 911) [9], which coordinates relief agencies in pre-hospital care (PHC) such as the Ministry of Public Health (MSP), the Fire Department, and the Ecuadorian Red Cross. During this period, trauma-related emergencies corresponded to 46% of all care provided, and 70% of this was managed at the public health hospital [4].

On those grounds, we have analyzed the interaction between the pre-hospital primary attention services and the transfer to the hospital. Based on this general analysis (response times, false trauma alerts, etc.) we have determined that the communication system between ambulances and hospitals requires improvements. Therefore, implementation of an improved data transmission system was undertaken. The aim of this paper is to describe how an ecosystem-related software can accomplish this improvement in patient care. Likewise, in this paper we will present preliminary results of the first support application developed; a mobile tool to improve the trauma data collection, communication with the hospital, route planning, and arrival estimation.

The rest of the paper is organized as follows: first, we present a general overview of the proposed ecosystem and its main components. Next, we detail the experiment we carried out as well as the preliminary results. Thereafter, we present some relevant research and discuss some applications of information systems for decision support and trauma care. Finally, our conclusions and future work are presented.

Methods

Trauma care is a complex field that currently requires an integrated solution able to face a wide spectrum of needs such as the following:

- Provide effective pre-hospital attention with the aim of reducing mortality.
- Raise awareness in people that are more prone to suffer accidents related with trauma (persons under 45 years).
- Have robust mobile systems to provide primary healthcare services during accidents.
- Have Information and Communication Technology (ICT) -based tools to support the learning process of medical students.
- Use standardized vocabulary with the aim of sharing and exchanging the patient's information.
- Use knowledge-based models for storing the clinical information.

On those grounds, we have designed an ecosystem that relies on a MLST system (mechanism of injury, suspected lesions, vital signs and effected treatment), and is able to manage critical information from pre-hospital care. Likewise, our proposal includes a prototype for the automatic capture of vital signs from equipment present in the ambulance, and an intelligent system with decision-making algorithms for the categorization of severity of trauma and prioritization of trauma alert. The captured information of the patient and his/her medical condition is sent to the nearest hospital as well as the geographical position of the ambulance, and the arrival time.

With the aim of providing complete support for trauma care, bearing in mind the needs mentioned above, we have designed a comprehensive ecosystem named SINATRA (Intelligent System to Support Trauma, for its acronym in Spanish). This model (Figure 1) relies on a layer-based approach that easily allows integrating more modules/services to cover new areas of trauma care, and supports the requirements of doctors, paramedics, students, and patients. The main objective of our ecosystem is to provide support to carry out activities and tasks that require decision support, and services to share, exchange and analyze information related to trauma care.

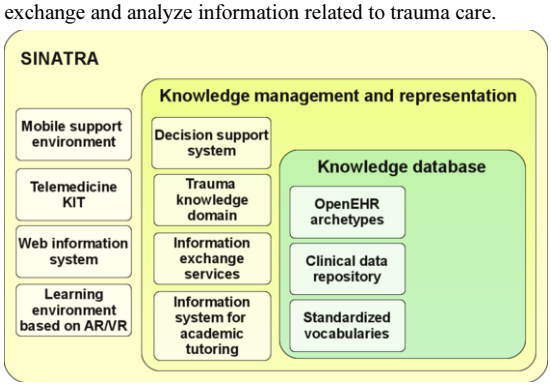

Figure 1– The proposed ecosystem for trauma support.

In this section we will provide a general description of the elements that make up the ecosystem as well as the preliminary achieved results using the mobile application.

Support tools based on ICTs

This layer is based on a set of ICTs tools that provide the interfaces to register medical information, access knowledge databases, and perform training with medical students:

- The *mobile support environment* is a set of mobile applications that provide support in the execution of several tasks such as registering critical information generated in the ambulance (pre-hospital care), remote patient monitoring, and registering and analyzing hospitals infrastructure for trauma care (staff, equipment, protocols, etc.).
- The *telemedicine KIT* is an electronic device that records patient vital signs (respiratory rate, blood pressure, pulse, and oxygen saturation) when he/she is being transported to the hospital.
- In order to manage the information stored in the knowledge database, the ecosystem includes a *web information system*. This tool is used to query a database, register new cases, generate reports, provide statistics, and support some data mining tasks like cluster creation according to several variables (geographical area of accident, demographic patient information, type of injury, etc.). Some components are based on OpenEHR archetypes and templates (www.openehr.org).
- With the aim of reinforcing some learning activities as well as raising the awareness about trauma, the ecosystem includes a *learning environment based on augmented reality and virtual reality (AR/VR)*. This environment can be used during classes at universities, or awareness campaigns for young drivers, seniors, and the general population.

Knowledge management and representation

This layer relies on a set of interfaces and provides several services to manage information. Additionally, in this layer it is possible to incorporate intelligent modules to cover areas related with machine learning, decision support, pattern recognition, data mining, and learning support, among others. Some of the most relevant elements are the following:

- The *decision support system* uses decision trees, neural networks and case-based reasoning to support decision-making in various aspects such as determining the type of alert that is sent to hospital after pre-hospital care (analysis of trauma, patient condition, etc.), allocation of resources for patient care (both human and material), as well as diagnosis and treatment.
- The *trauma knowledge domain* contains a complete set of protocols, procedures and trauma-related ontologies (initial management of trauma, shock, traumatic brain injury, infections, etc.).
- With the aim of providing the necessary tools to access to knowledge bases and share information with applications from other platforms, the ecosystem includes a set of *information exchange services*. These services include the templates generated from archetypes, exporting functionalities, and querying functions, among others.
- For a medical student that is in the academic training phase, it is very important to address real cases related to specific trauma situations. For this, our proposal incorporates an *information system for academic tutoring* that - can - generate random cases of patients with different cases of injuries. With the aim of saving the patient life or provide adequate treatment, the student should make a decision, according to the presented information. The system will rate the decision and will present a valid solution.

Knowledge database

- The *OpenEHR archetypes* allow us to model the different procedures, observations, instructions and data required to register information related to trauma. Figure 2 depicts an example of an archetype for a case of monitoring a blunt traumatic injury.
- In the *clinical data repository,* all information coming from different sources (prehospital, hospital, diagnosis, treatment, etc.) is consolidated.
- The *standardized vocabulary* contains the codes of classification and coding of diseases and a wide variety of signs, symptoms, abnormal findings, complaints, social circumstances and external causes of injury and/or illness.

Results

MOSPA is an Android ® application that is part of the mobile support environment of the proposed model. This application allows us to record the most important patient information from the MLST system (mechanism of trauma, suspected injury, vital signs, and treatment performed such as CPR, endotracheal tube placement, etc.). The pregnancy status and gestational age, among other prehospital information is also incorporated. In addition, the application cancalculate the type of alert (severe, mild or none) to be sent to hospital personnel and estimate travel time from the scene to the hospital (using Google® maps). The total number of variables that are handled by the application is 29 (according to MLST).

Figure 3 shows an example of the process that allows us to determine the kind of alert that must be sent from the ambulance to the receiving hospital. As shown, the system must analyze the values of each variable of MLST and how they are combined (two or more critical values, two or more

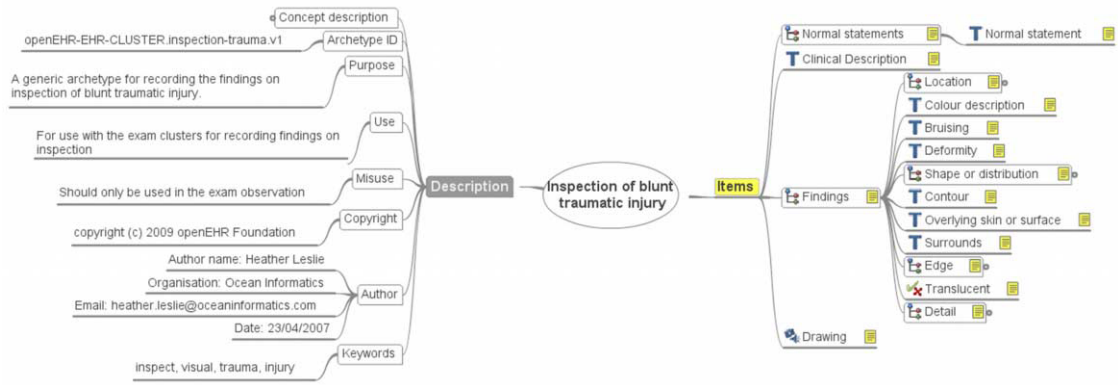

Figure 2 – Partial view of an OpenEHR archetype to perform the inspection of blunt traumatic injury (source: openehr.org).

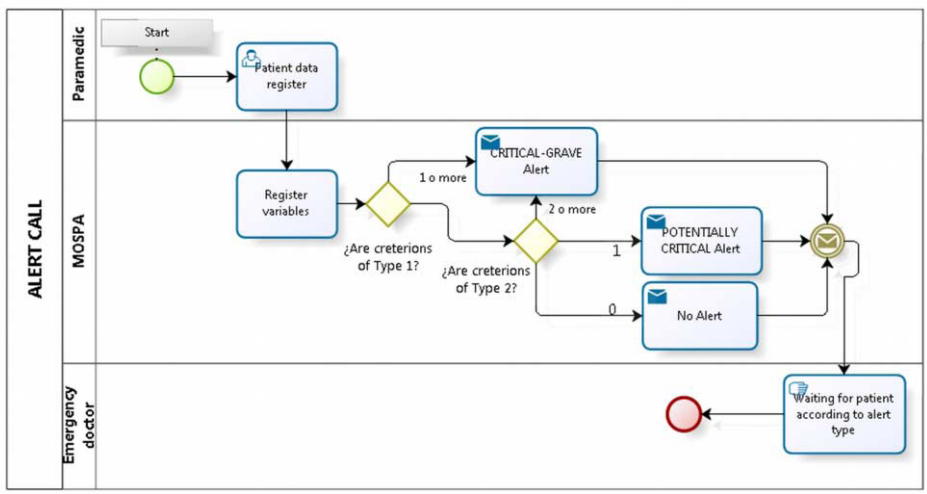

Figure 3– Logical process to determine the kind of alert that will be sent to hospital.

non-critical values, etc.). For example, whenever a patient presents arterial hemorrhage or major bleeding, the system must automatically send a critical alert to the hospital. Likewise, whether a patient has lost more than 500cc of blood and has been unconscious for more than five minutes, the system will send a critical alert.

To verify the tool, we conducted a laboratory pilot test with 32 participants who were trained in the use of the application. As a first step, random searches of trauma cases were generated, and then participants were requested to record such cases in the mobile application. As the participants filled-in all information of the cases, the time taken to record each was measured. This is illustrated in Table 1.

Table 1– Preliminary evaluation results of MOSPA.

Element	Value
Participants	32
Average filing time	59 seconds
Average number of errors comited	7

As we can see, the average time is about one minute, which is an encouraging result, since the participants involved are not professional paramedics, and this allowed us to establish that the application is an excellent alternative to be used in ambulances. To the best of our knowledge, the MLST system is commonly applied for trauma attention by using air transport. The maximum time to enter the information of trauma in these cases must be no more than one minute. Therefore, we consider that for terrain transportation of trauma patients, the time should be similar.

Figure 4a depicts a screenshot of the window that allows entry of information related to pregnancy. Figure 4b showed the route and estimated time of arrival of the ambulance to the receiving hospital.

Discussion

Today, intelligent systems have become a tool that supports the most diverse areas of science, providing various services such as support in decision-making, information discovery, pattern analysis, and artificial vision, among others. Just one of the sciences where such systems can provide important support is medicine because of the wide range of existing knowledge and the complex problems that must dealt with every day [10]. Existing developments are varied and include the application of various techniques related to the fields of engineering and especially with artificial intelligence.

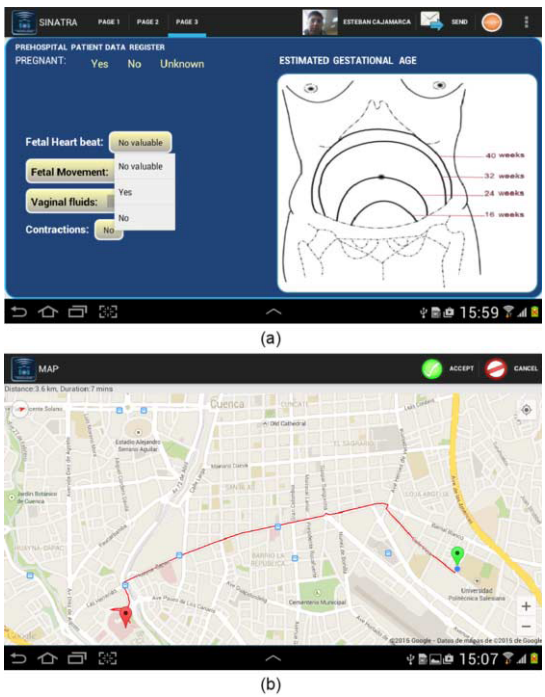

Figure 4 – (a) Screen capture of registration of pregnancy information, (b) Route and estimated time of arrival.

A report presented by Fitzgerar [11] aims to demonstrate that computer systems for decision support can reduce errors during the first 30 minutes of resuscitation when trauma occurs. Also, Han [12] presents a study on the use of expert systems to monitor biometric signals of patients who are at home.

Other areas of study on expert systems to support decision making in medicine focus on the following lines:

- Analysis and prediction of adult patients with intracranial hemorrhagic trauma (HIT): Nishijima conducted a study where an expert system based on rules to determine whether patients over 18 Years with HIT should move to the ICU [12]. The developed system used a set of rules derived from classification and regression trees and obtained promising results.
- Early diagnosis of cervical vascular injuries: Purvis [13] proposed using decision trees for the early detection of blunt cervical vascular injuries. Based on this research, the prevention of such injuries is expected, therefore should be improved outcomes for patients.

As shown, the proposed ecosystem could effectively replace the existing system given that the paramedics (in Cuenca) currently use only radio communication, and the staff hospital can not monitor in a real-time the patient condition. Likewise, currently the ambulance conductor provides an estimation of arrival time, but does not have automatized support to determine the nearest hospital or the best route to follow.

Conclusion

To the best of our knowledge, currently, Ecuador does not have an integrated environment to provide support at the different stages in trauma care. It is crucial to consider all actors involved in this process (doctors, paramedics, support staff, patients and their relatives), and try to optimize the response time and resources required to provide effective trauma care. We believe that the ecosystem described can be utilized as a tool in the process of managing and sharing information related to patient care.

Quantifying the Activities of Self-quantifiers: Management of Data, Time and Health

Manal Almalki[a], Fernando Martin Sanchez[a], Kathleen Gray[a]

[a] *Health and Biomedical Informatics Centre, University of Melbourne, Melbourne, 3010, Australia*

Abstract

Current self-quantification systems (SQS) are limited in their ability to support the acquisition of health-related information essential for individuals to make informed decisions based on their health status. They do not offer services such as data handling and data aggregation in a single place, and using multiple types of tools for this purpose complicates data and health self-management for self-quantifiers. An online survey was used to elicit information from self-quantifiers about the methods they used to undertake key activities related to health self-management. This paper provides empirical evidence about self-quantifiers' time spent using different data collection, data handling, data analysis, and data sharing tools and draws implications for health self-management activities.

Keywords:

Self-quantification; health self-management; participatory health; consumer health informatics; patient activation.

Introduction

A self-quantification system (SQS) is a tool for capturing personal data and an application for processing that data (e.g., analysing and visualising) according to an individual's objectives. SQS have the potential to track and measure various health aspects, such as sleep, weight, diet, and physical activity, and may offer opportunities for self-quantifiers to change behaviours and attitudes toward health self-care. In one study [1], 69% of US adults said that they tracked themselves, and 46% of those reported changing their behaviour based on the collected data.

There are two types of SQS: A primary SQS collects data directly from the users; health-related examples are MoodPanda for tracking mood and iBGStar for monitoring blood glucose. A secondary SQS can aggregate data delivered by multiple primary tools or apps, to facilitate data analysis; TicTrac, BodyTrack, and Argus are health-related examples [2].

Self-quantification for health consists of two main stages of activities in which a self-quantifier not only collects personal health measurements, but also manages and transform these data into actionable knowledge [2]. The first stage, data management, involves a chain of activites that are necessary to establish, use, and maintain a mapping between the individual's objectives and the information available. The second stage is health management; here the knowledge obtained from self-quantification is activley transformed into the desired health outcomes, a process that may be called health activation [3]. In these activities, the person attempts to establish self-awareness of one's health and functional status to actively engage with maintaining or improving it. Aggregating data from different devices and apps is a major facilitator in gaining a holistic view of one's health-related indicators [4].

To undertake this chain of activities for health data self-management, a self-quantifier may use multiple unconnected primary and secondary SQSs, and also ancillary tools – such as iPhone note apps, Microsoft Excel spreadsheet, or Dropbox. With their data and services scattered among different tools self-quantifiers may devote significant time for these activities. The aim of this paper is to characterise the experience of using combinations of such tools, particularly its impact on self-quantifiers' time and data, and to draw implications for health self-management and health activation.

Methods

Sample and demographic characteristics

An international online survey was conducted from December 2013 to March 2014 to elicit information from adult self-quantifiers, about the methods they used to perform key activities related to health data self-management - data collection, handling, analysis and aggregation, and sharing. Participants were recruited through Quantified Self meetup forums, Twitter, Facebook, and LinkedIn. People who used one or more self-quantification tools or apps as part of their health self-care were included. 103 individuals provided sufficient information for analysis.

Respondents from USA were the highest proportion (60%), followed by Australia (11%). Nearly two thirds (62%) were aged between 20 and 39 years. 75% were male. Almost one third (32.3%) had completed high school or equivalent; the rest had at least a university undergraduate degree. 68% reported good to very good health status. The top three motivations to use SQS were: to know if a certain health-related variable could affect another variable (64%); to find answers to specific questions related to health (62%); to proactively minimise possible future health problems (61%). The Eurostat's ICT (information and communication technology) model [5] was used to classify respondents into high (53%), medium (39%), and low (8%) level of ICT skills.

From the surveyed self-quantifiers, 89% used at least one tangible tracking device for self-quantification whereas 11% used only apps. The most popular primary tangible self-quantification devices were for tracking and quantifying physical activities, sleep, weight, calories burned, and diet: the Fitbit collection (e.g., Fitbit Ultra, Fitbit One, Fitbit Zip, etc.) with nearly 25% of the respondents; followed by Withings

tools (e.g., Withings scale, and Withings activity tracker) with 19%; and Jawbone Up with about 12%. The most popular primary tracking apps were 80Bites (for tracking food consumption), 42Goals (for tracking personal life goals such as quit smoking, lose weight, and reduce coffee consumption), and Moves (records walking, cycling, and running activities through step counter), among approximately 13%, 11%, and 9% of respondents respectively.

The most popular secondary self-quantification tool was BodyTrack (20% of respondents). In addition, two types of ancillary tools were used for collecting data and for handling the generated datasets. The most popular ancillary tools for data collection were diary apps such as Evernote, Microsoft One Note, and iPhone note apps (30% of respondents). Most popular tools for data handling were cloud storage services such as Dropbox, SkyDrive, and Google Drive, collectively used by nearly one quarter (24%) of respondents.

Statistical analysis

Data analysis to address the specific aim of this paper focused on responses to survey questions about the amount of time spent to undertake the key activities of health data self-management (i.e., data collection, handling, analysis and aggregation, and sharing). The survey devoted separate sections to each of the key activities where the participants were asked questions about the type of tools they used (i.e., primary, secondary, or ancillary); their experience in using these tools (i.e., less than 6 months, or 6 months or more); the frequency of tool usage (i.e., daily, weekly, or monthly) for these activities; the number of collected data types (such as blood pressure, weight, mood, coffee consumption, etc.); the methods used to collect these data (i.e., manual or automatic); and their ICT skills level. These questions represent a set of explanatory variables that were fitted in testing the statistical models.

General linear model for continuous outcomes, and logistic regression for binary outcomes, were conducted by using SPSS 22 Mac version. To construct these models, a manual backwards selection approach was used. We started with set of candidate explanatory variables and eliminated variables with large p-values one at a time. We stopped once all the remaining variables had relatively small p-values. It is worth noting that building these statistical models did not use only a simple analysis of concepts; rather, it involved exploring a more complex concept through testing for a two-way interaction. This two-way interaction is often thought of as a relationship between an explanatory variable and outcome variable that is moderated by a third explanatory variable. Once a two-way interaction between two varables was found, the main effects of the explanatory variables are not discussed given the presence of these interactions. Bootstrapping results were examined to check the robustness of our models. Also, SPSS 22 was used to run descriptive statistics, frequencies, and cross-tabulations to determine related demographics.

Due to the sample size limitation , we combined the two categories of medium and low ICT skills into one group (low to medium level). Also, the ICT skills level variable could not be fitted with other explanatory variables in a single logistic regression model. Adding this variable increases the number of categorical variables in the model which can result in empty cells and problems in model fitting. Therefore, two logistic regression models were built for these cases, one based on the ICT skills variable and the other including all other variables.

Results

Combined use of primary, secondary, and ancillary tools

No survey respondents were using only primary SQS for health data self-management. Nearly a third used all types of tools, i.e. primary, secondary, and ancillary. Nearly 80% used three primary tools to collect health related data; however, 51% stated that their primary tools did not offer the kind of data they needed and therefore had to use ancillary tools to collect the desired data.

75% of respondents used another type of ancillary tool for handling the collected data from these primary SQS, for example, to organise the collected data into folders, import or export data, update data or files. 70% of respondents were performing most of the related tasks manually. Thus, over two thirds (68%) had lost files permanently, and over three quarters (77%) had failed to locate old files.

75% of respondents used secondary SQS to aggregate the data generated from the primary SQS. In over a third (34%) of these cases the secondary tools did not connect automatically with the primary tools, requiring users to upload the datasets manually into the secondary SQS.

Time devoted to data collection

Survey respondents who used multiple primary and ancillary tools to collect the required data spent more time on average than those who used fewer tools. The data collection time was calculated by counting the cases that took over 10 minutes to acquire the needed data using these tools. For representation simplicity, we refer to this count with the symbol CTM (Count of Taking more than 10 Minutes). To measure the impact of using these tools on CTM, we identified a set of factors (explanatory variables) that had a statistically significant effect on the mean of CTM. These factors were: the number of primary and ancillary tools used for data collection; the number of collected data types; the method used to collect these data; and the ICT skills level. Three two-way interactions between these variables existed in this model (see Table 1 model number 1). The first two-way interaction was between the number of tools used and the number of data types collected (by the primary and ancillary tools used). The second interaction was between the number of data types collected and the method used to collect these data(manual or automatic). The last interaction was the number of collected data types and the ICT skills level. For reporting the results of these two-way interactions, the main effects of the explanatory variables that involevd in these interaction are not presented in the Table 1.

In a general linear model with the set of these factors and their interactions (Table 1 model 1), the effect of the number of tools on the mean of CTM was greater for users who collected relatively fewer types of data. For example, if the number of data types was five, and three tools (lower quartile) were used to collect these data, then the average CTM was 2.3; in comparison, adding one more tool (upper quartile) to collect these five data types increased the mean of CTM to 2.8 (Figure 1-A). The mean of CTM increased with the rise in the number of data collected manually. For example, if the number of data types was eleven and all were collected automatically (lower quartile), then the mean of CTM to collect these data was 1.7; however, if two (upper quartile) out of these eleven data types were collected manually, then the mean of CTM activity was 2.9 (see Figure 1-B). Similarly, the

mean difference in time taken for data collection between users with low to medium ICT skills and users with high ICT skills was statistically significant (mean difference=1.65). On average, for collecting five types of data, people with high level ICT skills took less time (0.4) relative to those with low to medium ICT skills (2.4) (Figure 1-C).

(C)

Figure 1 - Effects of three different two-way interactions on the mean of count of taking more than 10 minutes

Time devoted to data handling

Using ancillary tools for data handling increased the time needed to complete the activity. To measure the tools' impact, we identified three factors that had a statistically significant effect on the odds ratio of the duration of data handling. These factors were: using ancillary tools for data handling; the frequency the tool usage; and ICT skills level. Two models were built to examine this, due to model fitting problems as explained previously. One model included the first two factors and the other included the ICT skills level.

In the first logistic regression model, the odds of taking more than 10 minutes to complete the data handling activity were statistically significant - six times higher among users of ancillary tools relative to non-users (Table 1 model 2). With growing data volume, among people who used the tool less frequently (on a weekly or monthly basis), the odds of a longer duration of data handling activity were four times higher than among those who used the tool on a daily basis.

In the second logistic regression model (Table 1 model 3), the effect of having low to medium ICT skills on the odds of the data handling duration was significant - 18 times higher compared to users with high ICT skills.

Time devoted to data aggregation and analysis

Self-quantifiers who used secondary SQS took longer times to perform this activity. To measure the impact of using these tools, we identified four factors that had statistically significant effects on the odds ratio of the longer duration of data analysis. These factors were: using secondary SQS; the number of collected data types; the method used to collect these data manually; and ICT skills level. There was a two-way interaction between the number of collected data types and the method used to collect the data. These variables were fitted in two models (Table 1 model 4). One model included the first three factors and the two-way interaction, and the other included the ICT skills level.

In the first logistic regression model, the odds of taking more than 10 minutes to complete this activity were five times higher among secondary SQS users relative to the non-users. People who manually collected multiple types of data took a longer time to analyse these data. The longer duration odds increased with each additional type of data collected manually (see Figure 2). For example, if the number of data types was eleven (third quartile) and all were collected automatically (Manual data collection=0), the odds ratio of data analysis duration (taking more than 10 minutes) was 2.04; in comparison, if two out of these eleven data types were collected manually (Manual data collection=2), then the odds ratio was higher (Odds ratio=6.79) (Figure 2).

In the second logistic regression model (Table 1 model 5), the effect of having low to medium ICT skills on the data analysis duration odds was significant 17.6 times higher compared to users with high ICT skills.

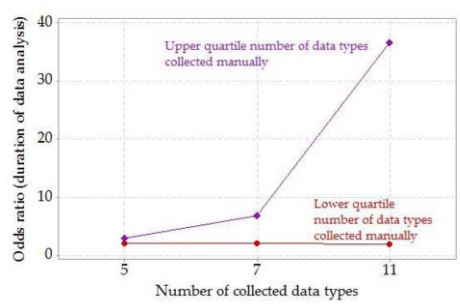

Figure 2 – Effect of the number of manually collected data types on the odds ratio of data analysis duration

Table 1 – Results from statistical models

Factors	Description of Estimate	Estimate Value	*P*	95% CI
Model (1): General linear model for the duration of data collection activity				
First interaction	Difference in regression slope between 'number of data types' and 'number of tools used to collect these data'	-0.073	0.012	-0.129, -0.017
Second interaction	Difference in regression slope between 'number of data types' and 'method used to collect these data (Manual)'	0.044	0.041	0.002, 0.086
Third interaction	Difference in regression slope between group with 'high' ICT skills and group with 'low to medium' ICT skills	0.126	0.024	0.017, 0.236
Model (2): Multiple binary logistic regression model for the duration of data handling activity				
Use ancillary tool	Odds ratio of taking more than 10 minutes in users compared to non-users groups	6.368	0.001	2.268, 17.876
Frequency of use	Odds ratio of taking more than 10 minutes in users who used this tool less frequently (weekly or monthly) compared to frequent users (daily)	4.061	0.004	1.556, 10.600
Model (3): Simple binary logistic regression model for the duration of data handling activity				
ICT skills	Odds ratio of taking more than 10 minutes in users with low to medium ICT skills compared to high level users	18.000	< 0.001	4.987, 64.971
Model (4): Multiple binary logistic regression model for the duration of data analysis activity				
Use secondary SQS	Odds ratio of taking more than 10 minutes in users compared to non-users	5.362	0.001	1.905, 15.091
Number of manually collected data (interaction)	Odds ratio of taking more than 10 minutes with increase in the number of data types collected manually	1.244	0.016	1.042, 1.486
Model (5): Simple binary logistic regression model for the duration of data analysis activity				
ICT skills	Odds ratio of taking more than 10 minutes for users with low to medium ICT skills compared to high level users	17.600	< 0.001	4.872, 63.575
Model (6): Multiple binary logistic regression model for the duration of data sharing activity				
Use secondary SQS	Odds ratio of taking more than 10 minutes in users compared to non-users	31.829	0.003	3.282, 308.7
Number of data collection tools (a)	Odds ratio of taking more than 10 minutes when (a) increased by $\frac{a+1}{a}$	0.283	0.012	0.106, 0.758
Method used for data collection (Manual) (b)	Odds ratio of taking more than 10 minutes when (b) increased by $\frac{b+1}{b}$	3.281	0.003	1.512, 7.122
Experience in using the tool (c)	Odds ratio of taking more than 10 minutes when (c) increased by $\frac{c+1}{c}$	2.667	0.023	1.146, 6.207
Model (7): Simple binary logistic regression model for the duration of data sharing activity				
ICT skills	Odds ratio of taking more than 10 minutes in users with low to medium ICT skills compared to high level users	50.667	< 0.001	11.567, 221.936

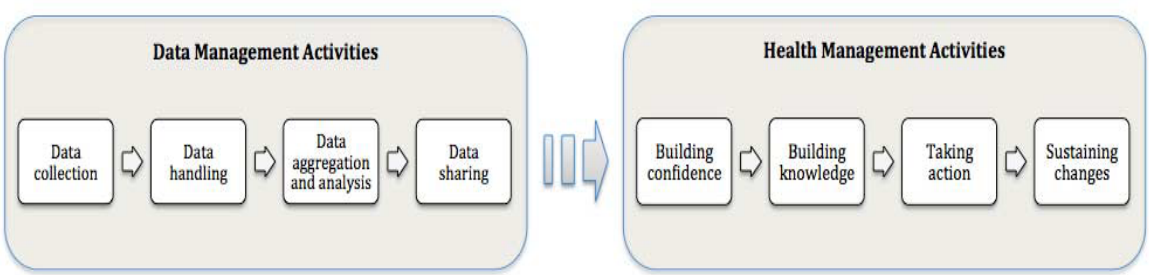

Figure 3 – The gap between data management activities and health management activities

Time devoted to data sharing

Most self-quantifiers in our study (73%) shared their data and findings with other people using primary and secondary SQS. Multiple primary tools usage was found to reduce the time needed to perform this activity; however, using secondary SQS increased the duration of this activity. To measure the impact of using these tools on the odds of the increased duration of data sharing we built two models. In the first logistic regression model, the variables were: using a secondary tool; the number of tools used for data collection; the method used for data collection (e.g., manual or automatica); the degree of experience using these tools; and ICT skills level.

The odds of taking more than 10 minutes to complete the data sharing activity increased 32 times in the secondary tools users compared to the non-users. On the other hand, the odds for longer duration reduced somewhat (0.3 times) for each additional primary tool the self-quantifiers used to share the data (Table 1 model 6). The range of the predicted estimates (confidence interval (CI)) of the odds of longer duration of data sharing when using secondary tools was wider due to limitation in the sample size. The odds of data sharing activity taking longer increased three times with additional types of data collected manually. The odds of longer duration also increased when self-quantifiers' experience in using the tools increased (Odds ratio=2.6).

In the second logistic regression model, the effect of having low to medium ICT skills on the odds of data sharing activity taking longer was 50 times higher compared to users with high ICT skills (Table 1 model 7).

Discussion

This study offers a detailed understanding of the SQS usage experience for health data self-management activities. The results show that managing day-to-day health requires individuals to interact directly with the chosen tools to collect, handle, analyse, or share the generated data. The time needed to go through each of these activities towards achieving one's desired health outcomes depends on the tools' ability to provide the required information and services. Having high ICT skills can slightly reduce the amount of time self-quantifiers have to devote to these activities. These findings are consistent with previous research studies [4, 6, 7].

Currently, few single primary self-quantification systems can support all information needs of a user. This limitation could generate a gap between the two critical stages of health self-quantification (Figure 3). We argue that as the gap gets wider, a self-quantifier has to focus more on managing data instead of managing health; thereby, facing information and time limitations on taking an active role to turn the collected data into knowledge, and subsequently take informed actions. Additionly, using multiple types of tools could diminish the data quality and increase the risk of losing data (files). The senario gets worse when the individuals do not have high ICT skills.

Conclusion

Using multiple types of tools for the purpose of health self-quantification complicates the health data management activities. In particular, it has implications for data and time management that pose challenges for achieving good health outcomes. We suggest that a framework representing and describing all key activities in health self-quantification could be beneficial. Application developers and health researchers could use this framework to improve the design and evaluation of health self-quantification solutions. Healthcare providers could use this framework to determine the applicability of these solutions and plan their implementation, based on the expected outcomes. Thus our current research focuses on the development of a framework, based on the theories of behaviour changes and human interactions with SQS tools, allowing a comprehensive view of all the essential activities and components of health self-quantification practice. We are also conducting further empirical research on the relationship between self-quantifiers' data management activities and health activation, to better understand the factors involved in their ability to achieve desired health objectives.

Mobile Usability Testing in Healthcare: Methodological Approaches

[a] *School of Health Information Science, University of Victoria, Victoria, BC, Canada*

Abstract

The use of mobile devices and healthcare applications is increasing exponentially worldwide. This has lead to the need for the healthcare industry to develop a better understanding of the impact of the usability of mobile software and hardware upon consumer and health professional adoption and use of these technologies. There are many methodological approaches that can be employed in conducting usability evaluation of mobile technologies. More obtrusive approaches to collecting study data may lead to changes in study participant behaviour, leading to study results that are less consistent with how the technologies will be used in the real-world. Alternatively, less obstrusive methods used in evaluating the usability of mobile software and hardware in-situ and laboratory settings can lead to less detailed information being collected about how an individual interacts with both the software and hardware. In this paper we review and discuss several innovative mobile usability evaluation methods on a contiuum from least to most obtrusive and their effects on the quality of the usability data collected. The strengths and limitations of methods are also discussed.

Keywords:
Usability; Mobile phone; Mobile health; In-situ; Healthcare; Consumer informatics; Clinical informatics; Human factors.

Introduction

The use of mobile devices and healthcare applications among consumers and health professionals is rapidly increasing [1, 2]. Athough there has been an exponential rise in the use of mobile devices in conjunction with m-health applications, few researchers have explored the methodological approaches and issues encountered when conducting in-situ usability testing (i.e. usability testing conducted in the setting of use) in environments where healthcare activities take place [1-3]. In this paper the authors will outline several innovative approaches to conducting mobile usability testing of mobile healthcare applications and their devices. This work will also include a discussion of the strengths and limitations of each of these approaches in the context of quality of data collection.

Review of the Literature

With the advent of mobile health or m-health, more and more health professionals and consumers are using mobile devices along with healthcare software applications (e.g. mobile devices that provide diet and excerise advice). Consumers are using these devices to self-manage their wellness activities (e.g. diet and exercise) as well as chronic illnesses (e.g. chronic obstructive pulmonary disease, hypertension). Health professionals are also using these devices to review, communicate and undertake health care activities (e.g. prescribing medications, reviewing clinical guidelines) [4]. Yet, even as the use of these devices has grown in the consumer and health professional space, there has been less attention given to evaluating the usability of mobile devices and their software applications in healthcare [5]. General issues in the usability testing of mobile devices and their software applications have been described by a number of authors, including Nielsen and Budiu [6], Weiss [7] and others such as Pearrow [8]. However, these works have focused on conducting laboratory-based studies with fixed recording of users using mobile applications in laboratory settings [6-8]. In addition, research is needed for exploring the usabilty of complex eHealth applications that involve understanding their use and usability under both laboratory and real-world conditions in healthcare contexts (e.g. hospitals, clinics) or in contexts where health is being managed (e.g. at home, at the gym or at work) [3-5]. We describe and compare a number of methods that we have employed in in-situ usability testing of mobile devices and healthcare applications in this paper.

Review of Existing Materials and Methods

We have employed several mobile usability testing approaches. The approaches also vary to the extent they are invisible or unobstrusive to the end user of the mobile device and the healthcare applications being tested. It has been our experience that some users may find being audio and video recorded to be obstrustive. Obtrusiveness may lead some users to modify their performance of tasks, improve their behavour in order to please the usability researcher, and/or limit their negative comments about the software features, functions and layout in order to “please” or to “not hurt the feelings” of the researcher. This is known as the Hawthorne effect. The Hawthorne effect can compromise the quality or representativeness of the study results. In our work, we have identifed that less obstrusive methods of audio and video recording user interactions with hardware and software devices leads to the collection of data that is more representative of real-world settings in terms of participant behaviour [9]. Yet, in the process of reducing the obstrusiveness of recording techniques, the quality of the data collected is diminished in some cases (such as losing data about finger and hand gestures) and may limit the researchers ability to identify all potential usability issues [10]. We have found that obtrusivness of recording methods exists on a continuum. There are a number of tradeoffs that exist when selecting an approach to usability testing where obtrusiveness is concerned. On one end of the continuum of obtrusivness of usability appraoches, the mobile device the user interacts with

is also used to audio record user's "think aloud" verbalizations and video record healthcare software application screens (directly to the mobile device) as the user is interacting with the software. On the other end of the continuum, the usability researcher uses external (i.e. visible to the user and researcher) audio and video recording devices to collect user interactions (including finger and hand gestures) with the mobile device and the eHealth application under study. In between these two points on the continuum, we have differing levels of obtrusiveness of audio and video recording software and devices where user interaction with the eHealth application and mobile device is concerned. As the obstrusiveness of the recording methods increase so does their influence on participant behaviour which may become less representative with the user describing fewer usability problems in an effort to please the researcher.

Figure 1 –Continuum of Obtrusiveness

In addition, the approaches vary in the extent to which they can be effectively used to collect data in laboratory-based and in-situ settings. All of the approaches can be used in a laboratory settting (i.e. a room set aside for usability testing). Many of the approaches can also be used in-situ, depending on the tasks that the users will be asked to perform and the level of user mobility that is required to perform the task; for example, a physician user may be asked to perform a task typically done while sitting at a desk such as ePrescribing versus the nurse user having to move, bend over and stand while performing a task such as taking and recording a patient's vital signs.

Usability Testing with the Device as Screen and Audio Recorder

Usability testing with a mobile device, where the device also audio records user verbalizations and records the screens the user is interacting with, is the least obstrusive of these approaches (see Figure 1, left side of the continuum). The mobile device provides the user with access to mobile eHealth applications and is also used to collect verbal and screen recording data (see the left side of Figure 2). In this way, the usability researcher can use the device to record the participant's "think aloud" verbalizations and video record the screens the user moves through while performing the task (see the right side of Figure 2 for the Data View i.e. the view the researcher sees when playing back the recording for analysis).

Figure 2 –Device as Screen and Audio Recorder

There are a number of advantages to using this approach. In terms of hardware, only the mobile device itself is used, so the cost of conducting such usability tests is low: limited to the cost of the mobile device and the audio and screen recording application. The usability researcher installs the eHealth application, and the audio and screen recording application (e.g. Screen Recorder by ToySoft® on the mobile phone). The audio and screen recording application is used to record the user's verbalizations and to record the eHealth software application screens as the user moves through the application (see Figure 2). The approach affords the usability researcher and user high levels of portability. The use of a single mobile device with a healthcare software application and audio/screen recorder allows the user to move freely in a laboratory or an in-situ setting, performing tasks that require walking or other types of movement (e.g. taking a picture of a surgical wound to document healing in the patient record). From an in-situ perspective, the usability researcher can easily bring the device into the users' environment, begin the recording, and the user can use the device as he or she would in their healthcare setting. The ecological validity of this approach is very high as the environment, software and hardware are representative of what is used in the real-world. In addition to this, for studies of use of mobile eHealth applications in collaborative settings, each user may have the recording software deployed on their own mobile device, allowing for multiple recordings (that can later be synchronized during the analysis).

The one significant disadvantage associated with using this approach is that the users' finger, stylus or hand gestures, are not recorded so it is unclear as to exactly what the user is touching on the eHealth application interface (e.g. a button several times before the software responds), as this is not recorded (see right side of Figure 2). In addition to this, the impact of the mobile device on user activities is not fully known. In our studies, features of the hardware device may have an impact upon users' perceived usability of the software and hardware and this information is not fully recorded as there is no external view of the participant handling the mobile device. It must also be noted that not all mobile devices have recording software that can be effectively used to capture the screens that the user is moving through and many mobile devices will not have sufficient room to store large files used in screen recording. Ideally, the device the consumer plans to use or the health care organization has mandated should be selected for the testing to ensure ecological validity and representativeness of the data [10,11]. Pilot testing [10] of the study data collection methods is recommended, including testing the mobile health application, mobile device and recording software to ensure no interactions between differing software and hardware lead to audio and video data being lost.

Usability Testing by Mirroring to a Computer

Along these lines, in cases where a mobile device has insufficient memory to store audio and screen recordings from the usability test or in cases where audio and screen recording applications are of insufficient quality to provide high quality recordings, devices can be mirrored to a computer (e.g. transmitting iPhone® or Samsung Phone® screens to a computer). Usability testing by mirroring a device screen to a computer or laptop computer remotely and then using audio and screen recording software installed on the computer can be done effectively to record audio and video data. In other studies, we have found that computer screens (including a mirror image of the mobile health or eHealth application

display) can be recorded using software installed on a computer. The approach is of higher cost as a laptop must be purchased; however, costs can be limited by using free software that can be downloaded off the web such as HyperCam® to record mobile device screens.

We recommend pilot testing this approach prior to collecting usability data [10]. Care must be taken by the usability researcher to ensure that the mirror image of the device is of sufficient quality to provide video data, and a portable external microphone is carried by the user that connects the user and their device to the laptop with its audio and video recording software so as to fully capture think aloud verbalizations in conjunction with video data of the user moving through the eHealth software application screens (see Figure 3).

Figure 3 –Mirroring to a Computer

The approach is more obtrusive than *usability testing with the device as screen and audio recorder* as the user is aware of the usability researcher reviewing the recording using a laptop and the user is physically wearing a portable microphone. However, the user is able to move freely when using the device (provided it is sufficiently close enough to the laptop for the computer screens and audio verbalizations to be recorded). *Mirroring to a laptop* does have a number of drawbacks – cost increases to conduct the test as the user now needs to use a laptop. In addition to this, less information is gathered as the researcher is unable to record user finger, stylus and hand gestures when touching eHealth application screens as they interact with the healthcare software. However, this approach takes care of the problem of not having enough space to record files on the mobile device, as the recordings are stored on the computer the mobile screens are mirrored to.

Usability Testing Using a Headcam

Head Cams can also be used to conduct mobile usability testing. Here, the individual wears a camera that is fixed to an adjustable strap that is worn on the forehead. As the user interacts with the mobile device, video and audio data are recorded by the headcam including finger and hand gestures. Usability researchers must take care when selecting a headcam when conducting this type of research. Headcams need to have audio equipment built in. Such headcams are currently available for purchase (e.g. the goPro® camera) with a high resolution and frame rate, thereby allowing for the usability researcher to capture user interactions with the mobile device and healthcare software application. The device is more obtrusive with it being worn by the user on their head. Alternatively, the device does afford the user participant greater mobility and it is possible to observe what the user is focusing on in terms of the mobile healthcare software. The user must be trained to position their head to ensure the headcam captures the mobile device screens and their finger/hand gestures for recording (see Figure 4).

Figure 4 –Using a Headcam

Here, the headcam improves the quality of the data collection by allowing the usability researcher to record how the user is interacting with the device (i.e. we can see the user touching differing user interface features and functions using a stylus). The approach is also reliant on only one device (the head mounted camera) so it requires limited equipment.

Usability Testing Using Glasses

We are currently adapting our approaches to using glasses that record audio and video for usability testing of healthcare applications. Our initial investigation suggests that such eyewear can be effectively used to collect information about what participants are viewing in addition to hand, finger or stylus movements (See Figure 5).

Figure 5 –Using Glasses

The advantage of the approach is that the researcher can view the world as the participant views it, and the participant is able to physically move while wearing the glasses. Our initial research has found that careful consideration must be taken when selecting the type of glasses that will be used in usability testing; for example, glasses should be selected with the ability to record audio and video data (as not all glasses record audio data). Attention must also be given to ensuring the glasses have sufficient storage space to collect the data that is being sought and there is a need to determine at what points downloading should take place. The glasses themselves must also be considered in terms of their usability and ergonomics. Some eyewears are difficult to position on the nose to fully record activities. Other glasses have been reported by users as difficult to wear. Some users find wearing glasses that can video and audio record to be irritating to the nose. As well, some glasses that record audio and video data do not respond well to participants head movements (i.e. the video may become choppy and may not

fully capture what the participant is looking at). Some that are able to record audio and video data may also have a headup display. The headup display provides information to the participant in the form of a transparent display. The user sees data in their visual field and does not have to look away in order to review the information, much as a pilot is able to continue looking forward at the data typically found on an instrument panel rather than needing to look down to view his or her instrument panel while flying an airplane [12]. The usability researcher must take into consideration if the headup display supports or distracts the user from focusing on the mobile device and healthcare application. Distractions may diminish the quality of the participants "think aloud" as they focus on the headup display instead of the mobile device. Lastly, some individuals use eye glasses for vision correction. Glasses used for audio and video recording usability data cannot correct a participant's vision. Therefore, some participants may be excluded from being part of this study. In summary, careful consideration must be taken by the usability researcher when procuring and pilot testing [10] glasses that record video and audio data for the purpose of collecting usability data about mobile device and software application use.

Usability Testing Using a Document Camera

Mobile usability testing can also be done using newer, more portable document cameras [14]. Products such as the Hue® document camera can be easily taken to a in-situ setting and used for usability testing. The quality of document cameras has improved significantly over the past few years. They are smaller in size (approximately 25 cm long and 10 cm wide), have built in microphones, 10x the zoom function, can be adjusted to focus on any device, and can be plugged into a computer where the images and audio it captures is easily recorded (see Figure 6).

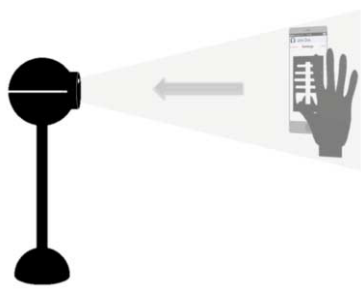

Figure 6 –Using a Document Camera

Document cameras offer a number of advantages. The smaller size of the camera allows for ease of portability and set-up in real-world settings, and the built in microphone no longer requires that the usability tester carry a microphone for capturing think aloud verbalizations [14]. A document camera has a number of advantages over the *use of the device alone for usability tests*, *mirroring to a computer* or *mirroring to a video projector*. Document cameras allow for recording of device screens, user hand and finger interactions with the software application as well as the mobile device. The document camera can be positioned to capture user interactions with the hardware and software. Some document cameras can be clipped to the device using plastic clips [14]. In capturing user interactions, the researcher is better able to link user activities involving the device to screen and audio recordings; for example, you can see what the user is touching with a stylus or their finger on the software application and this information is recorded. This approach does, however, require the mobile device to be located in a relatively fixed position, so its screen can be recorded by the camera (which makes it useful for laboratory style studies but less useful for studies where the user is moving around in a real or realistic environment). The methodology, although more intrusive, does provide additional insights as to what the user is doing with the software and the device.

Usability Testing Mirroring to a Projector

Early studies of mobile applications in healthcare focused on varying aspects of mobile device and software usability. For example, Kushniruk and colleagues found that the small screen size of a Personal Digital Assistant (PDA) could lead some users to make an error [11]. In this study, a statistical relationship between usability problems and medication errors was found by analyzing physician interactions with a mobile ePrescribing application installed on a PDA. The approach involved having end users of a prescription writing application (for use on a palm pilot) projected to a screen using an attachment called Presenter-to-go (which allows for connection of the mobile device to a data projector). Then, the usability researcher used a video camera to record both the computer screens and the audio of users while they interact with the ePrescribing application (see Figure 7).

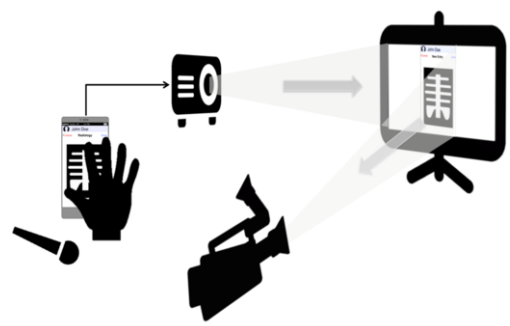

Figure 7 –Mirroring to a Projector

This approach allows for recording of mobile device screens and audio of the participants' "think aloud" verbalization, but requires a cable from the mobile device to the data projector. Usability testing mirroring to a projector is more obstrusive on the continuum of approaches, placing this method more to the right side of the continuum. Here, the user may become more aware of the presence of the video projector and the video camera. Also, the user is tethered to the projector and this limits what the user can do in terms of interacting with their environment (as they are limited by a cord), and less information is available about how the user is interacting with the mobile device (i.e. touching the screen). Using this approach requires more equipment, but as most of the equipment is normally available in most organizations it may be cost effective. Futhermore, the approach does not require installing software to record directly to the mobile device [11].

Discussion and Conclusion

When conducting usability tests involving devices, usability researchers must consider a number of differing issues, obstrusiveness is one of them. The level of obtrusiveness is

important to consider as participants may may modify their behaviours when performing study tasks as they are aware of the presence of equipment. In our work we have found that less obstrusive approaches to gathering usability data improve the ecological validity of the study, while at the same time reducing the likelihood of there being a Hawthorne effect.

Some less obtrusive approaches allow the user to move the mobile device and perform work activities more freely, but may not allow one to record stylus, finger or hand motions on the mobile device screen nor do they collect data about how the mobile device is held or used by the study participant (i.e. *usability testing with device as screen and audio recorder, mirroring to a laptop, mirroring to a projector*). Some more obstrusive recording approaches such as *using a document camera* may limit what the user can physicially do with a device, but will allow for recording of some more sedentary tasks such as entering medications into an ePrescribing system [11]. The headcam or glasses, although still obtrusive, may offer an advantage in that they allow for recording of user audio and video data involving hand gestures and finger touching where the healthcare software application and mobile device are concerned. Along these lines, some participants may find headcams and glasses to be a burden even though the recording method is less obtrusive than others used to collect data mentioned in this paper. There are advantages and disadvantages that need to be considered when planning for a study. Attention also needs to be paid to the types of tasks users will be asked to perform when identifying the best approach to data collection. For example, if the intent of the research is to study physicians using a Smartphone application that is used to for ePrescribing and there is interest in learning about how the device and the eHealth application work together, then using a document camera may be a solution.

Other factors may also influence the researchers' use of recording approaches. Availablity of screen and audio recording software for a Smartphone will determine if *usability testing with the mobile phone as recording device* can be employed as a methodology. Issues such as sufficient storage space for screen and audio recordings to be collected using a Smartphone is a concern. Some Smartphones do not have sufficient storage space to collect video and audio data from a usability session. As well, even if the Smartphone has sufficient storage space for usability recordings, the researcher needs to be able to determine at what point to download data to a computer or external hard drive from the device to free up space for continued recording. Use of laptops and video cameras to record data using mirroring overcomes some of these storage limitations. Cost is another aspect of mobile usability testing that needs to be considered. Using a Smartphone along with low cost screen and audio recording software is cost effective. The use of a headcam, glasses, laptop or a projector adds to the cost of conducting mobile healthcare research (if the equipment is not already in an organization).

In making these choices, researchers need to consider the strengths and limitations of each of these recording methods and their impacts on user behaviour to fully capture the data that answer the researcher's questions. From our work, we have also learned that pilot testing devices, study procedures and data collection approaches (audio and video) is key to avoiding any possible loss of data [10,13]. Also, a fullsome understanding of the tasks and activities that the user will be asked to perform will also influence selection of recording devices. For example, if the participant is asked to enter information into their mobile device while performing a physical activity (e.g. giving medication), the equipment that will be selected for use will differ from tasks where the user may be sitting (e.g. ePrescribing).

In summary, obtrusiveness influences ecological validity and the quality of the study results. Less obstrusive methods of capturing usability data may lead to poorer quality data. Consideration of study design is key when selecting from a range of approaches and taking into account whether the recording devices are obtrusive. This is particularly important in healthcare where there are many contexts and settings of use for mobile applications and devices (e.g. tablet and SmartPhone). In our studies, we have typically employed more than one of the methods described in this paper in combination. Such a multi-method approach may be useful when studies are used to assess both detailed and fine-grained user interactions as well as understanding how mobile applications fit into complex healthcare workflows.

Making an APPropriate Care Program for Indigenous Cardiac Disease: Customization of an Existing Cardiac Rehabilitation Program

[a]DanaKai Bradford, [a]David Hansen, [a]Mohan Karunanithi

[a]Australian eHealth Research Centre, Commonwealth Scientific and Industrial Organisation (CSIRO), Australia

Abstract

Cardiovascular disease is a major health problem for all Australians and is the leading cause of death in Aboriginal and Torres Strait Islanders. In 2010, more than 50% of all heart attack deaths were due to repeated events. Cardiac rehabilitation programs have been proven to be effective in preventing the recurrence of cardiac events and readmission to hospitals. There are however, many barriers to the use of these programs. To address these barriers, CSIRO developed an IT enabled cardiac rehabilitation program delivered by mobile phone through a smartphone app and succesfully trialed it in an urban general population. If these results can be replicated in Indigenous populations, the program has the potential to significantly improve life expectancy and help close the gap in health outcomes. The challenge described in this paper is customizing the existing cardiac health program to make it culturally relevant and suitable for Indigenous Australians living in urban and remote communities.

Keywords:

Health Services; Indigenous; Heart Diseases.

Introduction

Cardiovascular disease (CVD, including stroke, heart and vascular diseases) is a major health problem for all Australians and is responsible for over a third of deaths annually [1,2]. In 2010, more than 50% of heart attack deaths were due to repeated events. CVD is more prevalent in Indigenous people, and they do not receive the same level of care for primary and secondary prevention, treatment and management as non-Indigenous Australians[3]. Only 3% of remote Indigenous patients were shown to be fully engaged in cardiac rehab [4]. Perhaps as a consequence, Indigenous people are 2.3 times more likely to die within four years of a cardiac event.

Cardiac rehab programs have been proven to be effective in preventing the recurrence of cardiac events and readmission to hospitals [5] but uptake by those eligible for cardiac rehab has been low. Under utilization of these traditional, hospital or centre-based cardiac rehab program services is mainly due to personal barriers for the patient (motivational, cultural and financial) or system-related barriers (referral, timing, travel and accessibility of programs) [5].

To address barriers to cardiac rehab, CSIRO and Metro North Hospital and Health Services (HHS) designed and developed the "Care Assessment Platform" (CAP). This program used smart phones and the internet to deliver cardiac rehab in the patient's home to align with their lifestyle (Figure 1). The CAP is the first clinically validated mobile health delivery of cardiac rehabilitation in Australia, tested in a randomized controlled trial at Metro North HHS in 2012 [5]. The CAP program was delivered in accordance with national guidelines to address all components of a cardiac rehabilitation program. Of the 120 participants, 60 (50%) were randomly assigned to traditional cardiac rehabilitation (TCR) and the remaining to the Care Assessment Platform – Cardiac Rehabilitation (CAP-CR). Compared to the TCR, the CAP-CR had significantly higher rates of all three primary outcomes [5] (Table 1). Of the participants who did not complete the program, competing life demands and logistics accounted for the majority of attrition in the TCR group, whereas change of circumstances was the primary cause of attrition in the CAP-CR group. Only three of these latter participants cited difficulty in using information technology tools as a contributing factor.

Table 1– Mobile delivery significantly improves primary outcomes over traditional cardiac rehabilitation care[5]

Program	CAP-CR (*n*=60)	TCR (*n*=60)
Uptake	80% (*n*=48)	62% (*n*=37)
Adherence	94% (*n*=45)	68% (*n*=25)
Completion	80% (*n*=48)	47% (*n*=28)
Attrition	20% (*n*=12)	53% (*n*=32)

Participants in both programs had significant improvements compared to baseline measurements in secondary outcomes including dietary intake, mental health and functional capacity. Improvements in quality of life scores were only seen for the CAP-CR group, and these were significant compared to baseline measurements and compared to the TCR group [5].

These findings are similar to a smaller US study [6], which showed that patients who complemented their cardiac rehab with a smartphone health and activity diary were less likely to be rehospitalised than those who undertook rehab alone.

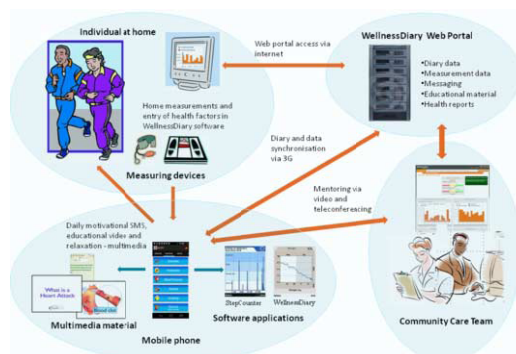

Figure 1 – The Care Assessment Platform for mobile health delivery of cardiac rehabilitation (source: M. Varnfield [7]).

At the time of writing, the authors are unaware of any phone-based cardiac rehab programs specifically for Indigenous communities, in Australia or internationally. Such programs may, however, be able to address the inequalities in provision of cardiac care due to flexible delivery of rehabilitation, health management and secondary prevention within the community.

The mobile cardiac rehabilitation health program has three main components:

- service delivery, encompassing the home care program, enrollment, the clinical portal and mentoring;
- education, comprising videos and motivational messages; and
- a smartphone app, containing a health diary and delivery of the educational material.

In this paper we describe changes to all three components to make the program suitable for rehabilitation of cardiac disease for Indigenous Australians. We have broadened the scope of the program to address risk factors for prevention in people with cardiac symptoms. Due to the popularity of iPhones, it was determined that the app needed to be available for both android and iOS phone users.

Methods

To customize the cardiac program for Indigenous Australians, involving Indigenous stakeholders was considered imperative. The research team followed National Health and Medical Research Council guidelines [8] by respecting culture and dignity, learning from Indigenous contributors, involving Aboriginal health workers, acknowledging the importance of family and carers, providing appropriate educational materials and including in the service delivery a setting comfortable for Indigenous people. In line with appropriate principles of engagement, CSIRO met with the Mayor and Council of a remote Aboriginal Community. During this meeting, the local Aboriginal Health Service received in principle agreement from the Council to provide a letter of support to hold discussions with the Health Service and members of the Community. Conversations were also held with a Indigenous health institute about the need to address cardiac health in the metropolitan community. The idea of conducting a pilot trial of the modified program was discussed with both communities.

Throughout the course of the program customizations, CSIRO actively engaged in meetings, workshops and interviews with six relevant healthcare providers who specialize in cardiac and/or Indigenous health, many of whose contributing staff members were themselves Indigenous. Weekly meetings were held with one group of stakeholders.

CSIRO identified an Indigenous production company to develop a culturally appropriate look and feel for the app using Indigenous artwork for the app icons. The company was provided with the original videos used in the urban program to be rescripted and remade to be culturally appropriate. An Aboriginal artist designed all the artwork for the videos and the app graphics.

Results

Customizations were made to all three main components of the mobile cardiac rehabilitation program: service delivery, education, and the app through which the program is delivered.

The service delivery model required minor modifications

Changes to the service delivery model included refinement of the rehabilitation program and inclusion of a focus on prevention, identification of relevant enrollment pathways, potential adaptations to the existing clinical portal, and mentor assignment and training. These are elaborated below.

The current rehabilitation program is conducted over a six week period with each week focusing on a specific set of themes supported by mentoring sessions over the phone. The themes designed by cardiac rehabilitation clinicians were not thought to require major changes, as they are clinical rather than cultural. Pending individual community feedback, the program has the flexibility to be extended to a twelve week program, covering the same material over a longer period, or implemented as a rolling program. For each week, theme-specific educational material would be provided to both rehabilitation and at risk patients, with weekly phone mentoring sessions in the rehabilitation program. At risk participants would have ad hoc access to a mentor as required.

Enrollment to the rehabilitation program would be through cardiac specialists based at proximal hospitals, with some recruitment through local Aboriginal health services. Enrollment for the 'at risk' program would be through identification of people with symptoms indicative of elevated risk of cardiac event determined by the local Aboriginal health service using a cardiac screening or decision support tool.

Generally, the format of the existing portal is considered appropriate, whereby following enrollment, patient data is entered into a website-based clinical portal. Throughout the program, data captured from patients are uploaded from the app to the clinical portal. A care delivery plan is tailored to each patient by the mentor with goals set according to their health condition profile and needs. Prior to each weekly phone call, mentors can review the data in the portal to inform their consultation. Based on feedback from an Aboriginal Health Unit, however, some minor modifications are required. These include building in the capacity to send compliance alerts when data points are missing, determining how often measurements need to be taken (eg. daily versus weekly) depending on the individual's cardiac health status, and including some positive measures, such as serves of fruit and vegetables each day.

It was determined that for some communities, it would be appropriate to establish a meeting place where participants meet regularly to discuss the program material and have their physiological measurements taken. The establishment of a meeting place was seen as a solution to several issues. Many communities have patchy mobile network coverage and community members are on prepaid mobile plan deals with limited data. The provision of free wifi to upload physiological measurements and download new app material would circumvent these issues.

To assist in developing community capacity and foster community ownership of the platform, mentors would be sourced from within the community wherever possible. Training packages include comprehensive guides for the mentoring role, the clinical portal, program content and the app. Where a meeting place is to be established, medical trainees from an appropriate institution would be sourced to take measurements and discuss educational material with participants under the supervision of a mentor.

The educational material required significant revamping

The original educational videos delivered as part of the six week rehabilitation program were caucasian-centric and heavily text based. Changes made to the video material

included reducing the length, simplifying the message and framing the videos in an appropriate context, with Indigenous artwork (Figure 2).

Figure 2 – The original text-based videos (left) were replaced with culturally relevant illustrated education delivery (right).

On each day of the six week program, a number of educational and motivational SMS messages are forwarded to the participant's smart phone. Due to issues with mobile coverage and data downloads in remote communities, these messages have been built into the app and appear as 'pop up' messages.

The current messages are considered to be too long, overcomplicated and lacking in persuasive delivery (Table 2). There is a strong feeling that the actual wording should be driven by individual communities. An example of the expected changes is provided in Table 2. The structure of the message delivery (week, day, time) aligns with the program themes and is therefore unlikely to undergo major change.

Table 2 – Examples of reworded motivational messages

Original message	Indigenous message
Did you know that there are driving restrictions after having a heart attack? It is important to discuss this with your doctor.	If your family depend on you to drive them around, then it's important to discuss this with your Doctor before getting behind the wheel after a heart attack because there are driving restrictions by Law.
Age is not a limitation to participation and success in Cardiac Rehabilitation. People of all ages do equally well!	You don't have to be young to participate and have success in Cardiac Rehabilitation. People of all ages do equally well!

The educational videos and messages are still a work in progress and will potentially undergo further changes through the course of community consultation.

The mobile app was customized for both iOS and android operating systems

The original app was functionally effective, but culturally inappropriate, for an Indigenous population, as it was text based, caucasian-centric and designed for individuals rather than community. An Indigenous production company was engaged to design new icons to improve the look and feel of the app. Based on feedback from Indigenous stakeholders (see Methods), the app icons needed to move away from the original text based format to a heavier reliance on visual appearance (Figure 3). They needed to be Aboriginal in context and aesthetically pleasing. The move to larger graphics was designed to accommodate for visual impairment, low literacy and persuasive appeal. All the artwork was designed by an Aboriginal artist.

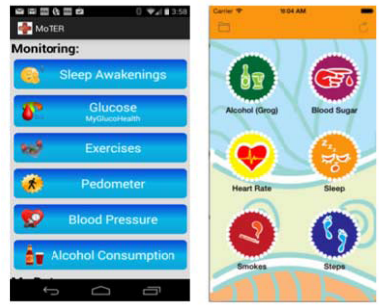

Figure 3 – The original text-based icons (left) were replaced with illustrated icons depicting Aboriginal artwork (right).

The heart symbol was chosen as the main program icon as it is intricately linked with family, health and life, and reflects the ultimate goal of the cardiac rehabilitation and prevention programs. Further customisations to the look and feel of the app were made to the sign-in screen, the screens in which measurements are recorded, the graphs and the general layout. These features were built using the artwork and colour schemes provided by the Indigenous production company.

Clear straightforward screen editors were developed with alternate entry options

A single screen editor was built for simple data entry, such as the count data; and individual screen editors for more complex measurements such as blood data (Figure 4). A generic screen editor was used for the remaining measurements.

Count measurements are provided for alcohol and cigarettes, with a custom option for the mentor to include, in consultation with the participant, any other substances recorded in the care plan (such as soft drinks). Pressing the icon takes the participant to recent history, where they can press the + sign to see their target for the day and update data using the + sign. Accidental data entry points can be deleted using the – sign. Alternatively, participants can press on the white box and enter a number directly (Figure 4). New functionality was added to count measurements whereby a single data point (ie. add one cigarette) can be entered by a long press on the respective icon on the home screen. This new functionality has been incorporated in the android version and is under development for the iOS version.

More complex screen editors are required for the collection of measurements relating to blood pressure and blood sugar. Data entry for blood pressure uses either a rolling counter or direct entry for systolic and diastolic values. While the android app can be updated directly from the blood pressure monitor using bluetooth, the iOS system requires manual input of values. Where blood sugar values are required as part of the care plan (ie. diabetes), values can be added as for count data. Once a value is entered participants nominate the context in which the blood sugar was measured (eg. before food).

For all other measurements, a generic screen editor automatically generates the editing panels for each measure.

Historical data can be viewed in list or graph form

For all health measurements, data can be viewed in list or graph format. Pressing any health icon displays the recent history page for that measure with a graph icon to display recent entries in graphical format. The graph displays data points for seven days (previous five days, today, tomorrow).

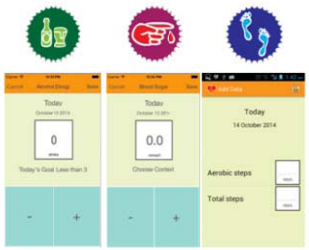

Figure 4 – Examples of simple, complex and generic screen editors built for iOS and android versions.

Educational videos can be viewed at any time

Prompts to access the educational material are meted out over the six weeks of the program. The five videos are now contained in the app and can be viewed at any time from the list function. As there are over 150 pop up messages, only the recent messages are now kept in the app. Motivational messages appear on the screen in the first instance in the same way text messages appear. Once read, the messages can be accessed from the list function icon, as for videos. Once the list display screen is full, older messages are deleted. New functionality is being developed to allow the text messages to have an audio option to accommodate for visual impairment, low literacy and sharing of message content in a group setting.

Functions outside the iOS–Android functionality overlap

App customizations were limited to functionality and appearances acceptable to both operating systems to maintain consistency. In the android version, however, there was the potential to include a traffic light system in the list function that was considered useful for the participant. This function allows a participant to see their program status at a glance. Green dots indicate that all health data has been entered, all scheduled videos have been viewed and that participation in the care plan is up to date. Yellow dots indicate that only some measures have been entered or videos still need to be viewed. Red dots indicate that no data has been entered and/or no scheduled videos viewed and/or that participation is required in the care plan. This functionality is under development in the android app. It is potentially possible to incorporate an equivalent system into the iOS app by adding compliance alerts to the threshold alerts contained in the clinical portal.

Summary of results

Modifications to the existing cardiac rehabilitation platform were made through initial community engagement, Indigenous health provider engagement, engagement with an Indigenous production company and in house software development. Modifications were made to all components of the platform (Table 3) including the service delivery model, the educational component, and the app based health diary. The revised app is available for both android and iOS operating systems.

Discussion

Closing the Gap between the health of Australia's Indigenous and non-Indigenous populations has been a campaign of the Australian Human Rights Commission since 2006 [9]. The improvement of Indigenous life expectancy, health and wellbeing was incorporated into health policy and formally supported by all Australian governments under the National Indigenous Reform Agreement which came into effect on 1 January 2009 [10]. In line with this agenda, this project aimed to develop a new model of service delivery by broadening an existing smartphone based cardiac rehabilitation program to encompass risk prevention, tailoring it for an Indigenous community and incorporating community capacity building into the implementation design. The aim of this model is to facilitate community autonomy of cardiac health management in the Indigenous population to assist in closing the gap in cardiac health outcomes.

The flexible delivery of mentored and supported cardiac rehabilitation can increase both uptake of, and adherence to, cardiac rehabilitation, as demonstrated in the CAP trial [5].

Table 3 – Summary of modifications

Component	Modifications
Service Delivery Model	
Rehabilitation and prevention programs	Programs developed and refined, identification of meeting place for discussions and taking of measurements.
Enrollment pathways	Aboriginal Health Services.
Clinical portal	Inclusion of positive measures.
Mentor assignment/ training packages	Mentors and trainees sourced from community. Training packages under development.
Educational Material	
Educational video scripts	New rescripted style frames and video, with Aboriginal artwork and emphasis on graphics.
Mentor messaging	Embedded messages. Rewording to make messages concise and culturally appropriate. Audio function for visual impairment, low literacy and sharing.
Look and Feel	
App program icon	Aboriginal artwork. Culturally relevant symbol.
Background graphic	Addition of a background using Aboriginal artwork.
Health diary	Aboriginal artwork, improved data entry functions, including one press entry. Larger graphics to accommodate visual impairment and low literacy levels and to add persuasive appeal. Traffic light code for missing data.
The Built Apps	App now available for both android and iOS operating systems.

The foundation of delivering a health program in a patient's home environment, rather than have them travel to a health setting, resulted in effective adherence to all components of the cardiac rehabilitation program. CAP-CR group adherence to attend to educational components and health measurements (≥80%) demonstrated patients' ownership of, and motivation to understand and address, their lifestyle and biomedical risk factors. The appeal of the home delivery was supported by the CAP-CR group showing reduced anxiety levels over those in the TCR group [5]. Key lessons from the trial can now be applied to a pilot of this program in an Indigenous community.

The introduction of a technology based program to provide information, mentoring and monitoring for a targeted intervention in Indigenous communities is likely to be well received. Indigenous people are rapid adopters of smart phones with a surprisingly high uptake in communities where there is coverage [11,12], hence smart phones provide an ideal platform for health engagement. While numerous succesful smartphone health apps are currently available on the global

market [13], few have been specifically designed for Indigenous populations. In Australia however, the recent development of smartphone apps by and for Aboriginal groups [14,15], suggests this technology will be key for healthy Indigenous futures.

Given the adoption of mobile phone use in Indigenous communities, similar adherence to educational delivery is likely, if the material and content modifications are suitable for an Indigenous audience. Similarly, adaptations to the health monitoring and program delivery through a culturally appropriate smartphone app, together with engagement with their peers and health service support, are likely to result in similar improvements in key health outcomes as those seen in the CAP-CR trial, including physical activity, psychological wellbeing (anxiety and depression), and overall quality of life.

Health engagement should be combined with capacity building to provide communities with the resources and knowledge to identify, prevent and manage cardiac risks within the community. In this program, community-sourced mentors and trainees would contribute to community capacity. Central to maintaining this capacity is the establishment of a gathering place for participants to meet regularly to discuss the program material and have their physiological measurements taken. Trainees play a crucial social role as well as ensuring consistency in measurements and hygienic care of equipment at the meeting place. Anecdotes from exemplars of community based health education programs [16] suggest that greater understanding and awareness is derived from group participation. Possibly of greatest import in a community environment, the meeting place fosters a social network system for participants and facilitates a whole of community approach to healthcare.

Integrated service delivery model for Community

The service delivery model for an Indigenous community would involve integrating the cardiac health program into the existing community health infrastructure (Figure 5).

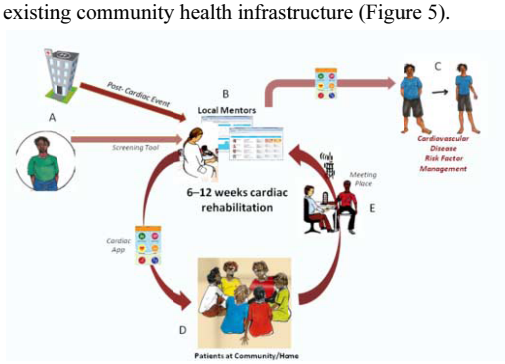

Figure 5 – Enrollment to the program would be through hospital-based cardiac specialists or screening tools (A). Mentors sourced from within the community would use the clinical portal to develop a care plan (B). People at risk (C) and those rehabilitating (D) can make and track data entries of their health and wellbeing using the cardiac app on their smart phone. Participants meet regularly in a meeting place to discuss the program material and have their physiological measurements taken (E).

Conclusion

This is the first smartphone app delivered cardiac health program designed specifically for Indigenous Australians. This novel program is now ready for further community consultation and pilot trial in an Indigenous community.

A Serious Game for Upper Limb Stroke Rehabilitation Using Biofeedback and Mirror-Neurons Based Training

Diego João Cargnin[a], Marcos Cordeiro d'Ornellas[a], Ana Lúcia Cervi Prado[b]

[a] *Laboratório de Computação Aplicada, Universidade Federal de Santa Maria, Santa Maria-RS, Brasil*
[b] *Hospital Universitário de Santa Maria, Universidade Federal de Santa Maria, Santa Maria-RS, Brasil*

Abstract

Upper limb stroke rehabilitation requires early, intensive and repetitive practice to be effective. Consequently, it is often difficult to keep patients committed to their rehabilitation regimen. In addition to direct measures of rehabilitation achievable through targeted assessments, other factors can indirectly lead to rehabilitation. Current levels of integration between commodity graphics software, hardware, and body-tracking devices have provided a reliable tool to build what are referred to as serious games, focusing on the rehabilitation paradigm. More specifically, serious games can captivate and engage players for a specific purpose such as developing new knowledge or skills. This paper discusses a serious game application with a focus on upper limb rehabilitation in patients with hemiplegia or hemiparesis. The game makes use of biofeedback and mirror-neurons to enhance the patient's engagement. Results from the application of a quantitative self-report instrument to assess in-game engagement suggest that the serious game is a viable instructional approach rather than an entertaining novelty and, furthermore, demonstrates the future potential for dual action therapy-focused games.

Computer Games; Patient Engagement; Rehabilitation; Stroke.

Introduction

Cerebrovascular diseases have a great impact on an individual's health. These diseases are one of the leading cause of hospitalizations, mortality and disability in the world population, surpassing heart disease and cancer, the two leading causes of death in industrialized countries. A stroke is defined as a sudden neurological impairment due to vascular injury, including lesions caused by hemodynamic disturbances. The severity of the condition and the functional impairment varies according to the affected area and to the vascular structures, and may cause cognitive, sensory and or functional deficit.

The advancement of technology has allowed the development of procedures enabling exploration of brain activity during rehabilitation therapies, where brain activity is a vital factor in motor rehabilitation. Recently, in order to determine the most effective and efficient techniques, a branch of study has focused on trying different methodologies relating biofeedback and mirror-neurons.

The treatment of neuromuscular disorders including hemiplegia and hemiparesis requires training of the remaining functional capacity. Thus, the motor training is based primarily on a rehabilitation process, in which the feedback is an essential component. Biofeedback goals in rehabilitation include the optimization of muscle contraction and elimination of mass movements and synkinesis. Therefore, patients can improve the symmetry and synchronization between the affected side and the healthy one, seeking functionality and spontaneity of movement. Mirror neurons are activated both when performing an action and during the observation of the same action performed by another person. As they seem to integrate observation and action, mirror neurons have been the focus of studies on how humans understand others and to what extent they are able to share experiences. Such integration includes an internal representation involving the same neural structures related in the execution of the observed action. It also has been considered as a key for rehabilitation purposes.

A Natural User Interface (NUI) represents a current concept that deals with the interaction between human beings and electronic devices. Through the identification of gestures, voice commands, expressions, body movements or detection of human body parts such as face, hand or joints, new games have been built, incorporating this technology.

The entertainment factor aside, serious games are designed to solve problems in several areas. Considering the health application, one can highlight the important contribution of these games to physical therapy and the rehabilitation of patients with motor disabilities secondary to neurological diseases. These patients require physical therapy programs appropriate to their problems in order to improve their quality of life, as much as possible. However, traditional physiotherapy is often boring and repetitive and can discourage patients, causing them to abandon their rehabilitation programs before they have finished.

This paper presents a serious game application for upper limb stroke rehabilitation based on biofeedback and mirror-neurons-based training, focusing on patients with mild or moderate stroke incapacity. The game helps the therapist by assessing the quality and efficiency of the patient's treatment. The patient participates by playing a game that uses quantitative measures to assess in-game engagement while incorporating existing interfaces for human-computer interaction.

The paper sections are laid out in the following order: Related Work, Hemiplegia and Rehabilitation, Game Framework and Design Elements, In-Game Engagement Assessment, Results, Discussion, and Conclusions and Further Work. The Related Work section displays some relevant information on the approaches and technologies concerning the rehabilitation process and the application of serious games within the field of rehabilitation. The section titled Hemiplegia and Rehabilitation briefly illustrates the causes, symptoms, and treatment of hemiplegia. The Game Framework and Design Elements section discusses the necessary components for serious game development, primarily focusing on rehabilitation. The following section reports initial upper extremity assessment based on a valid control group of physical therapists. The Results, Discussion, and Conclusion and Further Work sections present a

general discussion on game design, engagement, and use in upper limb rehabilitation, including therapist perspectives.

Related Work

Current research indicates that in the target audience, visibility and feedback may be considered for the development of serious games for rehabilitation, since they are important human factors [1]. The principles of game design that have particular relevance to rehabilitation are meaningful play and challenge. The former is the relationship between player's interactions and system reaction, while the latter aims at maintaining an optimal difficulty in order to engage the player [2][3]. Some important criteria for the design and evaluation of serious games in the rehabilitation area have been identified as game interaction and interface, number of players, genre, adaptability, performance feedback, game monitoring and portability [4]. It was also observed in [5] that serious games must ensure that patients are correctly performing the exercises as well as provide a motivating atmosphere for therapy, so as to yield maximum impact on the rehabilitation process.

Several technologies are used in serious games for physical therapy and rehabilitation, namely virtual reality and sensor networks. Games for physical therapy with severe injuries in the upper limb are proposed in [6]. The neurogame therapy, used for the rehabilitation of patients with severely compromised movements after stroke, is depicted in [7]. To improve the communication between physical therapists and patients with disabilities, a set of requirements for an authoring tool to enable therapists to create exercise animations for home viewing is presented in [8].

The benefit of almost all of these technologies is that they are inexpensive and can be implemented in any clinical environment. Perhaps their greatest benefit is that they provide real time feedback to the player and if designed effectively, they are more enjoyable than traditional exercises, and may therefore increase adherence.

Hemiplegia and Rehabilitation

Cerebral Vascular Accident

Stroke is the second major cause of death worldwide and is one of the greatest causes of overall disease burden. Each year more than 5.5 million deaths are attributed to cerebral vascular accidents. Despite this, less than one-third of countries take minor measures against it such as mortality reporting [9]. In 2010, 31% of stroke victims were children (aged <20 years old) and adults between 20 and 64 years old, with a higher overall proportion of strokes noted in the elderly [10]. In addition, [16] presents a complete statistical study on stroke by country income which reveals that fatality and incapacity rates are higher in low and middle-income countries. The high death rates among older people (aged > 75) indicates that younger adults suffer most from disability-adjusted life-years (DALYs).

Hemiplegia and Hemiparesis

Hemiplegia is a condition of full or partial paralysis of one side of the body that can occur secondary to a brain tumor, vascular accident, stroke, childhood head trauma, or congenital or perinatal injury. Unilateral impairment of hand and arm function are the most disabling symptoms of hemiplegia. Motor and sensory impairments in people with hemiplegia may compromise movement efficiency [11]. Hemiplegia is similar to hemiparesis, but it is far more serious. Hemiparesis is usually characterized by one side of the body being affected not by paralysis, but a less severe state of weakness.

Serious games are one possible clinical intervention for people living with the effects of stroke. In a serious game, a computer generates an engaging environment in which the patient must perform goal-oriented tasks that they find difficult. In this instance a serious game experience is similar to a regular video game experience, the key difference being the main goal: serious games aim to elicit physical movements. This treatment can be effective as the brain is a resilient organ that produces new neural connections in response to external stimuli and activity to compensate for damage.

Rehabilitation of Individuals with Disabilities

Physical therapy is the leading therapy in the treatment of individuals with disabilities. Therapy goals can include enabling people to reach and maintain optimal physical, sensory, psychological, social, and intellectual levels. Rehabilitation provides disabled people with the necessary tools to achieve independence and self-determination. To achieve these goals, physical therapists may apply various techniques to improve physical and mental capacity of the impaired patient.

In addition to sensory or motor deficit, people with disabilities can develop secondary pathological conditions such as shoulder pain, which affects 34% to 85% of those involved in the treatment. [12]. Rehabilitation and recovery constitutes a great challenge for both the complexity of the functions lost and the high incidence of shoulder pain, resulting in a negative impact on the overall rehabilitation process.

Game Framework and Design Elements

Natural User Interfaces in Physical Therapy

Nowadays, NUI is highly used in rehabilitation, generating research and applications that contribute to patient performance and facilitating the assessment of patient progress. NUI-based physical therapy has a functional, concrete, and challenging context, bringing a direct benefit for both the people with disabilities and the physical therapist through the adaptability of these systems. Advanced technologies are used to produce simulated interactive and multidimensional environments. Visual devices and hardware devices for body tracking are important to immerse patients in a virtual environment and give them the ability to modify the environment based on the rehabilitation goals.

NUI can also be considered more fun and appealing than the traditional set of exercises. The use of new tools, which certainly increases the quality of service they provide, also allow greater coverage without increasing risks. By using a NUI console, patients are encouraged to play games and stay engaged, rather than becoming bored. The console offers a variety of opportunities to work on physical abilities, depending on which game is selected.

Biofeedback and Mirror-Neurons

Various rehabilitation techniques such as biofeedback training to stimulate motor functions, have been studied and introduced in regular therapeutic techniques. Biofeedback techniques allow the patient to have an immediate response to exercise in view of the effects caused by neuronal stimulation, demonstrated with the aid of devices and tests that give a noticeable response externally. Thus, patients can monitor their motor and cognitive improvement, even if not visible at first sight, which reinforces the continued treatment while

stimulating other areas of the brain to recognize biofeedback response.

The biomechanical biofeedback involves measuring the movement, posture and control forces produced by the body [13]. Microsoft Kinect may represent a reasonable alternative for obtaining data that is relevant to the analysis due to its ability to map the body's joints of the patient participating in the game. The camera sensor helps physical therapists to examine movement quantitatively, which is beyond the game learning aspects, working as a learning speed-up tool so that the patient can quickly grasp the meaning. Based on these aspects, it is possible to use the Kinect to analyze the optimal position of upper limbs through the joints to make measurements of abduction and adduction as well as extension or flexion.

A small window in the game interface shows relevant information through a biofeedback character in stick figure (i.e. a digital goniometer), whereby patients as well as physical therapists can monitor real time movements. Based on this information, physical therapists can correct possible errors (i.e., movement or postural deviation errors) which can occur during the game. Physical therapists are allowed to monitor hardware and software setup, tailoring the game according to the levels of the treatment. The interface can be programmed to show several variables that may help rehabilitation and recovery.

A unique property of mirror-neurons is the ability to act both during the implementation of the action as well as in the observation of specific actions. This property allows humans to perceive the intentions of others through action observation. Therefore, observation is essential in imitation-based learning and empathy. While working with upper limb stroke rehabilitation, it has been observed that the mirror-neuron system in adults is still plastic and artificial activation of this system can provide the basis for cerebral post-stroke rehabilitation patients. The use of active observation as a form of rehabilitation is an asset in patients with severe paresis, for whom rehabilitation can be difficult [14]. Imitation-based learning requires a complex cognitive function that is constructed step by step, including motor observation. Therapies that activate mirror-neurons may be used along with the treatment, seeking a better post-stroke rehabiliation. The proposed serious game includes video recording of motor activities.

Playability and Usability

There are a number of aspects in the usability of digital games where the factor efficiency and effectiveness should be secondary to the satisfaction factor. Thus, game engagement must be addressed on a different perspective of the working software. The main point is to identify where the challenge must be and keep any other aspect out of this context according to the traditional recommendations of usability working software. Thus, the designer should create challenges that are part of the fun of achieving the goals of the game rather than undermine the patient's experience and effectiveness in tasks that should require some effort.

Serious Game into Play

After analyzing regular exercises with physical therapists in a rehabilitation ward, a decision was made in favor of shoulder abduction, as it was identified as the most common issue across various neurological diseases. Shoulder abduction is important for upper limb functions, as more distal functions depend on a stable shoulder.

Game prototyping is a high quality product development method in which a prototype is built, tested, and then reworked as necessary until an acceptable prototype is achieved. As a preliminary step in the prototype evolution, the target audience was defined. The proposed serious game is intended to be a complementary treatment to people with upper limb impairments after stroke in a mild or moderate condition.

The analysis of existing video games on the commercial market was important to support the concept and the choice for the game engine that integrates seamlessly with the Kinect. Later, it evolved to a concept that was more focused on patient engagement through a concept and argument that would provide an immersive environment necessary for their motivation. The biofeedback integration approach with mirror neurons served as support for the development of the serious game for physical therapy rehabilitation.

The game was implemented using Unity3D game engine and Kinect. Unity3D is a commercial engine, providing the developers with a large range of useful tools and scripts, as well as the underlying graphical tasks for game development. Even though such an engine is commonly used for entertainment games, a systematic move into serious game development has been recently detected. Given its integrated development environment with some set of game reusable components, Unity3D, in close cooperation with Kinect software development kit (SDK), reduces the workload needed to produce the game, allowing developers to concentrate on the higher levels modules of the game.

A screenshot of the serious game for upper limb stroke rehabilitation is shown in Figure 1. Control panels on the left and right side are intended for software setup. The goal of the game is to harvest as many fruits from the tree as possible and put them in the baskets within a certain time period. The winner will be the one who harvests more fruit. The angles shown in the interface are the measures of player abduction. Calculations are made based on the position of the joints. The shoulder angle is measured by the elbow, shoulder and pelvic tilt while the player is measured by the bowl and neck to the ground.

Figure 1 – Screenshot of the serious game for upper-limb stroke rehabilitation

The player collects the fruits by simply moving his/her hands until it touches the object on the screen. A Unity3D hand collider performs the detection so fruit coordinates become hand coordinates. Once the fruit is following the character's hand, the player must bring them to the basket where another collider transfers the coordinates to the fruit basket.

In-Game Biofeedback and Rapid Prototyping

After the game scenarios have been built, a feedback from the control group of therapists is needed as a particular step in the rapid game prototyping approach. The control group watches a therapy session of players and afterwards discusses it. This ensures that the scenarios are well adapted for the therapy and

appealing to the audience. After this step, strategies, game design ideas and concerns are evaluated and considered for the next prototype.

The effective user-centered design (UCD) issues on prototyping recommend prevention of implementing the final solution directly. Therefore, the serious game proposed is developed in an iterative manner. After the first prototype, UCD continues in an iterative process of evaluation and redesign. Observations and recommendations on the serious game are made by the control group of therapists while performing typical tasks for the game experience both in the process of doing the exercises and their relevant opinions about the game.

In-Game Engagement Assessment

Recruitment

Participants were instructed to play several rounds of the serious game. During the prototype development based on user-centered design, the game metaphor was chosen because it can be easily used to evaluate selection and reaching performance. Thus, the serious game is mildly challenging, has a player motivating potential, is not gender-specific and can be played by people of all ages. Furthermore, the game is easy to learn and understand.

Forty-eight participants (36 female and 12 male) took part in the in-game engagement assessment. Two participants (1 female and 1 male) had to be excluded due to impaired vision and the not meeting eligibility criteria. The age of participants ranged from 20 to 43 years. Participants had no prior knowledge of the experiment. They were recruited via academic and technical staff from the neuro-rehabilitation ward, including physical therapy undergraduates and graduate students, physical therapists and lecturers from the physical therapy department. Participants in the control group were required to have normal or corrected to normal vision as well as no physical impairment, to be eligible.

Preliminary Procedures and System Setup

Experiments were conducted on weekdays from 10 AM until 6 PM. The average time for an experimental session was 20 minutes, including setup and cleanup. Upon arrival, participants were informed about the nature of the experiment, which was the usability evaluation rather than a therapeutic application. Participants were also informed of the rehabilitation goals of the game, anonymity and ethical approval and the experimental procedure.

After description of the procedure, each participant signed an image consent release form and an informed consent form. Shoulder, elbow, and wrist joints were tracked and mapped to the avatar in the application scenario for upper limb rehabilitation. Since hemiplegia is characterized by unilateral impairments, the game was developed in such a way that the player could use both sides of the body.

Participants were led to the center of the room for the setup and sensor calibration. After this step, participants played the game levels in accordance with the goals set by the physical therapist. Each game session was set to 15 min, but participants could finish early. After the experiment, participants filled out a digital short-form version of the Game Experience Questionnaire (GEQ) to assess in-game engagement. Participants did not receive any kind of reward for their valuable participation in the evaluation experiment.

Measuring Serious Game Experience

A short version of GEQ was used to assess in-game assessment. The questionnaire has been validated as an effective tool both for commercial and non-commercial games. In this paper, only the first fourteen items were considered as a general metric to evaluate game experience. The findings cannot be considered to evaluate technical details in the user-centered development process.

The questionnaire links several game-related measures and implemented focusing on group research, consisting of seven dimensions: sensory and imaginative immersion, flow, competence, tension, challenge, positive and negative affect. Each dimension was measured by two questionnaire items on a Likert scale (0: no agreement with the statement to 4: complete agreement with the statement). The questionnaire[1] was clinician-administered upon participants' completion of the experiment.

Results

Results obtained from GEQ categories are represented in Figure 2. Our serious game prototype for upper limb stroke rehabilitation performed very well, considering the control group of therapists, in the positive affect dimension (M 3.22, SD 0.60). Players had a lot of fun playing the game and felt happy. Significant feelings of competence (M 2.20 SD 0.34) and challenge (M 2.8 SD 0.53) were observed. Participants lost their sense of time quite early in the game, suggesting substantial flow (M 2.98 SD 0.62).

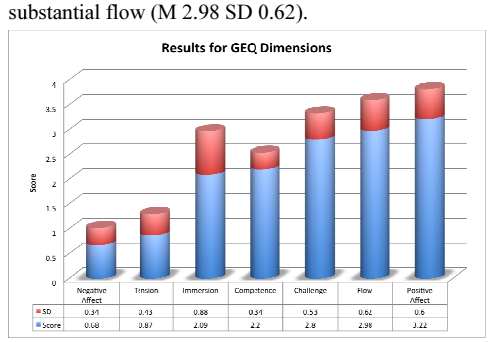

Figure 2 – Results of In-Game Engagement Assessment

The game performed reasonably well in the immersion dimension (M 2.09 SD 0.88). Almost all participants were visually delighted by the interface prototype (3.2) and were moderately impressed (2.04). The majority of players found that the game was neither tiresome nor boring (M 0.68 SD 0.34), suggesting that the prototype performed well in the negative affect dimension. A small amount of tension was observed (M 0.87 SD 0.43).

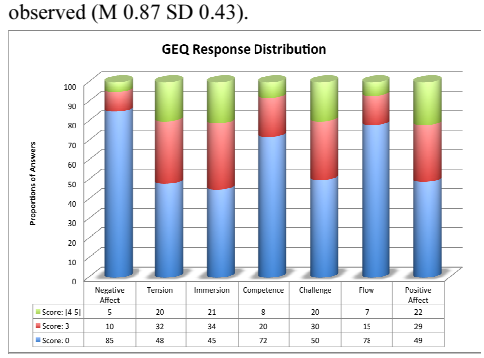

Figure 3 – GEQ Response Distribution

[1] The Game Experience Questionnaire captures game experience and playing experience based on a number of items. See more in http://www.allaboutux.org/game-experience-questionnaire-geq

Figure 3 presents the GEQ response distribution. T-tests were conducted to determine which response distributions differed significantly from the no agreement with the statement (score 0). A significant number of responses were either rather or exceptionally positive for items ($p < 0.05$) for dimensions competence $t_{14} = 2.92$, tension $t_{14} = 2.84$, positive affect $t_{14}= 2.41$, and sensory and imaginative immersion $t_{14}= 2.23$. Participants scored 0 exhaustively for negative affect, flow, and challenge dimensions.

Discussion

Results achieved during the in-game assessment suggest that the serious game prototype performed quite well in terms of usability and game experience. The serious game for upper limb stroke rehabilitation is rather new in the neurorehabilitation ward of the HUSM. Nevertheless, results gathered from the in-game assessment can be used as a standing point for new prototypes derived from the same game metaphor. Limitations include use of the short version of the GEQ scoring system and the need of functional evaluation using Capabilities of Upper Extremities Questionnaire (CUE-Q)[15].

Conclusion and Further Work

The main contribution of this work was the development of a serious game for upper limb stroke rehabilitation based on NUI, which allows the achievement of customized physical therapy sessions in real time. Measurements taken by the therapist allow the exercises to be kept within the limits of each individual, acting as an interface to the choice of how much and how long each movement should be performed based on competition and the entertainment stimuli provided by the game.

Besides assisting in the treatment of post-stroke rehabilitation, the serious game allows patients to enjoy the game and encourage movements that are generally repetitive. This extra motivation accelerates recovery and can be achieved by biofeedback and mirror-neurons through natural user interfaces. Results obtained during the in-game assessment were relevant to the evaluation of the prototype.

As future work, the interface may be enhanced using animation techniques to achieve a more engaging experience. A psychological and functional evaluation is planned in the near future to support therapist decisions over the course of treatment.

Acknowledgments

This research was partially supported by CAPES through the PROCAD Program. The participation of all individuals involved in the testing and evaluation step is thankfully acknowledged.

Usability and Safety of Software Medical Devices: Need for Multidisciplinary Expertise to Apply the IEC 62366: 2007

Abstract

Software medical devices must now comply with the "ergonomics" essential requirement of the Medical Device Directive. However, the usability standard aiming to guide the manufacturers is very difficult to understand and apply. Relying on a triangulation of methods, this study aims to highlight the need to combine various expertises to be able to grasp the standard. To identify the areas of expertise on which the usability standard relies, an analytical review of this document was performed as well as an analysis of a discussion forum dedicated to it and an analysis of a case study of its application for CE marking. The results show that the IEC 62366 is a usability standard structured as a risk management one. It obviously requires Human Factors/Ergonomics expertise to be able to correctly identify and prevent risks of use errors, but it also requires risk management expertise to be able to grasp the issues of the risk analysis and master the related methods.

Keywords:
Usability; Medical Device Software; Use Error; Risk Management; Standardization.

Introduction

It is widely accepted now that software can be either a component of a medical device (MD) or a medical device [1]. Thus, software for certain purposes is subject to the same regulation as MDs. Since 2010, software MDs must also comply with the "ergonomics" essential requirement aiming to ensure patient and users health and safety by preventing risks of use errors. The manufacturers must now integrate a Usability Engineering Process (UEP) in their MD design and development cycle and document it for CE marking. To comply with this requirement, the IEC 62366 standard [2] has been harmonized with the MD Directive to guide manufacturers.

However, this usability standard proves to be very difficult to be understood and applied by manufacturers, but also by competent authorities or even usability experts [3]. First, the IEC 62366 suffers the same design flaws as most of the standards [4]: references to many other standards, specific terminology, too general descriptions, etc. Futhermore, this standard is at the intersection of several areas of expertise: (i) it is a usability standard relying on a substantial Human Factors/Ergonomics (HF/E) conceptual and methodological expertise and (ii) it specifies a UEP that must be integrated into two other complex processes, the risk management process (RMP) [5] and the quality management process (QMP) [6], each one needing a specific expertise to be mastered.

Relying on a triangulation of methods, this study aims to highlight the need to combine these various areas of expertise to be able to correctly understand and apply the IEC 62366 usability standard. First, an analytical review of the structure and the content of the IEC 62366 standard document was performed to identify the domains of expertise on which it relies. Then, an analysis of a discussion forum dedicated to the IEC 62366 was undertaken to identify the difficulties expressed by the participants and the specific areas of expertise to which these difficulties were related. Finally, we took the opportunity to observe the real expertise-related difficulties for HF/E experts and a manufacturer during a case study of the application of the standard for a MD CE marking.

Methods

Analytical review of the standard document

A detailed analysis of the document was performed; only the results illustrating the purpose are presented here.

References

All the references made by the IEC 62366 to standard documents have been identified and linked to the area of expertise to which they refer for (i) the normative parts of the IEC 62366 (Articles 1 to 7) and (ii) the Bibliography section.

Terms and definitions

For the “Article 3. Terms and definitions”, the analysis goes further with a particular comparison. The terms defined without specific reference, i.e. exclusively decreed by the IEC 62366, were compared with classic HF/E terms defined in the ISO 9241 standards. This series of essential standards in the HF/E field is a reference in the domain and includes a wealth of information that covers every aspect of usability.

Usability Engineering Process

The Article 5 "Usability Engineering Process" describes specifically the requirements for the UEP implementation as well as its documentation. Its analysis also goes further than the analysis of the references with a comparison of the description of the processes between the IEC 62366 and the admitted standards of the different areas of expertise: (i) the ISO 13407:1999 [7] and the ANSI/AAMI HE74:2001 [8] for the UEP process, (ii) the ISO 14971:2007 for the risk management process, and (iii) the ISO 13485:2003 for the quality management process. The comparison was focused on

the objectives of each standard, the required steps and methods for each process and the intended level of requirements (normative or informative requirement).

Analysis of the discussion forum

Data selection and extraction

The queries "*IEC 62366 forum*" and "*IEC 62366 blog*" were performed in the Google® search engine. The first result was a discussion forum named Elsmar Cove with multiple threads on the IEC 62366. In December 2012, the query "62366" was performed in this forum's search engine. All the threads discussing the IEC 62366 standard were included in the study; those that only cited the standard were excluded.

Data analysis

An automatic textual data analysis of the threads' content was performed with the ALCESTE software [10]. It aims to extract the strongest significant structures of the text, named the "lexical classes", so as to draw the essential information contained in the textual data. After conducting a clean to avoid methodological biases, the ALCESTE software performed the analysis:

i. a basic vocabulary dictionary was created: lexical forms were simplified to gather together forms with the same lexical roots (e.g. "*required*", "*requirement*" or "*requirements*" were turned into "require+");

ii. the corpus was divided into Elementary Context Units (ECU) which correspond to the "units of text" within which ALCESTE was able to calculate words' co-occurence frequencies;

iii. ALCESTE crossed the ECU and the presence/absence of the lexical forms to form classes. The Chi-Square Test revealed the associative strength between a word and a class. For a class, ALCESTE was also able to compute a list of words that were characteristics of the class.

Application of the standard: a case study analysis

Context of the study

MDoloris Medical Systems® had designed an innovative analgesia monitor named PhysioDoloris® (Figure 1). It provided a new pain indicator called A.N.I. (Analgesia Nociception Index) to support better management of the monitoring of a patient's pain during general anesthesia. HF/E experts were asked to (i) perform the usability verification and validation as required by the IEC 62366 standard and (ii) support the UEP documentation for CE marking. The manufacturer and the HF/E specialists had never applied the standard at the time of the study.

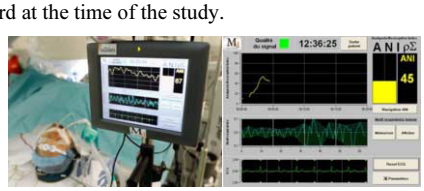

Figure 1 – The PhysioDoloris® monitor in operating room

The HF/E intervention [3] consisted of (i) collecting the mandatory information to prepare the usability plan, (ii) performing the usability verification and validation and (iii) documenting the Usability Engineering File.

HFE experts point of view

An inspection of the Usability Engineering File provided by the HF/E experts to the manufacturer was performed to analyze the type of UEP implemented (steps and methods), the terms used in the document and the reported use error risks. All those elements were compared with the intended classic UEP in the domain of HF/E (ISO 13407) and the intended UEP in the MD regulation (IEC 62366).

Manufacturer point of view

An inspection of the documents provided by the manufacturer to the HFE experts at the beginning of the intervention was performed (accompanying document and first version of the risk management file). The objective was to analyze the usability items already documented by the manufacturer before the HFE experts intervention with regard to the intended IEC 62366 requirements (the application specifications (with the intended user profiles, the intended conditions of use, etc.), the frequently used function, the hazards and hazardous situation related to usability, etc.). Then, the last version of the file given for CE marking by the manufacturer was analyzed to identify the way the items of the Usability Engineering File provided by the HFE experts were integrated: what items have been included? Were they modified and, if yes, how?

Results

Analytical review of the standard document

References

The results show that the ISO 14971 (i.e. the RMP) is the founding reference of the IEC 62366. On the one hand, 93.4% of the references of the normative part refer to the ISO 14971 (the remaining 6.6% concern the IEC 61258 which outlines a generic process for developing materials for education and training for medical electrical equipment). On the other hand, the ISO 14971 is the only referenced document cited as indispensable for the application of the IEC 62366 (Article 2. Normative references).

Table 1 – Distribution of the standards quoted in the IEC 62366 bibliography section by field of expertise

Areas of expertise	Standards cited in the Bibliography section
Quality management system	ISO 9000:2005; ISO 9001:2000; ISO 13485:2003; ISO/TR 16142:2006; EN 1041:1998
Basic safety and essential performance	CEI 61258:1994; ISO/CEI 51:1999; CEI 60601-1:2005; CEI 60601-1-8:2006
Usability (HF/E)	ISO 9241-1:1998; ANSI/AAMI HE48:1993; ANSI/AAMI HE74:2001

The analysis of the Bibliography section shows that references to standards of the HF/E domain are almost non-existent. A total of 75% of the standards cited in the bibliography refer to other fields of expertise as HF/E (Table 1): 5/12 rely on quality management expertise, 4/12 on basic safety and essential performance and, only 3/12 on HF/E expertise.

Terms and defintions

These results are confirmed by the vocabulary listed in Article 3 of the IEC 62366 which relies mainly on other fields of expertise as HF/E. Only 2 terms explicitly refer to standards of the HF/E domain (i.e "effectiveness" to the ISO 9241-11 and "user interface" to the ANSI/AAMI HE74). All other terms (46.2% corresponding to 12/26 terms) refer to standards of other fields of expertise as HF/E (i.e. 9/26 on basic safety and essential performance standards, 2/26 on QMP standards and 1/26 on RMP standards).

Twelve terms have no specific references meaning that they are defined by the IEC 62366 itself. It has to be noted that among these 12 terms, some of them (4/12) have been modified from usual definitions of the HF/E domain: “Usability”, “Use error”, “User” and "Efficiency". For instance, the definition of "Usability" is quite different from the ISO 9241-11 definition (Table 2).

Table 2 – Comparison between the ISO 9241-11 and the IEC 62366 for the definition of the term "Usability"

IEC 62366 (Article 3.17)	**ISO 9241-11** (Article 3.1.)
« *Characteristic of the user interface that establishes effectiveness, efficiency, ease of user learning and user satisfaction* »	« *Extent to which a product can be used by **specified users** to achieve **specified goals** with effectiveness, efficiency and satisfaction in a **specified context of use*** »

Usability Engineering Process

The UEP objectives described in the IEC 62366 differ slightly from those of the ISO 13407. The classic UEP aims to support the design of interactive systems ensuring their usability on the whole while the usability MD regulation aims to identify and prevent risks of use errors. IEC 62366 adopts a safety point of view while the classic usability approach is more global.

This discrepancy obviously impacts the requirements of each standard. The main difference is that the ISO 13407 stresses the importance of understanding and specifying the context of use on the whole (Figure 2), i.e. considering the intended users, their tasks with the device and the corresponding work organization. In contrast, the IEC 62366 emphasizes the need to describe the specifications of the application, the frequently used functions and the identification of hazards and hazardous situations related to usability, getting closer to the risk analysis step of the ISO 14971. Accordingly, the ISO 13407 sets usability objectives related to users and organizational requirements for the evaluation step while the IEC 62366 imposes usability objectives related to frequent and hazardous functions.

Concerning the intended level of requirements, the normative part of the IEC 62366 presents a UEP process similar to the UEP process described in the ISO 14971. The UEP as described in usual HF/E standards (ISO 13407 & ANSI/AAMI HE74) is in an informative section of the IEC 62366 (Annex D).

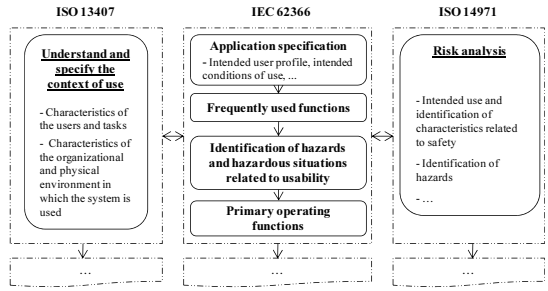

Figure 2 – Description of the first steps of the processes described in the IEC 62366, ISO 13407 and ISO 14971

Analysis of the discussion forum

Twenty-eight threads were included in the analysis corresponding to 295 posts. ALCESTE classified 563 ECU out of 793 created. It revealed 5 stable lexical classes which were pooled into 2 lexical meta-classes (Table 3).

In the first meta-class (45.65% of ECU), the participants want to understand how to reach compliance with the HF/E regulatory requirement. Two lexical classes are included in this meta-class. The first one (Class A, 23.09% of ECU) represents discussions where participants give information about harmonized standards (role and status). It highlights difficulties of the participants to identify the suitable usability standard regarding their MD. In the second class (Class B, 22.56% of ECU), difficulties are expressed with the understanding of the IEC 62366, participants asked for feedbacks and trainings on this purpose.

Table 3 – Lexical meta-classes and classes and examples of typical lexical features

Lexical meta-class (ECU %)	**Lexical classes (ECU %)**	**Examples of typical lexical features**
1. Searching the compliance with the ergonomics regulatory requirement (45.65%)	A. Provide information on compliance with the regulatory requirements in general and especially with the usability harmonized standards (23.09%)	iec6060116, standard<, harmonized, adopted, solution+, why, mandatory, regulation+
	B. Search for information and help to understand the IEC 62366 standard (22.56%)	help, thanks, committee, publication, feedback, follow, training, experience, provide+, us, hope
2. Understanding the application of the IEC 62366 (54.35%)	C. Guidance in understanding the UEP principles (27.35%)	user+, design+, error+, interface+, verification, HF, environment+, pati+ent, test+, population+, clear+, real
	D. Search for information about the documentation of the UEF and its link with the RMP (19.36%)	file+, usability, engineering, template+, document+, manage+, plan, existing, procedure, include, risk+, require+, process+, our+

	E. Search for information about the RMP methods to identify risks of use errors (7.64%)	DFMEA, analysis+, detectability, risk+, hazard+, covered, failure+, chang+er, determine+, incorrect+, control+

The second lexical meta-class (54.35% of ECU) includes discussion aiming to understand the application of the IEC 62366 principles. Three classes are part of it. The Class C (27.35% of ECU) includes explanatory utterances about the objectives, the scope and the definitions of the IEC 62366. The Class D (19.36% of ECU) highlights difficulties of participants with the documentation of the UEF. The items "file+" and "document" are the most typical items of this class and one of the most repeated utterance is "usability engineering file" showing that participants are focused on the UEF documentation. Participants try to understand the benefits of the UEP as they don't grasp the relationship between UEP and RMP processes, e.g. how are these two processes different from each other. For example, a representative ECU of this class is: *"Annex of iec14971 takes usability into account, [...] etc. can iec62366 requirements just be implemented in the overall risk plan for the product, or will the auditor want to see a separate usability specification like annex h?"*

Finally, the last class, Class E (7.64% of ECU), includes utterances discussing the methods of the RMP that can be used to identify and prevent the risks of use errors expected by the IEC 62366. The typical lexical features highlight (i) a risk management vocabulary as "hazard", "failure", control", "severity" and "risk" and (ii) a vocabulary related to methods as "determine", "list", "detectability", "analysis", "organized", "method". The primary methods cited are "FMEA" and "FTA", typical risk management methodologies. For example, the most representative ECU of this class is the following: *"My question is whether or not it is recommended to use detectability in an FMEA to comply with iec62366?"* In this class, the ISO 14971 annexes are regularly cited as good guidance to identify use error.

Application of the standard : case study analysis

HFE experts point of view

It has to be noted that the IEC 62366 does not require a specific format for the Usability Engineering File.

In this case study, the results show that the HF/E experts had adopted a classic UEP with comprehensive analysis of the context of use and the evaluation of the designed solutions. Likewise, the documentation of the Usability Engineering File was done following a usual usability report. Although some terms of the IEC 62366 were used (e.g. application specification, frequently used functions, etc.), HF/E experts mainly used specific terms of the classic UEP (e.g. context of use, heuristic analysis, usability testing, etc.).

In regards to the methods, one main difficulty emerged. The HF/E experts have had some difficulties in defining thresholds for the usability goals as they were not used to doing that exclusively in a safety-oriented point of view. These criteria for determining adequacy to the requirements referred to the criteria defined for risk acceptability in the ISO 14971. Moreover, they didn't distinguish in the usability engineering file the safety-oriented usability aspects of the problems, rather they were related to ease-of-use as required by the IEC 62366.

Manufacturer point of view

Analysis of the documentation recovered from the manufacturer shows that only one intended user profile was documented, i.e. the anesthetist, while another major user of the MD was the nurse. In France, indeed, an anesthetist is often in charge of 5-6 patients inside an operating room while nurses are assigned to a given patient. Nurses are also the ones monitoring the patient state and even making some decisions, although obviously the physician is the final decision maker. The manufacturer knew this specific work organization, but in order to be able to control risks associated with this additional user profile, he had decided at the time to consider only the physician's profile as the physician was legally the only one responsible for the drugs administered to a patient. At the end of the study, the nurse profile was added into the documentation by the manufacturer.

Another major finding was that the manufacturer only focused on technical risks (e.g. related to electrical problems). Even if they knew the problems identified by the HF/E experts, they had not identified them as risks of use errors. For instance, Figure 3 illustrates a severe usability problem identified by the HF/E experts generating a risk of misinterpretation of the index which was potentially dangerous for patient safety.

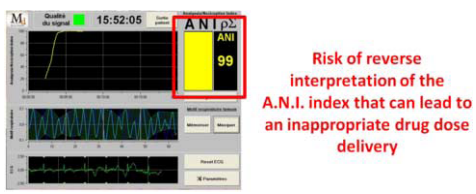

Figure 3 – Example of a dangerous usability problem identified by HFE experts

From the manufacturer's point of view, it was not a risk as the choice of the direction of the index relied on a clinical explanation (the A.N.I. indicates the proportion of parasympathetic tone in the autonomous nervous system). According to the manufacturer, once the care providers have understood it (during MD training), it would no longer be a problem. He did not consider that training was a low-level risk control measure while an easy high-level countermeasure could have been implemented with the redesign of the Graphic User Interface (GUI). They had difficulties in linking a design choice of the GUI with a potential risk of use error.

Discussion/Conclusion

This study highlights the need of multiple expertises to be able to understand and apply the IEC 62366 standard; it especially shows the need of a double expertise: the HF/E and the risk management expertises. The results show that the QMP expertise is not essential to grasp the content of the IEC 62366 as the standard does not really rely on the ISO 13485.

Firstly, even if the IEC 62366 standard claims to be a usability standard, it has little explicit elements about usability (few references to HF/E, key usability elements only in informative parts). Moreover, it clearly looks like the ISO 14971standard (a lot of references to it and a normative part dedicated to the description of a process very close to the RMP).

Secondly, these results are confirmed by those of the discussion forum analysis. Participants have difficulty understanding the distinctive feature of the IEC 62366 since, for them, the process is similar to the process of the ISO 14971. They also tend to interpret the IEC 62366 based on the risk management process which make easier things for them. As the risk management requirements have been mandatory since the 1990s, it is a process already systematized for most of the manufacturers and thus, well-known by them.

Thirdly, the analysis of the case study reveals that the manufacturer does not really understand the usability-related risks as shown by their not considering the nurse's user profile. As in many French operating rooms, nurses have a major role in the process of anesthesia, and as such cannot be ruled out. A problem would be considered as a use error and not as an abnormal use (i.e. outside the manufacturer's obligations).

Finally, problems of misinterpretation of the IEC 62366 were also observed with the HF/E experts. Spontaneously, they have adopted a classic UEP and have not emphasized the safety-oriented point of view of the identified usability problems (no clear distinction of the usability problems linked to risks of use errors).

Based on all these results, it seems that the IEC 62366 is a usability standard presented and structured as a risk management one. It requires the RMP expertise to be able to grasp the issues of the risk analysis and to master the related methods, but it also requires HF/E expertise to be able to correctly apply the UEP with the identification and prevention of the major risks of use errors.

The Health Information Technology (HIT) community must today be attentive to the MD regulation which has a strong impact on the software MD design and development. The major risk with the IEC 62366 standard lies in the problem of misinterpreting the requirements without realizing because each person understands the standard based on his/her own expertise. The recent focus on patient and user safety related to HF/E aspects makes the usability engineering aspects in development, implementation, and use of medical software a key issue that requires the development of good practice guidelines and standards in this area.

Standards are designed by several international or national standardization organizations (e.g. ISO or IEC) involving many technical committees. HF/E standards are developed and published by these standardization groups [10]. In the HF/E domain, the International Ergonomics Association (IEA) initiates in 1974 was the first HF/E technical committee (TC 159) for the ISO. Today, every standardization organization has a technical committee dedicated to HF/E. But it seems that the international Standard IEC 62366 has been prepared by a joint working group of three committees (subcommittee 62A: Common aspects of electrical medical equipment used in medical practice; IEC technical committee 62: Electrical medical equipment in medical practice and technical committee; ISO/TC 210: Quality management and corresponding general aspects for medical devices) not by integrating HF/E committees. Moreover, the technical committees are usually composed of manufacturers and customers [11]. One action to be taken is to ensure that at least domain experts understanding the issues discuss them within the committees.

From the practical and organizational perspective, we need to make the HF/E and risk management expertises and guidance more visible and accessible to the IEC 62366 intended users and to support all forms of education and training of stakeholders for HIT and MD.

Acknowledgments

Part of this research was funded by the ANR-11-TECS-0011 grant. We wish to thank MDoloris Medical Systems® for sharing their time and expertise.

Evidence-based Heuristics for Evaluating Demands on eHealth Literacy and Usability in a Mobile Consumer Health Application

Helen Monkman[a], Janessa Griffith[a], Andre W. Kushniruk[a]

[a] *School of Health Information Science, University of Victoria, Victoria, BC, Canada*

Abstract

Heuristic evaluations have proven to be valuable for identifying usability issues in systems. Commonly used sets of heuritics exist; however, they may not always be the most suitable, given the specific goal of the analysis. One such example is seeking to evaluate the demands on eHealth literacy and usability of consumer health information systems. In this study, eight essential heuristics and three optional heuristics subsumed from the evidence on eHealth/health literacy and usability were tested for their utility in assessing a mobile blood pressure tracking application (app). This evaluation revealed a variety of ways the design of the app could both benefit and impede users with limited eHealth literacy. This study demonstrated the utility of a low-cost, single evaluation approach for identifying both eHealth literacy and usability issues based on existing evidence in the literature.

Keywords:

Consumer health informatics; usability; eHealth literacy; health literacy; heuristic evaluation; mHealth

Introduction

Potential patient safety implications arise from the use of consumer health applications (apps), and consumer health information systems (HISs) more generally. As such, new strategies should be explored to identify potential problems and resolve them. To this end, the National Health Service (NHS) currently offers a "Health Apps Library" which endorses apps that are considered to a) be relevant to British people, b) provide trustworthy information, c) abide by data storage regulations, and d) not pose potential risks due to improper use [1]. The clinical assurance team, comprised of doctors, nurses and safety specialists, review apps and collaborate with app developers to ensure clinical safety standards are met before they are accepted into the Health Apps library [1]. However, the review appears to focus solely on guided user decision-making without the oversight of a healthcare professional, as the only potential clinical risk consumer HISs can generate. Although this is a promising and important new strategy, other factors may create clinical risk through the use of consumer HISs. For example, incongruence between the demand the system places on eHealth literacy and the user's actual eHealth literacy skills could result in misinterpretation of information.

Health Literacy is the "the degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions" [2]. However, technology has the potential to introduce entirely new challenges for consumer seeking health information health literacy stemming from system interactions. Emphasizing this argument, eHealth Literacy is "the ability to seek, find, understand, and appraise health information from electronic sources and apply the knowledge gained to addressing or solving a health problem" [3]. Moreover, it is not prudent to investigate the demand placed on eHealth literacy by a system without considering the system's usability more generally, as either factor being suboptimal may deter or prevent consumer HISs use.

Heuristic evaluation is a popular usability inspection method because it is a rapid, low-cost, investigation that often provides useful insights to improve system usability. Heuristic evaluation could be considered as a complementary and/or preliminary method of identifying potential usability issues that can be remedied before investing in more expensive and time consuming usability testing with representative users.

Although commonly used sets of heuristics (e.g., Nielsen's 10 [4]) are typically applied, these generic sets of heuristics may not always be the most suitable for a particular evaluation, user group, or system. Thus, some researchers have opted to develop their own heuristics based on the specific goal(s) of an assessment. For example, heuristics have been developed to evaluate health information system safety [5].

Another shortcoming of commonly applied sets of usability heuristics is that they predominantly focus on the analysis of the software component and neglect the system content or information presentation. It has been previously argued that special design considerations are necessary for users with limited health literacy, as they often use systems differently than more health literate users [6]. This argument led to the development of new heuristics, potentially more suitable for consumer health information systems [6]. However, a limitation of the previous work [6] is that the heuristics were generated from a single resource: *Health Literacy Online: A guide to writing and designing easy to use Web sites* [7]. Albeit composite and thorough, Health Literacy Online was published in 2010; since its publication, there has been an influx of research on eHealth/health literacy and usability. Thus, there is an opportunity to refine heuristics initially proposed by Monkman and Kushniruk [6], as well as generate new heuristics based on the recent literature.

This study will test the utility of a new set of evidence-based heuristics derived from the literature on eHealth literacy and usability. The heuristics will be used to evaluate a mobile blood pressure app to determine how using this app might benefit consumers, as well as what obstacles this app might present to users in terms of both demands on eHealth literacy and usability.

Methods

Heuristics and Severity Scale

Building on previous work [6], the current investigation sought to expand on the heuristics orginally proposed by the

authors, by incorporating recommendations from additional research on eHealth/health literacy and usability. Therefore, the body of literature investigating eHealth/health literacy and usability in conjunction were used to generate a novel set of heuristics. Barriers and recommendations reported in the literature were then subsumed into heuristics. This analysis identified a total of 8 essential heuristics (see Table 1) with an additional 3 heuristics relevant to specific types of content or medium that can be used dependent upon the system under investigation (see Table 2). This set of heuristics were then applied to test their utility assessing a mobile consumer health application to identify potential issues related to demands on eHealth literacy and usability.

Table 1– Evidence-Based Heuristics for Health Literacy and Usability

	Heuristic	Description
1.	**Immediately Inform Users of Purpose and Engage Users, Avoid Registration**	Identify the purpose and audience on the home screen/page. If unavoidable, make registration and logging in simple and obvious.
2.	**Use Complementary Interaction Methods**	Make use of alternative inputs (e.g., touch screen, barcode scanning, voice commands) and outputs (e.g., audio recordings, videos, text to speech engines).
3.	**Leverage Interactivity**	Offer interactive tools (e.g., quizzes, questionnaires, glossaries, tutorials) to engage with the information and provide performance feedback. Allow users to share information (e.g., print, email) with others.
4.	**Provide Accurate, Colloquial, Comprehensive, Succinct Content**	Written information should be brief, relevant, and in users' vernacular.
5.	**Provide Tailored, Flexible, Layered Content**	Prioritize information according to importance. If possible, personalise informtion. Provide succinct summaries but allow users to access more detailed information. Offer content in multiple languages.
6.	**Use Visuals to Complement Text, But Avoid Tables**	Visuals (e.g., pictures, videos, animations) may enhance written information. If unavoidable, tables should should be designed as independent, simplistic representations of information
7.	**Simplistic, Consistent Navigation**	Keep users oriented. Use linear navigation to facilitate forward and backward movement. Use large buttons, clearly labeled links, and provide a search engine.
8.	**Simplistic, Consistent Displays**	Avoid on screen complexity. Avoid the need for scrolling by limiting information on a page / screen.

Table 2– Optional Evidence-Based Heuristics for Health Literacy and Usability For Specific Content or Device

	Heuristic	Description
9.	**Clear and Comprehensive Communication of Risks**	Describe risk terminology in ways users will understand. Use 100 as upper limit on bar graphs. Avoid logarithmic scales.
10.	**Clear Depiction of Monitoring Data and/or Test Results**	Emphasize values outside acceptable ranges. Facilitate pattern recognition and rapid identification of influential factors.
11.	**Considerations for Mobile Devices**	Allow users to adjust the display size using familiar input (e.g., pinch to zoom, turning to landscape orientation). Use appropriately sized interface elements. Limit the amount of information displayed.

The severity scale used for this evaluation was specifically developed for rating health literacy or usability issues identified in consumer HISs [6]. The three severity levels (i.e., mild moderate, severe) are used to [6]:

1. Prioritize issue resolution
2. Estimate the likelihood consumers will understand the content and the gravity of the consequences associated with misunderstanding
3. Indicate the extent to which users will be able to circumvent the obstacle posed by the issue

System Under Evaluation

A mobile blood pressure tracking application (app) was selected as the system for this evaluation. This app operates on iOS systems (i.e., iPhone, iPad, iPod) and the full version is available for $0.99 CAD. Although its primary purpose is to record blood pressure values over time, this app also tracks heart rate and weight. This app was selected because it is an affordable solution that may appeal to people with limited ehealth literacy who are at risk or have been diagnosed with high blood pressure.

Procedure

In addition to the eight essential heuristics, the optional heuristics, Clear Depiction of Monitoring Data and/or Test Results and Considerations for Mobile devices, were both relevant to this system and therefore applied in this evaluation.

Given that the mobile blood pressure tracking app aimed to facilitate the monitoring of data over a time period, the evaluation focused on two stages of app usage: 1) the initial profile generation, and 2) reviewing data trends. As such, the investigators populated the app with several blood pressure measurements, both in and out of the acceptable range. This approach is recommended for tracking/monitoring apps, as it makes the evaluation more representative of what users would view after using the system multiple times.
